TABLE OF CONTENTS

1.A.1.Ea. Caribbeo-Mesoamerican Dry Forest

M134. Caribbean Coastal Lowland Dry Forest

CES411.421 Caribbean Coastal Dry Evergreen Forest

CES411.421 CLASSIFICATION

Concept Summary: This system represents tropical forests characterized by a dry season of several months, that occur in coastal lowlands, littoral or sub-littoral flatlands with rock outcrops and higher terraces facing the sea, on limestone coral shelves, humic carbonate soils, shallow red ferrallitic soils, or sandy soils close to the coast in the Greater Antilles and other Caribbean islands such as those of the Bahamas and Virgin Islands archipelagos. The species composition and structure of these forests vary depending upon the substrate and climate across their distribution. They are evergreen forests, or at least most of the dominant tree species are evergreen, with thick, sclerophyllous, small leaves and only a third of the trees deciduous or semi-deciduous (Wadsworth 1964, cited in Murphy and Lugo 1995). They have relative low floristic diversity and a tendency to have high species dominance. The canopy is somewhat open, between 6-10 m in height or taller in the case of occurrences in Cuba and sites in St. John where they have two canopy layers, with the upper layer reaching 12-15 m and occasional emergents up to 20 m tall. The density of stems tends to be very high. The woody understory is mostly evergreen. The herb layer is poorly developed or completely lacking. Species composition varies depending on past uses, substrate, and local climate. The following list of species is diagnostic for this system: *Bursera simaruba, Coccoloba diversifolia, Erythroxylum areolatum, Eugenia axillaris, Exostema caribaeum, Exothea paniculata, Guettarda krugii, Guaiacum sanctum, Guapira obtusata, Gymnanthes lucida, Metopium toxiferum, Sideroxylon foetidissimum*, and *Sideroxylon salicifolium*. Common accompanying species are *Pisonia albida, Pictetia aculeata, Thouinia striata var. portoricensis, Coccoloba krugii, Erithalis fruticosa, Guettarda elliptica, Lysiloma latisiliquum (= Lysiloma bahamense), Thrinax radiata, Ficus aurea, Capparis cynophallophora, Capparis flexuosa, Chrysophyllum oliviforme, Tabernaemontana amblyocarpa, Caesalpinia* spp., *Ateleia gummifera, Eugenia foetida, Eugenia confusa, Erythroxylum rotundifolium, Bourreria succulenta, Amyris elemifera, Krugiodendron ferreum, Bucida buceras, Terminalia neglecta, Chionanthus ligustrinus (= Linociera ligustrina), Chrysobalanus icaco, Colubrina* spp., *Randia aculeata, Coccothrinax littoralis*, and *Sabal parviflora*. The species composition reported for St. John includes as dominants *Guapira fragrans (= Pisonia fragrans), Nectandra coriacea (= Ocotea coriacea), Coccoloba microstachya, Maytenus laevigata, Bourreria succulenta*, and *Tabebuia heterophylla*.

Description Author: C. Josse

CES411.421 CONCEPTUAL MODEL

Environment: Precipitation in the distribution range of this forest in Puerto Rico and over most of the islands of Culebra and Vieques ranges from 600 to 1100 mm per year (Brandeis et al. 2006), with two dry seasons, the longer one from December to April and a shorter one from June to August. The annual precipitation range is somewhat higher across much of the distribution of this forest type (800-1300 mm) (Murphy and Lugo 1995).

Limestone is the dominant substrate in Caribbean coastal dry forests, with skeletal organic soils with minor mineral components, rarely exceeding 20 cm in depth (Snyder et al. 1990, cited in Gillespie 2006). In the Greater Antilles the distribution of dry forests is indicative of limestone substrates occurring in narrow strips on the northern and southern coastal areas. Rocky limestone soils have low water-holding capacity and nutritional limitations imposed by their calcareous composition. Isolated inland, ultramafic soils associated with limestone also support dry forests. In flat low-lying limestone archipelagos, such as the Bahamas, the Cayman Islands, Mona and Anegada, dry forests and shrublands dominate. In volcanic, low mountainous islands of the Lesser Antilles, dry forests dominate except for protected sites and ravines where moist forest can grow (Lugo et al. 2006).

Caribbean dry forests have to cope with highly stressful conditions given the combination of environmental features such as low moisture availability, long dry seasons, decadal cycles of pronounced drought, wind exposure and salt spray in littoral locations. These forests are also periodically exposed to hurricane conditions with effects that span from flooding with seawater to treefall and other structural changes due to strong winds.

Key Processes and Interactions: Caribbean coastal dry forests are exposed to harsh environmental conditions that, depending on their intensity, can cause damage or diebacks, such as seasonal water deficit, nutrient stress, strong winds and salt spray, and saltwater storm surge. This has influenced in the development of structural and physiological mechanisms to cope, making them very resilient to disturbance. Among the more outstanding ones are a high resistance to wind (short stature), a high proportion of root biomass, high soil carbon and nutrient accumulation below ground, the ability of most tree species to resprout, and high nutrient use efficiency (Lugo et al. 2006). Fire is not part of the natural dynamics of Caribbean coastal dry forests, but hurricanes are, which naturally results in considerable heterogeneity in habitat structure and food availability on small spatial scales. This structuring of coastal dry forest by frequent natural disturbance may favor their resilience to anthropogenic disturbance and fragmentation.

Threats/Stressors: These dry forests, as with other more developed and moister seasonal dry forests in the American tropics, have suffered from widespread deforestation, starting long before the arrival of Europeans at the end of the 15th century, but increasing markedly since. The reason for this is that most of the human population centers have settled in areas where the ratio of potential evapotranspiration to precipitation has a value close to one, areas where dry forests occur. Even dry forests located in areas of nutrient-poor soils have been impacted either by conversion to urban areas, to some agricultural use, or by harvesting of trees for lumber, fenceposts, firewood and charcoal, as well as by grazing in the understory (Murphy and Lugo 1995). The impact has been extensive in the Caribbean Islands due to high human population densities, and more recently due to land-use changes from historically extensive (selective logging, agriculture) to currently intensive (resorts, second homes, and energy development) (Franklin and Steadman 2013 and references therein). Important extensions of these open and degraded areas have been readily occupied by alien species (Martinuzzi et al. 2013). Areas originally covered by dry forest tend to be very susceptible to the establishment of introduced species, particularly on alluvial, volcanic and sedimentary substrate, but less so on more specialized substrates such as limestone and ultramafic.

Ecosystem Collapse Thresholds: Some of the mechanisms that these dry forests have developed to cope with drought and hurricane stress, such as resprouting and large root biomass, help them to respond to disturbance; however, the threshold related to the frequency and extent of disturbance that determines the path to forest recovery, its transition to an arrested seral stage, or the transformation to a new system composed of assemblages of only introduced species or a mixture of native and exotics is not known.

CES411.419 Bosque Semideciduo de Tierras Bajas del Caribe

CES411.419 CLASSIFICATION

Concept Summary: This system is found in lowlands and low hills (ca. 300 m elevation) that are characterized by a dry season. It is composed of two canopy layers with the upper canopy 18-25 m tall and about 75% deciduous species. The woody understory, 6-12 m, is mostly evergreen. The herb layer is poorly developed or completely lacking. The prevailing conditions determine if this forest type is deciduous or semi-deciduous. In sandy or rocky areas with nutrient-poor soils, forests are lower in height and include a spiny sclerophyllous shrub layer. The following list of species is diagnostic for this system: *Acacia muricata, Allophylus cominia, Amyris balsamifera, Andira inermis, Ateleia cubensis, Brya ebenus, Byrsonima spicata, Capparis* spp., *Catalpa macrocarpa (= Catalpa punctata), Cedrela odorata (= Cedrela mexicana), Coccoloba* spp., *Copernicia baileyana, Copernicia sueroana, Copernicia textilis, Cordia laevigata, Diospyros crassinervis, Diospyros halesioides, Eugenia confusa, Ficus citrifolia, Hymenaea courbaril, Manilkara jaimiqui, Manilkara bidentata, Maytenus buxifolia, Myrcia citrifolia, Myrciaria floribunda, Phyllostylon brasiliensis, Picramnia pentandra, Guapira fragrans (= Pisonia fragrans), Pisonia subcordata, Savia sessiliflora, Swietenia mahagoni, Tabebuia heterophylla (= Tabebuia pallida), Tabebuia shaferi, Trichilia hirta, Trichilia pallida*, and *Zanthoxylum martinicense*. In Puerto Rico, the following species are typical: *Bucida buceras, Citharexylum spinosum (= Citharexylum fruticosum), Coccoloba diversifolia, Cordia laevigata, Guaiacum officinale, Guazuma ulmifolia, Lonchocarpus domingensis*, and *Rauvolfia nitida*. The species composition reported for St. John includes as dominants *Inga laurina, Byrsonima spicata, Acacia muricata, Nectandra coriacea (= Ocotea coriacea), Tabebuia heterophylla, Faramea occidentalis, Chionanthus compactus*, and *Guazuma ulmifolia*.

Distribution: This system is found in Cuba, the Dominican Republic, the Lesser Antilles, Puerto Rico, the coast of Venezuela, and the Virgin Islands.

Nations: CU, DO, PR, VE, VI, XD

Concept Source: C. Josse

Description Author: C. Josse

CES411.419 CONCEPTUAL MODEL

Environment: In the Greater Antilles the distribution of dry forests is indicative of limestone substrates occurring in narrow strips on the northern and southern coastal areas. Isolated inland, ultramafic soils associated with limestone also support dry forests. Annual precipitation ranges from 1500 mm to less than 1000 mm with one or two long and pronounced dry seasons. Mean temperatures between 24-27°C are typical throughout the area of distribution. This type of forest with local variations occurs throughout moister areas, in protected uplands with more elevational range, drainage areas, and coastal protected valleys.

Key Processes and Interactions: Overall, Caribbean coastal dry forests are exposed to harsh environmental conditions that, depending on their intensity, can cause damage or diebacks, such as seasonal water deficit, nutrient stress, strong winds and salt spray, and saltwater storm surge. This has influenced the development of structural and physiological mechanisms to cope, making them very resilient to disturbance. Among the more outstanding ones are a high resistance to wind (short stature), a high proportion of root biomass, high soil carbon and nutrient accumulation below ground, the ability of most tree species to resprout, and high nutrient use efficiency (Lugo et al. 2006).

Fire is not part of the natural dynamics of Caribbean coastal dry forests (though many dry forests are now subject to anthropogenic fires).

Threats/Stressors: These dry forests, as other more developed and moister seasonal dry forests in the American tropics, have suffered from widespread deforestation, starting long before the arrival of Europeans at the end of the 15th century, but increasing markedly since. The reason for this is that most of the human population centers have settled in areas where the ratio of potential evapotranspiration to precipitation has a value close to one, areas where dry forests occur. Even dry forests located in areas of nutrient-poor soils have been impacted either by conversion to urban areas, to some agricultural use, or by harvesting of trees for lumber, fenceposts, firewood and charcoal, as well as by grazing in the understory (Murphy and Lugo 1995). The impact has been extensive in the Caribbean Islands due to high human population densities which results in small proportions of forest remnants. Important extensions of these open and degraded areas were readily occupied by alien species (Martinuzzi et al. 2013). Areas originally covered by dry forest tend to be very susceptible to the establishment of introduced species, particularly on alluvial, volcanic and sedimentary substrate, less so on more specialized substrates such as limestone and ultramafic.

Ecosystem Collapse Thresholds: Some of the mechanisms that dry forests have developed to cope with drought stress, such as resprouting and large root biomass, help them to respond to disturbance; however, the threshold related to the frequency and extent of disturbance that determines the path to forest recovery, its transition to an arrested seral stage, or the transformation to a new system composed of assemblages of only introduced species or a mixture of native and exotics is not known.

CES411.287 South Florida Hardwood Hammock

CES411.287 CLASSIFICATION

Concept Summary: This rockland tropical hammock system, as currently defined, occurs only in extreme southern Florida. It consists of upland hardwood forest on elevated ridges of limestone in three discrete major regions; the Keys, southeastern Big Cypress, and the Miami Rock Ridge. Tropical hardwood species are diagnostic of the system. Among the species likely to be encountered throughout are *Bursera simaruba, Coccoloba diversifolia*, and *Eugenia axillaris*. *Quercus laurifolia* is one of the few temperate species which attains prominence in this system. These forests tend to have a dense canopy that produces deeper shade, less evaporation, and lower air temperature than surrounding vegetation. This microclimate, in combination with high water tables, tends to keep humidity levels high. A number of orchid and bromeliad species thrive in such conditions. Unlike most coastal plain systems, fire is a major threat to ~South Florida Hardwood Hammock (CES411.287)$$. For this reason, many examples occur alongside natural firebreaks.

- Live Oak: 89 (Eyre 1980) **<**
- Tropical Hammock (Snyder et al. 1990) **=**
- Tropical Hardwoods: 105 (Eyre 1980) **<**

Distribution: This system is endemic to south Florida.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and C.W. Nordman

CES411.287 CONCEPTUAL MODEL

Environment: This system occurs in three discrete regions of south Florida. Underlying geology and soils are somewhat different among these regions, and the juxtaposition of the system may be somewhat unique. Generally, soils are highly organic with uneven and widely ranging thickness (Snyder et al. 1990). These forests tend to have a dense canopy that produces deeper shade, less evaporation, and lower air temperature than surrounding vegetation. This microclimate, in combination with high water tables, tends to keep humidity levels high and the community quite mesic (FNAI 1990). Unlike most coastal plain ecological systems, fire is a major threat to ~South Florida Hardwood Hammock (CES411.287)$$. For this reason, many examples occur alongside natural firebreaks, such as the leeward side of exposed limestone (Robertson 1955), moats created by limestone solution (Duever et al. 1986), and elevated outcrops above marshes, scrub cypress, or sometimes mangrove swamps (Snyder et al. 1990).

Key Processes and Interactions: Groundwater and seasonal pooling and drying of the soil are important dynamics. There is organic soil accumulation, thick in some areas and thin in others. Solution-eroded limestone provides wet pockets and dry patches in the environment. Thick organic soil helps maintain high levels of moisture in the system. Hurricanes are a part of the natural dynamics of this ecological system. Fire is very infrequent, due to the protection of this ecological system, many examples occur alongside natural firebreaks.

Threats/Stressors: Unlike most coastal plain systems, fire is a major threat to ~South Florida Hardwood Hammock (CES411.287)$$. Deep duff burning will kill >75% of the upper canopy layer, due to root and cambial damage (Landfire 2007a). Lowered water tables contribute to drying out of the litter and duff, which can allow wildfires to burn much more severely (Enge et al. 2002). The drainage and extensive severe wildfires early in the 20th century led to the loss of much of this habitat. Much of the remaining habitat has now been developed (Enge et al. 2002). Commercial and residential development are threats. Invasive exotic species are a threat, both plants and animals. There are many exotic tropical plants and animals which have naturalized in south Florida. Species such as *Colubrina asiatica, Leucaena leucocephala, Manilkara zapota, Schinus terebinthifolius*, and *Thespesia populnea* invade and displace native species. Dumping of yard waste can lead to the invasion of species such as *Sansevieria hyacinthoides* and *Epipremnum pinnatum* (FNAI 2010a).

Ecosystem Collapse Thresholds: *Landscape Context:* Fragmentation and isolation of the remaining habitat patches within the Miami Rockridge have led to decline in the dispersal of native trees and shrubs and an increase in the dispersal of invasive plants, especially by birds. These habitats can occur within a larger matrix of pine rockland, but are now most commonly found as islands surrounded by development or agriculture (FNAI 2010a). *Size:* Remaining occurrences in the Miami area are mostly small fragments, the largest are protected as Dade County Parks. The current extent is much reduced from the presettlement extent of <~South Florida Hardwood Hammock (CES411.287)$$ (Enge et al. 2002). *Condition:* Invasive plants, such as *Colubrina asiatica, Leucaena leucocephala, Manilkara zapota, Schinus terebinthifolius*, and *Thespesia populnea* invade and displace native species (FNAI 2010a).

CES411.369 Southeast Florida Coastal Strand and Maritime Hammock

CES411.369 CLASSIFICATION

Concept Summary: This ecological system occurs as a narrow band of hardwood forest and shrublands along the Atlantic Coast of southeastern Florida (approximately Volusia County southward). It is found on stabilized, old, coastal dunes, often with substantial shell components. The vegetation is characterized by hardwood species with tropical affinities, such as *Guapira discolor* and *Exothea paniculata*. As such, the northern extent of this type is limited by periodic freezes. This system is closely related to both inland tropical hammocks and southwest Florida maritime hammocks, and may share some species overlap with each.

- Southern Scrub Oak: 72 (Eyre 1980) **<**
- Tropical Hardwoods: 105 (Eyre 1980) **<**

Distribution: Endemic to south Florida.

Nations: US

Concept Source: R. Evans, after Johnson and Muller (1993a)

Description Author: R. Evans, after Johnson, Muller (1993a), C.W. Nordman

CES411.369 CONCEPTUAL MODEL

Environment: This system occurs along the coast on stabilized, old coastal dunes, often with substantial shell components. The northern extent of this type is limited by periodic freezes.

Key Processes and Interactions: The northern extent of this type is limited by periodic freezes and lack of cold tolerance of tropical plants, such as *Guapira discolor* and *Exothea paniculata* (Johnson and Muller 1993a). Maritime hammocks are relatively stable forest communities, as long as the canopy remains intact and the underlying landform is stable (FNAI 1990). Surface fires may help to maintain the open understory (Landfire 2007a). The shrub-dominated, coastal strand communities are considered ecotonal, and historically burned more frequently than maritime hammocks, possibly every 4-5 years (Austin and Coleman-Marois 1977). However, there is some disagreement on this point. There is little information on natural fire frequency in coastal strand (FNAI 2010a). The low stature of strand is due to the influence of storms and the ongoing salt spray pruning (FNAI 2010a). Fire is not needed to explain the shrub-dominated vegetation of coastal strands (Landfire 2007a).

Threats/Stressors: Coastal development has been and remains a big threat to this vegetation. Fragmentation of remaining areas is also a threat. Invasion by exotic plants, such as *Casuarina equisetifolia, Colubrina asiatica, Cupaniopsis anacardioides, Neyraudia reynaudiana, Scaevola sericea var. taccada (= Scaevola taccada)*, and *Schinus terebinthifolius* following natural disturbance (such as hurricanes) is an ongoing threat (Johnson 1994b, FNAI 2010a). *Casuarina equisetifolia* is the biggest invasive exotic plant threat. Due to its competitive abilities, *Casuarina equisetifolia* can completely replace the native plant species in recolonizing coastal strand after storms or as beaches build out after natural coastal disturbances (Johnson 1994b). *Persea borbonia* in coastal strand communities has been affected by laurel wilt disease, which is caused by a fungus (*Raffaelea lauricola*) spread by an exotic wood-boring beetle (*Xyleborus glabratus*) and is fatal to *Persea borbonia* shrubs over 2.5-cm dbh (FNAI 2010a).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from increases in the dominance of invasive exotic plants and the associated lack of regrowth or reproduction of the native coastal trees and shrubs. When ecological collapse has occurred, the vegetation is dominated by invasive exotic plants, and the native coastal trees and shrubs have declined. Where the natural vegetation is fragmented, the disturbance to the canopy caused by a hurricane can facilitate ecological collapse, when nearly all the plants which have high fecundity are invasive exotic species.

CES411.368 Southwest Florida Coastal Strand and Maritime Hammock

CES411.368 CLASSIFICATION

Concept Summary: This ecological system occurs as a narrow band of hardwood forest and strand lying just inland of the coastal dune system in southwestern Florida. It is found on stabilized, old, coastal dunes, often with substantial shell components. The vegetation is characterized by hardwood species with tropical affinities. As such, the northern extent of this type is limited by periodic freezes and cold tolerance of tropical constituent species, such as *Piscidia piscipula* and *Eugenia axillaris*. This system is closely related to both inland tropical hammocks and southeast Florida maritime hammocks, and may share some species overlap with each.

- Tropical Hardwoods: 105 (Eyre 1980) **<**

Distribution: Endemic to south Florida.

Nations: US

Concept Source: R. Evans, after Johnson and Muller (1993a)

Description Author: R. Evans, after Johnson, Muller (1993a), C. Nordman

CES411.368 CONCEPTUAL MODEL

Environment: This system occurs along the coast on stabilized, old coastal dunes, often with substantial shell components. The northern extent of this type is limited by periodic freezes.

Key Processes and Interactions: The northern extent of this type is limited by periodic freezes and lack of cold tolerance of tropical plants, such as *Piscidia piscipula* and *Eugenia axillaris* (Johnson and Muller 1993a). Maritime hammocks are relatively stable forest communities, as long as the canopy remains intact and the underlying landform is stable (FNAI 1990). Surface fires may help to maintain the open understory (Landfire 2007a). The shrub-dominated, coastal strand communities are considered ecotonal, and historically burned more frequently than maritime hammocks, possibly every 4-5 years (Austin and Coleman-Marois 1977). However, there is some disagreement on this point. There is little information on natural fire frequency in coastal strand (FNAI 2010a). The low stature of strand is due to the influence of storms and the ongoing salt spray pruning (FNAI 2010a). Fire is not needed to explain the shrub-dominated vegetation of coastal strands (Landfire 2007a).

Threats/Stressors: Coastal development has been and remains a big threat to this vegetation. Fragmentation of remaining areas is also a threat. Invasion by exotic plants, such as *Casuarina equisetifolia, Colubrina asiatica, Cupaniopsis anacardioides, Neyraudia reynaudiana, Scaevola sericea var. taccada (= Scaevola taccada)*, and *Schinus terebinthifolius* following natural disturbance (such as hurricanes) is an ongoing threat (Johnson 1994b, FNAI 2010a). *Casuarina equisetifolia* is the biggest invasive exotic plant threat. Due to its competitive abilities, *Casuarina equisetifolia* can completely replace the native plant species in recolonizing coastal strand after storms or as beaches build out after natural coastal disturbances (Johnson 1994b). *Persea borbonia* in coastal strand communities has been affected by laurel wilt disease, which is caused by a fungus (*Raffaelea lauricola*) spread by an exotic wood-boring beetle (*Xyleborus glabratus*) and is fatal to *Persea borbonia* shrubs over 2.5-cm dbh (FNAI 2010a).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from increases in the dominance of invasive exotic plants and the associated lack of regrowth or reproduction of the native coastal trees and shrubs. When ecological collapse has occurred, the vegetation is dominated by invasive exotic plants, and the native coastal trees and shrubs have declined. Where the natural vegetation is fragmented, the disturbance to the canopy caused by a hurricane can facilitate ecological collapse, when nearly all the plants which have high fecundity are invasive exotic species.

M294. Caribbean Dry Limestone Forest

CES411.457 Caribbean Edapho-Xerophilous "Mogote" Complex

CES411.457 CLASSIFICATION

Concept Summary: This system includes the steep slopes and plateaus of towerlike karstic hills up to 300-600 m elevation, with bare karstic rock or more-or-less eroded skeletal soils, or limestone cliffs, and the narrow valleys and gorges in between. Puerto Rican karst forests, regardless of rainfall conditions, share common characteristics, including physiognomy and leaf characteristics. Karst forests are characterized by trees of small diameter, high tree density, and leaf scleromorphy. Stands have a tendency to show signs of being exposed to frequent drought conditions. Even in the moist and wet karst belt, forests have a high proportion of deciduous tree species and show a high degree of scleromorphism (Chinea 1980). This is probably due to the rapid rate of runoff and infiltration of rainwater, low water storage in shallow soils, and high sunlight. Depending on the position and the substrate. At the base of mogotes the forest can be mesic with a closed canopy of evergreen species 25-30 m tall. On slopes and tops the vegetation is a deciduous forest/woodland with trees of 16-18 m and sclerophyllous leaves. In Cuban mogotes, the slope forest has a 10- to 16-m high open canopy of deciduous trees with barrel-like trunks and abundant columnar cacti, but can grade to a shrubland dominated by terrestrial bromeliads and diverse sclerophyllous shrubs and trees. The following list of species is diagnostic for this system: *Bombacopsis cubensis, Gaussia princeps, Spathelia brittonii, Thrinax punctulata, Omphalea hypoleuca, Microcycas calocoma, Plumeria emarginata, Trichilia havanensis, Hohenbergia penduliflora, Vriesea dissitiflora, Tillandsia* spp., *Ceratopyxis verbenacea, Eugenia galleata, Psidium vicentinum, Malpighia roigiana, Guettarda calcicola, Agave tubulata, Leptocereus assurgens, Siemensia pendula, Pilosocereus brooksianus, Agave* spp., *Coccothrinax elegans, Tabebuia albicans, Alvaradoa arborescens, Plumeria* spp., *Swietenia mahagoni, Colubrina elliptica, Catalpa brevipes, Zanthoxylum spinosum, Cordia alliodora, Dendropanax arboreus, Bernardia dichotoma, Eugenia monticola (= Eugenia maleolens), Forsteronia corymbosa*. In Puerto Rico, the following species are common: *Dendropanax arboreus* and *Quararibea turbinata* in the mesic forest, *Coccoloba diversifolia* and *Bursera simaruba* in the deciduous forest, and *Clusia rosea* on the cliffs.

Related Concepts:

- Seasonal-evergreen Forest Zone (Dansereau 1966) **>**

Distribution: This system is found in Cuba, Dominican Republic, Jamaica, and Puerto Rico.

Nations: CU, DO, JM, PR

Concept Source: C. Josse

Description Author: C. Josse

CES411.457 CONCEPTUAL MODEL

Environment: In northern Puerto Rico karst, mogotes are isolated, steep-sided hills or towers that rise out of the blanket sand deposits. Mogotes may be aligned in ridges along which they form a series of sawteeth. Solution caves are visible on the sides of the mogotes, but they don't usually pass through the hill. Mogotes have a rounded or pointed hard cap, generally 5 to 10 m thick. Reprecipitated limestone on slopes tends to form nearly vertical slopes. Since the rate of this process is dependent on climatic factors which are not uniform around the hill, the mogote tends to become asymmetric, with a steep slope on one side and a gentler slope on the other. The ecological system is called a complex because of the diversity of vegetation types resulting from ecological gradients due to different exposures to precipitation, wind and substrates, with deep fertile soils in valleys and shallow, rocky, and infertile soils on tops of mogotes, and slopes exhibiting intermediate edaphic conditions.

Key Processes and Interactions: Droughts and hurricanes are the main drivers of the natural dynamics of this system. Low rainfall intensities of 76 mm/d have a recurrence interval of 1 year while high rainfall intensities of >305 mm/d are possible during hurricane conditions or when low-pressure systems become stationary. These events have a recurrence interval of 100 years (Gómez Gómez 1984). Forests and other natural ecosystems of the limestone region recover quickly from hurricanes and storms (Wadsworth and Englerth 1959, cited in Lugo et al. 2001). Moreover, these events transport vast amounts of freshwater to the island and trigger many ecologically beneficial functions such as the reproduction of karst forest plants and animals, and the maintenance of the hydrological cycle of the karst area.

Threats/Stressors: Shallow soils on mogote hillsides are generally too steep and rocky to cultivate or even graze livestock (Pool and Morris 1979). Cultivation was possible on the sinkholes and solution valleys between mogotes. In these regions, pockets of deep fertile soils occur, but their extension is limited. On the mogotes themselves, soils are very difficult to cultivate, and it has to be done with hand tools and on very small areas. Therefore, the most extensive use of the hilly areas of the karst belt was brush and forest. Mogotes furnished most of the wood for charcoal used for fuel throughout the island. They also produced other forest products,

such as fenceposts and handles for broomsticks. Coffee was grown under the shade of timber tree species, which themselves were useful as a local source of lumber and other forest products. Economic transitions in the case of Puerto Rico have eased the pressure for timber and agricultural uses in the valleys of the karst area but urbanization, land levelling, river damming, water pollution, and aquifer overdrafts are drastically changing the topography and the hydrology and causing irreversible damage to the karst systems.
Ecosystem Collapse Thresholds: In spite of changes in composition and structure as a result of natural vegetation removal or past agricultural land uses, the forests of the Caribbean mogote complex can recover from these types of disturbance. However, given the dependencies of the vegetation types on moisture and substrate gradients, the levelling of mogotes for urban development, the mining of limestone deposits, and the transformation of the hydrological cycle due to human interventions would cause the collapse of this system.

CES411.465 Caribbean Submontane/Montane Karstic Forest

CES411.465 CLASSIFICATION

Concept Summary: This system occurs as small patches in submontane or montane rainforest zones, below 600 m elevation in Puerto Rico and up to 1100 m in higher mountains with karst outcrops. It is composed of drought-tolerant deciduous trees with open canopy layers, 6-8 m tall. The shrub layer is 2-3 m high and very dense. Rocks and trunks are covered by mosses and epiphytes. The following list of species is diagnostic for this system: *Thouinia clarensis, Fadyenia hookeri (= Garrya fadyenii), Mahonia tenuifolia (= Berberis tenuifolia), Coccothrinax trinitensis, Terminalia neglecta, Ocotea floribunda, Tabebuia sauvallei, Tabebuia bibracteolata, Bernardia dichotoma, Citharexylum matheanum, Savia sessiliflora, Erythroxylum clarense, Karwinskia potrerilloana, Psychotria martii, Zanthoxylum cubense, Agave* and Cactaceae. In Puerto Rico, the following species are typical: *Coccoloba diversifolia, Bursera simaruba, Bucida buceras*, and *Zanthoxylum martinicense*. Other characteristic species include *Thouinia striata, Nectandra coriacea (= Ocotea coriacea), Tetrazygia elaeagnoides, Gaussia attenuata, Rondeletia inermis, Guettarda scabra, Eugenia confusa, Eugenia* spp., *Coccothrinax barbadensis (= Coccothrinax alta), Leucothrinax morrisii (= Thrinax morrisii)*, and *Aiphanes minima (= Aiphanes acanthophylla)*. In Jamaica common species are *Sideroxylon portoricense (= Bumelia nigra), Cedrela odorata, Cinnamomum montanum, Coccoloba swartzii, Guapira fragrans, Nectandra patens*, and *Pisonia subcordata*.

M296. Caribbean-Mesoamerican Pine Dry Forest

CES411.463 Bahamas Pine Barrens

CES411.463 CLASSIFICATION

Concept Summary: These are open pine woodlands on limestones. The canopy is formed by pines and silver-thatch palm and reaches between 4-10 m high. There is substantial grass coverage. These woodlands occur on the boundary between wetland and upland situations. The following list of species is diagnostic for this system: *Coccothrinax argentea, Ernodea littoralis, Pinus caribaea var. bahamensis, Sabal palmetto, Setaria pumila (= Setaria glauca), Tabebuia bahamensis, Tetrazygia bicolor, Vernonia bahamense*, and *Zanthoxylum fagara*.
Related Concepts:
Distribution: Grand Bahama and Abaco on the Little Bahama Bank, and Andros and New Providence on the Great Bahama Bank.
Nations: BS
Concept Source: C. Josse
Description Author: C. Josse

CES411.463 CONCEPTUAL MODEL

Environment: These woodlands occur on the boundary between wetland and upland situations.
Key Processes and Interactions: In addition to fires, hurricanes are the major natural disturbance affecting the distribution, composition and structure of the pine forests.
Threats/Stressors: The major threats to pine forests include irrational timber extraction and frequent man-made fires which change the age structure and density of the pine forests, and exotic species which displace native species in the understory modifying the fire regime, water and nutrient availability. Land clearing for agriculture and other uses is another important threat.
Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct land conversion. Few remnants exist for understanding the factors (beyond conversion) causing collapse. However, alteration to natural fire regime would likely result in a shift in plant species composition, either from canopy closure (in the case of human suppression of natural fires) or from loss of fire-sensitive species and surface soil impacts from overly intense and frequent fires.

Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra. Quedan pocos remanentes, principalmente convertido en pastos. Sin embargo, la alteración al régimen natural de incendios probablemente daría lugar a un cambio en la composición de especies de plantas, ya sea desde el cierre del dosel (en el caso de supresión de incendios naturales humano) o de la pérdida de especies sensibles de fuego e impactos de suelo superficie de los incendios demasiado intensos y frecuentes.

CES401.294 Meso-American Dry Evergreen Oak Forest

CES401.294 CLASSIFICATION

Concept Summary: Este sistema abarca una gran variedad de comunidades caracterizadas por la presencia de *Quercus* en tierras bajas tropicales. Las comunidades son azonales, es decir que ocurren por causa de determinados sustratos, más que por el clima. Este sistema representa a los bosques puros de *Quercus* o comunidades mixtas con especies de los bosques deciduos o semideciduos circundantes. Son más comunes en la vertiente del Caribe de México, pero hay ejemplos de ellos hasta en Costa Rica. En su mayoría ha sido muy alterado y actualmente la mayor parte de su extensión se ha convertido en pastos de jaragua, una graminea introducida, sabanas pastizal o plantaciones. La siguiente lista de especies es diagnóstica para este sistema: *Acrocomia aculeata, Annona reticulata, Apeiba tibourbou, Byrsonima crassifolia, Cochlospermum vitifolium, Cordia alliodora, Curatella americana, Guazuma ulmifolia, Luehea candida, Luehea speciosa, Quercus affinis, Quercus glaucescens, Quercus oleoides, Quercus peduncularis, Quercus sororia, Spondias mombin, Tabebuia rosea, Zinowiewia integerrima, Zuelania guidonia*.

This system encompasses a variety of communities characterized by the presence of evergreen *Quercus* in tropical lowland communities. Communities are azonal, i.e., they occur because of certain substrates, rather than the climate. This system represents a pure oak or mixed forest with species from surrounding deciduous forests. They are more common on the Caribbean side of Mexico, but there are examples of them south to Costa Rica. Mostly it has been altered and now most of its length has been converted to jaragua pastures, an introduced graminea, savanna grassland or plantations. The following list of species is diagnostic for this system: *Acrocomia aculeata, Annona reticulata, Apeiba tibourbou, Byrsonima crassifolia, Cochlospermum vitifolium, Cordia alliodora, Curatella americana, Guazuma ulmifolia, Luehea candida, Luehea speciosa, Quercus affinis, Quercus glaucescens, Quercus oleoides, Quercus peduncularis, Quercus sororia, Spondias mombin, Tabebuia rosea, Zinowiewia integerrima*, and *Zuelania guidonia*.

CES411.468 Cuban Lowland Pine Forest on Ferritic Soils

CES411.468 CLASSIFICATION

Concept Summary: Found covering all the ridges and slopes on the northern part of the Cajálbana hills of western Cuba, on ferritic soils, with a closed canopy strongly dominated by *Pinus caribaea var. caribaea*. Typical accompanying species of this low-altitude pine forest include *Neomazaea phialanthoides, Coccothrinax yuraguana*, and *Phania cajalbanica*. A well-developed herb layer is dominated by grasses (e.g., *Andropogon gracilis, Aristida refracta*) is present. Also on the ferritic soils of the foothills of subcoastal plains of eastern Cuba, it develops a lowland pine forest very rich in endemic species. The rather closed canopy of this forest is strongly dominated by *Pinus cubensis* with *Dracaena cubensis, Coccothrinax orientalis*, and *Guatteria moralesii* also present. Both the shrub and herbaceous layers are well-developed in this community. Characteristic species are *Sideroxylon cubense (= Bumelia cubensis), Callicarpa oblanceolata, Casearia bissei, Casearia moaensis, Chaetocarpus oblongatus, Cyrilla cubensis, Eugenia pinetorum, Guettarda crassipes, Guettarda ferruginea, Jacquinia roigii, Myrtus ophiticola, Ossaea pauciflora, Phyllanthus myrtilloides ssp. erythrinus, Psidium parviflorum, Rhynchospora lindeniana, Schmidtottia sessiliflora*, and *Schmidtottia shaferi*.

CES411.469 Cuban Lowland Pine Woodland on Sand

CES411.469 CLASSIFICATION

Concept Summary: Originally a pine forest with loose canopy and a shrub layer rich in species, growing on nutrient-poor, light gray quartz sand. Logged forests have been replaced by scrub and savanna. Occurs on the hillsides of Isla de Pinos, Cuba. The following list of species is diagnostic for this system: *Acoelorraphe wrightii, Byrsonima crassifolia, Byrsonima wrightiana, Chaetolepis cubensis, Cladium mariscus ssp. jamaicense (= Cladium jamaicense), Coccothrinax miraguama, Colpothrinax wrightii, Kalmiella aggregata, Dichanthelium longiligulatum (= Panicum longiligulatum), Pinus caribaea var. caribaea, Pinus tropicalis, Syngonanthus insularis, Tabebuia lepidophylla*, and *Xyris longibracteata*.

CES411.469 CONCEPTUAL MODEL

Environment: [from M296] *Climate*: Mean annual temperatures in the area of distribution of the type range from 23°C (74°F) in the north to 26°C (77°F) in the Lower Keys. Mean annual temperature in the West Indies distribution of the macrogroup is around 25°C. Precipitation primarily occurs from May or June to October and ranges from 1650 mm along the Atlantic coast decreasing southward to less than 1000 mm in the Lower Keys (Gillespie 2006). Annual precipitation in the distributional range of this forest in Cuba is less than 1500 mm in the west part of the range and increases towards the east.

Soil/Substrate: Limestone is the dominant substrate in the macrogroup distribution in Florida and the Bahamas, with skeletal organic soils with minor mineral components, rarely exceeding 20 cm in depth (Snyder et al. 1990, as cited in Gillespie 2006). In Cuba, the pine forests included in this macrogroup are found primarily on acidic soils that have little water-retention capacity and are poor in essential elements. The principal soil types on which they occur are quartziferous sands, pseudo-spodosols in the west and lateritic soils in the east. Only pine trees, which have an ectomycorrhizal symbiosis with fungi, are capable of obtaining in this way a sufficient amount of nutrients to achieve the size of trees. In Florida and the Bahamas, pine rockland occurs on relatively flat, moderately to well-drained terrain, from 2-7 m above sea level (Snyder et al. 1990). The oolitic limestone is at or very near the surface, and there is very little soil development. Soils are generally composed of small accumulations of nutrient-poor sand, marl, clayey loam, and organic debris in depressions and crevices in the rock surface. Organic acids occasionally dissolve the surface limestone causing collapsed depressions in the surface rock called solution holes (Outcalt 1997b). Drainage varies according to the porosity of the limestone substrate, but is generally rapid. Consequently, most sites are wet for only short periods following heavy rains. During the rainy season, however, some sites may be shallowly inundated by slow-flowing surface water for up to 60 days each year (FNAI 2010a).

The macrogroup occurs in lowlands and low hills, littoral or sublittoral flatlands on limestone or on thin sandy soils over limestone, or on light gray quartz sand or soils derived from sandstone or serpentine bedrock in the case of communities in Cuba. All these different substrates are nutrient-poor and drain very rapidly. Consequently, most sites are wet for only short periods following heavy rains.

Key Processes and Interactions: In addition to fires, hurricanes and landslides are the major natural disturbances affecting the distribution, composition and structure of the pine forests.

Threats/Stressors: The major threats to pine forests include irrational timber extraction and frequent man-made fires which change the age structure and density of the pine forests, and exotic species which displace native species in the understory modifying the fire regime, water and nutrient availability. Land clearing for agriculture and other uses is another important threat.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct land conversion. Few remnants exist for understanding the factors (beyond conversion) causing collapse.

Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra. Quedan pocos remanentes, principalmente convertido en pastos.

CES411.432 Cuban Sandstone Mixed Pine-Broad-leaved Forest

CES411.432 CLASSIFICATION

Concept Summary: This ecological system is found in the sandstone belt of western Cuba, from lowlands to submontane zones, on yellow soils derived from slatey sandstone rocks. The canopy is rather closed with pines, palms and evergreen trees. In Pinar del Rio the mixed pine-oak type occurs. The understory is rich in species of Melastomataceae. The following list of species is diagnostic for this system in the canopy layer: *Calophyllum calaba ssp. pinetorum, Clusia rosea, Matayba apetala (= Matayba oppositifolia), Pinus caribaea var. caribaea, Pinus tropicalis, Quercus oleoides ssp. sagraeana*, and *Xylopia aromatica*; in the understory: *Acoelorraphe wrightii, Befaria cubensis, Byrsonima crassifolia, Coccothrinax miraguana, Curatella americana, Leptocoryphium lanatum, Miconia ibaguensis, Phyllanthus junceus, Rhus copallinum, Tabebuia lepidophylla, Tetrazygia delicatula, Trachypogon filifolius, Vaccinium cubense, Xylopia aromatica*, and *Zamia silicea*. In early-seral stages or degraded conditions the canopy is fairly open, forming a woodland with *Byrsonima crassifolia, Curatella americana*, and grasses *Eragrostis cubensis, Paepalanthus seslerioides*, and *Syngonanthus insularis*.

CES411.435 Cuban Serpentine Mixed Pine-Broad-leaved Forest

CES411.435 CLASSIFICATION

Concept Summary: On ferritic soils of lowlands and hilly serpentine areas of the Sagua-Baracoa range in eastern Cuba. The canopy of forests growing on deep soils is high and relatively open with a well-developed shrub layer. On cliffs or submontane rocky substrate, the canopy cover is only 30-50%. The following list of species is diagnostic for this system: *Agave shaferi, Anemia coriacea, Anemia nipensis, Sideroxylon cubense (= Bumelia cubensis), Casearia* spp., *Coccothrinax orientalis, Coccothrinax yuraguana, Cyrilla cubensis, Cyrilla nipensis, Dracaena cubensis, Eugenia pinetorum, Malpighia cnide, Neobracea valenzuelana, Ossaea acunae, Paspalum breve, Pinus cubensis, Psidium parviflorum, Rondeletia myrtacea, Tabebuia dubia, Tabebuia pinetorum, Tabebuia shaferi*, and *Vaccinium alainii*.

CES411.435 CONCEPTUAL MODEL

Environment: In the foothill of serpentine ranges of eastern Cuba, on ferritic soils.
Key Processes and Interactions: In addition to fires, hurricanes are the major natural disturbance affecting the distribution, composition and structure of the pine forests.
Threats/Stressors: The major threats to pine forests include irrational timber extraction and frequent man-made fires which change the age structure and density of the pine forests, and exotic species which displace native species in the understory modifying the fire regime, water and nutrient availability. Land clearing for agriculture and other uses is another important threat.
Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct land conversion. Few remnants exist for understanding the factors (beyond conversion) causing collapse. However, alteration to natural fire regime would likely result in a shift in plant species composition, either from canopy closure (in the case of human suppression of natural fires) or from loss of fire-sensitive species and surface soil impacts from overly intense and frequent fires.

Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra. Quedan pocos remanentes, principalmente convertido en pastos. Sin embargo, la alteración al régimen natural de incendios probablemente daría lugar a un cambio en la composición de especies de plantas, ya sea desde el cierre del dosel (en el caso de supresión de incendios naturales humano) o de la pérdida de especies sensibles de fuego e impactos de suelo superficie de los incendios demasiado intensos y frecuentes.

M561. Caribbean & Mesoamerican Seasonal Dry Forest

CES401.615 Meso-American Pacific Deciduous to Semi-deciduous Forest

CES401.615 CLASSIFICATION

Concept Summary: Este sistema ocurre generalmente sobre suelos profundos y ricos de tierras bajas hasta los 800 m de altitud, con un clima estacional tropical/subtropical de 4-6 meses secos (con precipitación menor a 50 mm), y con precipitaciones totales anuales entre 1000 y 1600 mm, aunque puede llegar a los 2000 mm, y una temperatura media sobre 24oC. Bosques en el extremo húmedo del rango de precipitación son semi-deciduos y de mayor estatura - hasta 20-25 m de alto, mientras que los bosques que crecen en zonas de menor precipitación son casi 100% deciduos y en general presentan una estatura menor y un dosel más abierto que no pasa de 15-18 m. Las epífitas son ocasionales siendo las bromelias las más conspicuas. Durante la época seca hay una acumulación de hojarasca debido a que la mayoría de la vegetación es decidua (Holbrook et al. 1995) y la luz solar penetra al suelo del bosque lo que reduce la tasa de descomposición al disminuir la humedad relativa del suelo (Pennington et al. 2006). La fenología floral y de fructificación es altamente estacional y muchas especies florecen sincrónicamente durante la transición entre la época seca y la lluviosa cuando aún los árboles están sin hojas (Bullock et al. 1995). En numerosas localidades de la vertiente del Pacífico en Centro América y a medida que aumenta la altitud, este sistema colinda con bosques premontanos sub-húmedos.

Especies características de este ecosistema son: *Astronium graveolens, Calycophyllum candidissimum, Maclura tinctoria, Chomelia spinosa, Casearia arguta, Enterolobium cyclocarpum, Guazuma ulmifolia, Jacquinia pungens, Tabebuia ochracea, Thouinidium decandrum, Trichilia colimana, Zanthoxylum setulosum, Luehea candida, Spondias mombin, Simarouba glauca, Simarouba amara, Cochlospermum vitifolium, Bursera simaruba, Ceiba aesculifolia, Ardisia revoluta, Andira inermis, Ficus* spp., *Mastichodendron capiri, Sterculia apetala, Guarea excelsa, Genipa americana, Exostema mexicanum, Hemiangium excelsum, Arrabidaea mollissima, Cydista diversifolia, Allophyllus occidentalis, Bauhinia glabra, Lonchocarpus phaseolifolius, Stemmadenia obovata, Combretum farinosum, Gyrocarpus americanus, Acacia collinsii, Adenocalymma inundatum, Apeiba* spp., *Bombacopsis quinata, Cedrela odorata, Guaiacum sanctum, Lonchocarpus phlebophyllus, Platymiscium pleiostachyum, Swietenia humilis, Swietenia macrophylla*.

This system usually occurs on deep, rich soils of lowlands up to 800 m altitude, with seasonal tropical / subtropical dry months (with precipitation less than 50 mm), and total annual precipitation between 1000 and 1600 mm , although it may reach 2000 mm, and an average temperature of 24oC. Forests in the wet end of the precipitation range are semi-deciduous and taller (up to 20-25 m high), while the forests that grow in areas of lower rainfall are nearly 100% deciduous and generally have a lower height and more open canopy that bypasses 15-18 m. Epiphytes are occasional, bromeliads being the most conspicuous. During the dry season there is an accumulation of litter because most vegetation is deciduous (Holbrook et al. 1995) and sunlight penetrates to the forest floor which reduces the rate of decomposition by decreasing the relative soil moisture (Pennington et al. 2006). The floral and fruiting phenology is highly seasonal and many species flower synchronously during the transition between the dry season and the rainy season when the trees are still leafless (Bullock et al. 1995). In many localities of the Pacific slope of Central America and as altitude increases, this system abuts sub-humid premontane forests.

Characteristic species of this ecosystem are: *Astronium graveolens, Calycophyllum candidissimum, Maclura tinctoria, Chomelia spinosa, Casearia arguta, Enterolobium cyclocarpum, Guazuma ulmifolia, Jacquinia pungens, Tabebuia ochracea, Thouinidium decandrum, Trichilia colimana, Zanthoxylum setulosum, Luehea candida, Spondias mombin, Simarouba glauca, Simarouba amara, Cochlospermum vitifolium, Bursera simaruba, Ceiba aesculifolia, Ardisia revoluta, Andira inermis, Ficus* spp., *Mastichodendron capiri, Sterculia apetala, Guarea excelsa, Genipa americana, Exostema mexicanum, Hemiangium excelsum, Arrabidaea mollissima, Cydista diversifolia, Allophyllus occidentalis, Bauhinia glabra, Lonchocarpus phaseolifolius, Stemmadenia obovata, Combretum farinosum, Gyrocarpus americanus, Acacia collinsii, Adenocalymma inundatum, Apeiba* spp., *Bombacopsis quinata, Cedrela odorata, Guaiacum sanctum, Lonchocarpus phlebophyllus, Platymiscium pleiostachyum, Swietenia humilis, Swietenia macrophylla*.

CES401.615 CONCEPTUAL MODEL

Environment: Estos bosques crecen sobre una variedad de suelos y de situaciones topográficas a lo largo de su distribución, desarrollados sobre materiales geológicos de origen volcánico reciente, o sobre calizas o areniscas. En general, se trata de suelos fértiles (Leiva et al. 2009). Las condiciones climáticas que los caracterizan son algo más constantes, con una precipitación anual total promedio en el rango de 1000-2000 mm, siempre con una estación seca de 4 a 6 meses, cuyo periodo del año varía según las localidades.

These forests grow on a variety of soils and topography along its distribution, geological materials developed over recent volcanic or limestone or sandstone situations. In general, it is fertile soil (Lewis et al. 2009). Weather conditions that characterize them are more constant, with an average annual precipitation in the range of 1000-2000 mm, always with a dry season of 4-6 months from a year period varies according to locality.

Key Processes and Interactions: En bosques como éstos, con precipitación limitada y estacional, los procesos de ciclaje de nutrientes son característicamente muy especializados y eficientes y por lo tanto las características edáficas juegan también un papel clave en los procesos de regeneración del bosque. Estudios edáficos realizados en bosques de distinta edad en Santa Rosa, Costa Rica han encontrado una alta heterogeneidad de suelos a muy pequeña escala relacionada con la alta heterogeneidad espacial del ambiente físico y sobre todo de los usos, que aparte del efecto directo sobre el suelo pueden originar erosión tanto eólica como hídrica. Los datos indican que los cambios observados en el suelo son resultado de la presencia anual de fuego, la adición de materia orgánica y minerales al suelo conforme la regeneración avanza, las condiciones microclimáticas más benignas gracias al desarrollo progresivo del bosque, el creciente ciclaje de nutrientes, y la predominancia de texturas franco-arenosas en los suelos examinados. Estos cambios en las propiedades del suelo con la sucesión pueden tener importantes consecuencias sobre la fisiología y la fenología de las diversas formas de vida vegetal observadas durante la regeneración de los bosques tropicales estacionalmente secos (Leiva et al. 2009). El estudio también observó que bosques más maduros tienen mayor desarrollo de la biomasa radical (Raich 1980) y suelos con mejor estructura y aireación y mayor disponibilidad de cationes (Ca, Mg, K, Na y CIC), pero el contenido de agua disponible para las plantas disminuye. Esto podría modificar la severidad de la sequía experimentada por diferentes formas de vida en diferentes estados de sucesión, así como las respuestas fenológicas de las plantas, que podrían experimentar déficit hídricos más severos y mayor competencia por los recursos del suelo en estados más avanzados de sucesión (Leiva et al. 2009).

Debido a los extremos característicos de la estacionalidad, las especies de plantas muestran estrechas relaciones entre polinizadores (abejas) y la flor dentro de períodos limitados durante las estaciones secas o de lluvia. La posterior dispersión de semillas es realizada por las aves, pequeños mamíferos y hormigas. Se piensa que la herbivoría natural es mucho más reducida en la mayoría de los bosques secos ahora con respecto a los niveles históricos, lo que resulta en la estructura de la vegetación alterada (cuando no se trata de alteraciones producidas por el sobrepastoreo o por el fuego). La dinámica en el sistema de agua de la superficie y del subsuelo pueden proporcionar fuentes críticas de humedad durante los periodos de sequía más largos, afectando el establecimiento de las plantas y su reclutamiento.

In these forests, with limited seasonal rainfall, nutrient-cycling processes are typically very specialized and efficient and therefore soil characteristics also play a key role in the processes of forest regeneration. Soil tests conducted in forests of different ages in Gunacaste National Park, Costa Rica, found a high heterogeneity of soils at very small scale related to the high spatial heterogeneity of the physical environment and above all uses, apart from the direct effect on the soil, can cause both wind and water erosion. The data indicate that the observed changes in soil resulting from the annual presence of fire, the addition of organic matter and minerals down as regeneration progresses, more benign microclimate thanks to the progressive development of forests, increasing nutrient cycling and the predominance of French-gritty textures in soils examined. These changes in soil properties with the succession may have important consequences on the physiology and phenology of the various forms of plant life observed during regeneration of the seasonally dry tropical forests (Leiva et al. 2009). The study also found that mature forests have greater development of root biomass (Raich 1980) and better soil structure and aeration and increased availability of cations (Ca, Mg, K, Na and CIC), but the content of water available for plant decreases. This could modify the severity of drought experienced by different life forms in different stages of succession, and phenological responses of plants, they may experience more severe water deficit and increased competition for land resources in more advanced stages of succession (Lewis et al. 2009).

Because of characteristic extremes in seasonality, plant species show close relationships between certain pollinators (bees) and flowers within limited periods during rainy or dry seasons. Subsequent seed dispersal is mediated by birds, small mammals, and ants. Natural herbivory is thought to be much reduced in most dry forests from historic levels, resulting in altered vegetation structure (where not then overgrazed or otherwise altered by human-induced fire). The dynamics in the surface and subsurface water system may provide critical sources of moisture during the longest dry periods, affecting plant establishment and recruitment.

Threats/Stressors: Las alteraciones antropogénicas más comunes en los bosques tropicales estacionalmente secos son la colección de leña, el pastoreo y el fuego, generalmente utilizado en la preparación de parcelas para agricultura de rotación o para promover el desarrollo de pasto. Se ha encontrado que la intensidad y la frecuencia de estas alteraciones está directamente relacionada con la riqueza de especies de árboles y arbustos y con la abundancia de lianas. Fuegos frecuentes en estos bosques disminuyen la diversidad de especies al favorecer la selección solo de especies resistentes y de sucesionales tempranas y eliminan muchas especies de arbustos y lianas que representan una parte significativa del componente leñoso de estos bosques (Gillespie et al. 2000 y las referencias en él). La recolección intensiva de leña es otro factor que reduce la diversidad de especies y selecciona a favor de las especies mas resistentes y con capacidad de rebrote luego de la corta. Estos cambios en la estructura del bosque favorecen a su vez el crecimiento agresivo y dominancia de enredaderas que sofoca a las plantas, especialmente las leñosas juveniles y arbustos causando su muerte o retardando considerablemente la regeneración natural del bosque, todo lo cual contribuye a disminuir la diversidad del bosque (Gillespie et al. 2000 y las referencias en él).

La compactación causada por la presencia de ganado reduce la porosidad del suelo, disminuyendo el flujo de agua y aire. Este proceso reduce la posibilidad de germinación para algunas semillas y afecta los sistemas radiculares superficiales comunes en especies de arbustos y árboles de estos bosques (Maass 1995). Al tratarse de bosques que crecen en condiciones que a la vez son muy aptas para el establecimiento de poblaciones humanas, actualmente los parches remanentes de bosques secos estacionales de la vertiente Pacífica de Centro América representan apenas algo como el 0.1% of de su distribución original (Janzen 1988) y por tanto pueden ser considerados como uno de los ecosistemas más amenazados de los trópicos (Gillespie et al. 2000).

The most common anthropogenic changes in the seasonally dry tropical forests are the collection of firewood, grazing and fire, often used in the preparation of plots for shifting cultivation and to promote the development of grass. It has been found that the intensity and frequency of these alterations are directly related to the diversity of species of trees and shrubs and liana abundance. Frequent fires in these forests decrease species diversity by favoring only the selection of resistant and early-successional species and eliminating many species of shrubs and vines that are a significant part of the woody component of these forests (Gillespie et al. 2000 and references therein). Intensive firewood collection is another factor that reduces species diversity and selects for the most resistant species and those capable of regrowth after wood harvest. These changes in forest structure in turn favor the aggressive growth and dominance of vines that suffocate plants, especially woody shrubs, significantly retarding the natural regeneration of the forest, all of which reduces the forest diversity (Gillespie et al. 2000 and references therein).

The compaction of soil due to the presence of cattle reduces soil porosity, slowing the flow of water and air. This process reduces the possibility for some seed germination and affects the common superficial root systems in species of shrubs and trees of these forests (Maass 1995). Since these forests grow in conditions that also are very suitable for the establishment of human populations, the remaining patches of seasonally dry forests of the Pacific slope of Central America represent only about 0.1% of its original distribution (Janzen 1988) and therefore can be considered one of the most threatened ecosystems in the tropics (Gillespie et al. 2000).

Ecosystem Collapse Thresholds: Numerosos estudios en los bosques estacionalmente secos de México, el Caribe y Centro América destacan su alta resiliencia a la perturbación antrópica, posiblemente derivada de mecanismos de adaptación desarrollados en respuesta a condiciones naturalmente difíciles como la temporalidad en la disponibilidad de recursos asociada a la estacionalidad de la lluvia y la temperatura, alta mortalidad asociada a sequias extremas, variabilidad en la disponibilidad de nutrientes, composición química demandante de adaptaciones especiales debido a las características de los suelos y su asociación con el clima estacional. Se ha encontrado también que aún parches muy pequeños de bosque seco tropical contienen niveles relativamente altos de diversidad y no se han registrado extinciones de plantas en los bosques estacionalmente secos de Centro América pese a sus extremos niveles de reducción de distribución (Gillespie et al. 2000). Si bien esto indica también una alta resiliencia a la fragmentación, no es claro si estos fragmentos pequeños pueden retener los niveles de diversidad genética necesarios para asegurar la regeneración y el éxito a largo plazo de sus poblaciones de especies leñosas.

La combinación de los efectos de la erosión del suelo, la apertura del dosel, las quemas repetidas y los efectos del ganado en el suelo y la vegetación, dan paso a la transformación de estos bosques en comunidades distintas, indicando su colapso. En algunos casos y principalmente cuando se introducen quemas periódicas se transforman en sabanas, que pueden llegar a ser dominadas por gramíneas exóticas y en casos extremos se producen procesos de desertificación. En otros casos se transforma en una comunidad boscosa pero con una combinación de especies nativas y exóticas entre las leñosas arbóreas y arbustivas, que cambia significativamente la estructura y la composición del bosque original. No se conocen todavía las características de resiliencia de estos nuevos ecosistemas.

Numerous studies in the seasonally dry forests of Mexico, Caribbean and Central America indicate its high resilience to human disturbance, possibly derived from adaptive mechanisms developed in response to naturally difficult conditions such as seasonality in resource availability associated with the seasonality of rainfall and temperature, high mortality associated with extreme drought, variability in nutrient availability, soil chemical composition demanding highly specific adaptations due to soil characteristics and their association with seasonal climate. It has also been found that even very small patches of tropical dry forest contain relatively high diversity levels and there have been no extinctions of plants in the seasonally dry forests of Central America despite its extreme reduction of distribution (Gillespie et al. 2000). While this also indicates a high resilience to fragmentation, it is unclear whether these small fragments can retain the levels of genetic diversity to ensure the recovery and long-term success of their populations of woody species.

The combined effects of soil erosion, canopy openness, repeated burning and the effects of livestock on soil and vegetation give way to the transformation of these forests in different communities, indicating its collapse. In some cases and especially when periodic fires are introduced, they transform into savannas, which can become dominated by exotic grasses and in extreme cases desertification processes occur. In other cases it is transformed into a wooded community but with a combination of native and exotic species, including woody trees and shrubs, which significantly changes the structure and composition of the original forest. Resilience in these novel ecosystems is not yet understood.

CES401.293 Motagua and Honduran Valleys Dry Forest

CES401.293 CLASSIFICATION

Concept Summary: Este sistema ocurre generalmente sobre suelos profundos y ricos de tierras bajas con un clima estacional tropical/subtropical (4-6 meses secos), con precipitaciones anuales entre 1000 y 1500 mm, aunque puede llegar a los 2000 mm y una temperatura media sobre 24°C. Occurre solo en valles secos de Gutemala y Honduras, y a mayor altitud, este sistema colinda con bosques premontanos húmedos. La siguiente lista de las especies es de diagnóstica para este sistema: *Andira inermis, Apeiba* spp., *Ardisia revoluta, Astronium graveolens, Bombacopsis quinata, Bursera simaruba, Calycophyllum candidissimum, Casearia arguta, Cavanillesia platanifolia, Ceiba aesculifolia, Chomelia spinosa, Cochlospermum vitifolium, Enterolobium cyclocarpum, Ficus* spp., *Genipa americana, Guarea excelsa, Guazuma ulmifolia, Hymenaea courbaril, Jacquinia pungens, Luehea candida, Maclura tinctoria, Manilkara zapota, Mastichodendron capiri, Samanea saman (= Pithecellobium saman), Simarouba glauca, Spondias mombin, Sterculia apetala, Swietenia macrophylla, Tabebuia ochracea, Tabebuia* spp., *Thouinidium decandrum, Trichilia colimana, Zanthoxylum setulosum*.

This system usually occurs on deep, rich soils of lowland seasonal tropical / subtropical climate (4-6 months dry), with annual rainfall between 1000 and 1500 mm, but can reach up to 2000 mm and an average temperature of 24oC. It occurs in dry valleys of Guatemala and Honduras, and as altitude increases, this system borders premontane wet forest. The following list of species is diagnostic for this system: *Andira inermis, Apeiba* spp., *Ardisia revoluta, Astronium graveolens, Bombacopsis quinata, Bursera simaruba, Calycophyllum candidissimum, Casearia arguta, Cavanillesia platanifolia, Ceiba aesculifolia, Chomelia spinosa, Cochlospermum vitifolium, Enterolobium cyclocarpum, Ficus* spp., *Genipa americana, Guarea excelsa, Guazuma ulmifolia, Hymenaea courbaril, Jacquinia pungens, Luehea candida, Maclura tinctoria, Manilkara zapota, Mastichodendron capiri, Samanea saman, Simarouba glauca, Spondias mombin, Sterculia apetala, Swietenia macrophylla, Tabebuia ochracea, Tabebuia* spp., *Thouinidium decandrum, Trichilia colimana*, and *Zanthoxylum setulosum*.

CES401.293 CONCEPTUAL MODEL

Environment: Estos sistemas ocurren en mesetas, terrazas coluviales, laderas con afloramientos rocosos y calas protegidas. Basáltica derivado de los suelos, o de cenizas volcánicas, o arcilloso y generalmente bien drenados.

These system occur on plateaus, colluvial terraces, slopes with rock outcrops and sheltered coves. Basaltic derived soils, or from volcanic ashes, or clayish and usually well drained.

Key Processes and Interactions: Los procesos clave y las interacciones son similares a los de otros tipos de bosque seco.

Threats/Stressors: Este sistema ha sufrido fragmentación y disturbios antropogénicos intensos.

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

CES401.309 Yucatán Dry Deciduous Forest

CES401.309 CLASSIFICATION

Concept Summary: Es un sistema que en la mayoría de su distribución se relaciona con afloramientos de calizas de origen coralino, relieve plano a colinado y soporta un clima muy estacional con baja precipitación anual. En general el bosque es de estatura baja a media, con la mayoría de las especies deciduas, algunas comunidades más cercanas a la costa se caracterizan por poseer numerosas cactáceas arborescentes. Los suelos son variables y generalmente muy bien drenados. La siguiente lista de las especies es diagnóstica para este sistema: *Acacia* sp., *Bauhinia jennigsii, Beaucarnea pliabilis, Bursera simaruba, Caesalpinia gaumeri, Caesalpinia vesicaria, Ceiba aesculifolia, Diospyros cuneata, Guaiacum sanctum, Gymnopodium floribundum, Hampea trilobata, Jatropha gaumeri, Lemaireocereus griseus, Lemairocereus aragonii, Lonchocarpus rugosus, Lysiloma latisiliquum, Manilkara sapota, Metopium brownei, Parmentiera aculeata, Piscidia piscipula, Plumeria obtusa, Pseudophoenix* sp., *Pterocereus gaumeri, Thrinax radiata, Vitex gaumeri*.

In most of its distribution, this system is related to limestone outcrops of coral origin, up to hilly terrain and supports a seasonal climate with low annual rainfall. Overall the forest is short to medium, with mostly deciduous species. Some communities closest to the coast are characterized by numerous arborescent cacti. Soils are variable and generally well-drained. The following list of species is diagnostic for this system: *Acacia* sp., *Bauhinia jennigsii, Beaucarnea pliabilis, Bursera simaruba, Caesalpinia gaumeri, Caesalpinia vesicaria, Ceiba aesculifolia, Diospyros cuneata, Guaiacum sanctum, Gymnopodium floribundum, Hampea trilobata, Jatropha gaumeri, Lemaireocereus griseus, Lemairocereus aragonii, Lonchocarpus rugosus, Lysiloma latisiliquum, Manilkara sapota, Metopium brownei, Parmentiera aculeata, Piscidia piscipula, Plumeria obtusa, Pseudophoenix* sp., *Pterocereus gaumeri, Thrinax radiata*, and *Vitex gaumeri*.

CES401.309 CONCEPTUAL MODEL

Environment: Ocurre en las planicies costeras y colinas sobre calizas porosas o suelos superficiales sobre calizas, con clima estacionalmente seco y precipitación anual entre 1000-2000 mm. Hay diferencias de la profundidad del suelo que inciden en la estructura del bosque, con suelos mas delgados generando un bosque mas bajo, pero de troncos gruesos.

Occurs on coastal plain and low hills on porous limestone or shallow soil on limestone, with seasonal dry climate and annual precipitation somewhat less than 1500 mm.

Key Processes and Interactions: En estos bosques la principal fuente de disturbio natural son los huracanes (Morales 1993, Boose et al. 2003). La frecuencia de estos eventos es altamente variable si se calcula por décadas, pero un promedio general es 0.7 huracanes por año. La intensidad también varía y son más comunes los de menor intensidad. El frente de impacto y su posterior dirección siguen diferentes patrones pero los más comunes implican que el área más afectada es el norte y noreste de la Península. Estos patrones de impacto posiblemente generan una diversidad de habitats que influyen en la distribución de los tipos de bosque seco. Gracias a la estructura de los árboles y a la alta proporción de biomasa radicular, el daño causado por vientos o huracanes derriba pocos árboles, produciendo claros pequeños y/o pocos claros grandes (Dickinson et al. 2001), lo clave es que no causan remoción o disturbios importantes de suelo. La regeneración se da fundamentalmente por retoños, adaptación que se facilita por la cantidad de biomasa radicular que provee mayor circulación del agua disponible, nutrientes del suelo y reservas de materia orgánica. Esta estrategia de recuperación causa una composición con alta dominancia y poca diversidad. A este factor se añade la presencia humana en la Península que data de siglos de activa utilización de los recursos por una población importante y que introdujo el fuego como un mecanismo de manejo de la vegetación. El efecto de los huracanes también tiene incidencia por el nivel de inundación debido a la precipitación y la duración de la presencia de zonas inundadas, especialmente con aguas salobres, pues esto causa mortalidad incluso en mayor grado que la caída de árboles por los vientos.

In these forests the main source of natural disturbance are hurricanes (Morales 1993, Boose et al. 2003). The frequency of these events is highly variable when calculated for decades, but an overall average is 0.7 hurricanes per year. The intensity also varies but lower intensity is more common. Different patterns form based on distance to the costal impact area. The most affected area is north and northeast of the peninsula. These patterns of impact may generate a variety of habitats that influence the distribution of dry forest types. Thanks to the structure of the trees and the high proportion of root biomass, wind damage from hurricanes fells few trees, causing small gaps and/or a few large clearings (Dickinson et al. 2001); the key is to not cause removal or significant disturbance to soil. Regeneration occurs primarily by suckers, and adaptation is facilitated by the amount of root biomass which provides greater flow of available water, soil nutrients and organic matter reserves. This recovery strategy causes a composition with high dominance and low diversity. Human presence in the peninsula is centuries-long and active use of resources includes introduced fire as a mechanism for vegetation management. The effect of hurricanes also has implications for the level of flooding due to rainfall and the duration of the presence of water in flooded areas, especially saltwater, as this causes mortality to an even greater degree than treefall from wind.

Threats/Stressors: Agricultura de escala industrial, con soya y cítricos, conversión de gran escala. Aprovechamiento para leña, mucha entresaca de plantas nativas como ornamentales. Ganadería en la región oriente cerca de Quintana-Roo. La práctica de tumba, roza y quema, típica de los cultivos itinerantes, y muy generalizada en la región, altera los patrones espaciales de propiedades edáficas que son biológicamente muy importantes, con lo que se limitan las posibilidades de regeneración del bosque. Fuegos que alcanzan altas temperaturas tienen el potencial de convertir en cenizas gran parte de la materia orgánica de la superficie, y por lo tanto volatilizar grandes cantidades de nutrientes claves tales como el nitrógeno. En los suelos muy poco profundos de la Península de Yucatán, estos procesos pueden ir acompañados de pérdidas erosivas y los cambios resultantes en la fertilidad y estructura del suelo pueden ser de recuperación muy lenta (Boose et al. 2003).

Industrial-scale agriculture, soy and citrus, large-scale conversion. Exploitation for firewood, thinning of many native plants as ornamentals. Livestock in the eastern region near Quintana-Roo. The practice of slash-and-burn shifting cultivation, typical and widespread in the region, alters the spatial patterns of soil properties that are biologically very important, so the possibilities are limited for forest regeneration. Fires reaching high temperatures have the potential to burn off organic matter from the surface, and

therefore vaporize large amounts of key nutrients such as nitrogen. In very shallow soils of the Yucatan Peninsula, these processes may be accompanied by erosive losses and the resulting changes in fertility and soil structure can be a very slow recovery (Boose et al. 2003).
Ecosystem Collapse Thresholds: El riesgo de colapso del ecosistema se puede dar en función de escenarios que combinan una serie de factores, desde los regímenes de dinámica naturales, más las dinámicas antrópicas influidas por políticas que conllevan incentivos de mal uso del suelo. La presencia de especies invasoras es un indicador medible de colapso, en función de la proporción de invasoras en la composición. Degradación del medio ambiente: Escenarios de cambio climático señalan que este ecosistema desaparecería como se lo conoce en composición y estructura. Interrupcion de flujos hídricos superficiales por construcción de infraestructura como carreteras. Interrupcion de procesos bióticos: uso del suelo para ganadería con introducción de gramíneas, cambio irreversible de composición. Según la disponibilidad de recursos, hay una intensidad de uso que está dada por el acceso humano.

The risk of ecosystem collapse can be viewed in terms of scenarios that combine a number of factors, from natural dynamic regimes, more influenced by resource management policies involving incentives resulting in poor land use. The presence of invasive species is a measurable indicator of collapse, in terms of the proportion of invasives in the composition. Degradation of the environment: Climate change scenarios indicate that this ecosystem would disappear as it is known in composition and structure. Disruption of surface waterflows from construction of infrastructure such as roads. Disruption of biotic processes: land use with livestock grass introduction, irreversible change in composition. Depending on the availability of resources, there is an intensity of use that is given by human access.

CES401.312 CONCEPTUAL MODEL

Environment: Planicie costera con clima estacional en la costa Pacífica de Panamá.
Key Processes and Interactions: En bosques como éstos, con precipitación limitada y estacional, los procesos de ciclaje de nutrientes son característicamente muy especializados y eficientes y por lo tanto las características edáficas juegan también un papel clave en los procesos de regeneración del bosque. Estudios edáficos realizados en bosques de distinta edad en Santa Rosa, Costa Rica han encontrado una alta heterogeneidad de suelos a muy pequeña escala relacionada con la alta heterogeneidad espacial del ambiente físico y sobre todo de los usos, que aparte del efecto directo sobre el suelo pueden originar erosión tanto eólica como hídrica. Los datos indican que los cambios observados en el suelo son resultado de la presencia anual de fuego, la adición de materia orgánica y minerales al suelo conforme la regeneración avanza, las condiciones microclimáticas más benignas gracias al desarrollo progresivo del bosque, el creciente ciclaje de nutrientes, y la predominancia de texturas franco-arenosas en los suelos examinados. Estos cambios en las propiedades del suelo con la sucesión pueden tener importantes consecuencias sobre la fisiología y la fenología de las diversas formas de vida vegetal observadas durante la regeneración de los bosques tropicales estacionalmente secos (Leiva et al. 2009). El estudio también observó que bosques más maduros tienen mayor desarrollo de la biomasa radical (Raich 1980) y suelos con mejor estructura y aireación y mayor disponibilidad de cationes (Ca, Mg, K, Na y CIC), pero el contenido de agua disponible para las plantas disminuye. Esto podría modificar la severidad de la sequía experimentada por diferentes formas de vida en diferentes estados de sucesión, así como las respuestas fenológicas de las plantas, que podrían experimentar déficit hídricos más severos y mayor competencia por los recursos del suelo en estados más avanzados de sucesión (Leiva et al. 2009).

Debido a los extremos característicos de la estacionalidad, las especies de plantas muestran estrechas relaciones entre polinizadores (abejas) y la flor dentro de períodos limitados durante las estaciones secas o de lluvia. La posterior dispersión de semillas es realizada por las aves, pequeños mamíferos y hormigas. Se piensa que la herbivoría natural es mucho más reducida en la mayoría de los bosques secos ahora con respecto a los niveles históricos, lo que resulta en la estructura de la vegetación alterada (cuando no se trata de alteraciones producidas por el sobrepastoreo o por el fuego). La dinámica en el sistema de agua de la superficie y del subsuelo pueden proporcionar fuentes críticas de humedad durante los periodos de sequía más largos, afectando el establecimiento de las plantas y su reclutamiento.

In these forests, with limited seasonal rainfall, nutrient-cycling processes are typically very specialized and efficient and therefore soil characteristics also play a key role in the processes of forest regeneration. Soil tests conducted in forests of different ages in Gunacaste National Park, Costa Rica, found a high heterogeneity of soils at very small scale related to the high spatial heterogeneity of the physical environment and above all uses, apart from the direct effect on the soil, can cause both wind and water erosion. The data indicate that the observed changes in soil resulting from the annual presence of fire, the addition of organic matter and minerals down as regeneration progresses, more benign microclimate thanks to the progressive development of forests, increasing nutrient cycling and the predominance of French-gritty textures in soils examined. These changes in soil properties with the succession may have important consequences on the physiology and phenology of the various forms of plant life observed during regeneration of the seasonally dry tropical forests (Leiva et al. 2009). The study also found that mature forests have greater development of root biomass (Raich 1980) and better soil structure and aeration and increased availability of cations (Ca, Mg, K, Na and CIC), but the content of water available for plant decreases. This could modify the severity of drought experienced by different life forms in different stages of succession, and phenological responses of plants, they may experience more severe water deficit and increased competition for land resources in more advanced stages of succession (Lewis et al. 2009).

Because of characteristic extremes in seasonality, plant species show close relationships between certain pollinators (bees) and flowers within limited periods during rainy or dry seasons. Subsequent seed dispersal is mediated by birds, small mammals, and ants. Natural herbivory is thought to be much reduced in most dry forests from historic levels, resulting in altered vegetation structure (where not then overgrazed or otherwise altered by human-induced fire). The dynamics in the surface and subsurface water system may provide critical sources of moisture during the longest dry periods, affecting plant establishment and recruitment.

Threats/Stressors: Las alteraciones antropogénicas más comunes en los bosques tropicales estacionalmente secos son la colección de leña, el pastoreo y el fuego, generalmente utilizado en la preparación de parcelas para agricultura de rotación o para promover el desarrollo de pasto. Se ha encontrado que la intensidad y la frecuencia de estas alteraciones está directamente relacionada con la riqueza de especies de árboles y arbustos y con la abundancia de lianas. Fuegos frecuentes en estos bosques disminuyen la diversidad de especies al favorecer la selección solo de especies resistentes y de sucesionales tempranas y eliminan muchas especies de arbustos y lianas que representan una parte significativa del componente leñoso de estos bosques (Gillespie et al. 2000 y las referencias en él). La recolección intensiva de leña es otro factor que reduce la diversidad de especies y selecciona a favor de las especies mas resistentes y con capacidad de rebrote luego de la corta. Estos cambios en la estructura del bosque favorecen a su vez el crecimiento agresivo y dominancia de enredaderas que sofoca a las plantas, especialmente las leñosas juveniles y arbustos causando su muerte o retardando considerablemente la regeneración natural del bosque, todo lo cual contribuye a disminuir la diversidad del bosque (Gillespie et al. 2000 y las referencias en él).

La compactación causada por la presencia de ganado reduce la porosidad del suelo, disminuyendo el flujo de agua y aire. Este proceso reduce la posibilidad de germinación para algunas semillas y afecta los sistemas radiculares superficiales comunes en especies de arbustos y árboles de estos bosques (Maass 1995). Al tratarse de bosques que crecen en condiciones que a la vez son muy aptas para el establecimiento de poblaciones humanas, actualmente los parches remanentes de bosques secos estacionales de la vertiente Pacífica de Centro América representan apenas algo como el 0.1% of de su distribución original (Janzen 1988) y por tanto pueden ser considerados como uno de los ecosistemas más amenazados de los trópicos (Gillespie et al. 2000).

The most common anthropogenic changes in the seasonally dry tropical forests are the collection of firewood, grazing and fire, often used in the preparation of plots for shifting cultivation and to promote the development of grass. It has been found that the intensity and frequency of these alterations are directly related to the diversity of species of trees and shrubs and liana abundance. Frequent fires in these forests decrease species diversity by favoring only the selection of resistant and early-successional species and eliminating many species of shrubs and vines that are a significant part of the woody component of these forests (Gillespie et al. 2000 and references therein). Intensive firewood collection is another factor that reduces species diversity and selects for the most resistant species and those capable of regrowth after wood harvest. These changes in forest structure in turn favor the aggressive growth and dominance of vines that suffocate plants, especially woody shrubs, significantly retarding the natural regeneration of the forest, all of which reduces the forest diversity (Gillespie et al. 2000 and references therein).

The compaction of soil due to the presence of cattle reduces soil porosity, slowing the flow of water and air. This process reduces the possibility for some seed germination and affects the common superficial root systems in species of shrubs and trees of these forests (Maass 1995). Since these forests grow in conditions that also are very suitable for the establishment of human populations, the remaining patches of seasonally dry forests of the Pacific slope of Central America represent only about 0.1% of its original distribution (Janzen 1988) and therefore can be considered one of the most threatened ecosystems in the tropics (Gillespie et al. 2000).

Ecosystem Collapse Thresholds: Numerosos estudios en los bosques estacionalmente secos de México, el Caribe y Centro América destacan su alta resiliencia a la perturbación antrópica, posiblemente derivada de mecanismos de adaptación desarrollados en respuesta a condiciones naturalmente difíciles como la temporalidad en la disponibilidad de recursos asociada a la estacionalidad de la lluvia y la temperatura, alta mortalidad asociada a sequias extremas, variabilidad en la disponibilidad de nutrientes, composición química demandante de adaptaciones especiales debido a las características de los suelos y su asociación con el clima estacional. Se ha encontrado también que aún parches muy pequeños de bosque seco tropical contienen niveles relativamente altos de diversidad y no se han registrado extinciones de plantas en los bosques estacionalmente secos de Centro América pese a sus extremos niveles de reducción de distribución (Gillespie et al. 2000). Si bien esto indica también una alta resiliencia a la fragmentación, no es claro si estos fragmentos pequeños pueden retener los niveles de diversidad genética necesarios para asegurar la regeneración y el éxito a largo plazo de sus poblaciones de especies leñosas.

La combinación de los efectos de la erosión del suelo, la apertura del dosel, las quemas repetidas y los efectos del ganado en el suelo y la vegetación, dan paso a la transformación de estos bosques en comunidades distintas, indicando su colapso. En algunos casos y principalmente cuando se introducen quemas periódicas se transforman en sabanas, que pueden llegar a ser dominadas por gramíneas exóticas y en casos extremos se producen procesos de desertificación. En otros casos se transforma en una comunidad boscosa pero con una combinación de especies nativas y exóticas entre las leñosas arbóreas y arbustivas, que cambia significativamente la estructura y la composición del bosque original. No se conocen todavía las características de resiliencia de estos nuevos ecosistemas.

Numerous studies in the seasonally dry forests of Mexico, Caribbean and Central America indicate its high resilience to human disturbance, possibly derived from adaptive mechanisms developed in response to naturally difficult conditions such as seasonality in resource availability associated with the seasonality of rainfall and temperature, high mortality associated with extreme drought, variability in nutrient availability, soil chemical composition demanding highly specific adaptations due to soil characteristics and their association with seasonal climate. It has also been found that even very small patches of tropical dry forest contain relatively high diversity levels and there have been no extinctions of plants in the seasonally dry forests of Central America despite its extreme reduction of distribution (Gillespie et al. 2000). While this also indicates a high resilience to fragmentation, it is unclear whether these small fragments can retain the levels of genetic diversity to ensure the recovery and long-term success of their populations of woody species.

The combined effects of soil erosion, canopy openness, repeated burning and the effects of livestock on soil and vegetation give way to the transformation of these forests in different communities, indicating its collapse. In some cases and especially when periodic fires are introduced, they transform into savannas, which can become dominated by exotic grasses and in extreme cases desertification processes occur. In other cases it is transformed into a wooded community but with a combination of native and exotic species, including woody trees and shrubs, which significantly changes the structure and composition of the original forest. Resilience in these novel ecosystems is not yet understood.

CES401.289 Guerreran Dry Deciduous Forest

CES401.289 CLASSIFICATION

Concept Summary: Se encuentra este sistema de bosque seco tropical caducifolio de Jalisco sur a través de Oaxaca. Encontrado en cañones y empinadas laderas con suelos arenosos finos, estas áreas típicamente experimentan una temporada húmeda distinta (Mayo a Noviembre) cada año. Una moderada a alta diversidad de especies de árboles de hojas caducas tropicales dominan las copas de árboles en niveles un complejo multi alrededor de 9-12 m de altura. Este bosque tiene una alta densidad de pequeños tallos y lianas. La estructura y composición varían a lo largo de la gran distribución de este sistema forestal, que incluye las topografías montañosas que influyen en la disponibilidad de humedad y el carácter del suelo. La siguiente lista de las especies es de diagnóstica para este sistema: *Achatocarpus oaxacanus, Aphipterygium glaucum, Bombax ellipicum, Bombax palmeri, Bursera* *fagaroides, Bursera instabilis, Bursera longipes, Bursera morelensis, Bursera fagaroides var. elongata (= Bursera odorata), Caesalpinia coccinea, Ceiba aesculifolia, Cephalocereus* spp., *Coccoloba* spp., *Cyrtocarpa procera, Gyrocarpus mocinnoi, Hibiscus kochii, Jatropha alamani, Jatropha cordata, Leucaena esculenta, Lonchocarpus* spp., *Lysiloma* spp., *Pachycereus* spp., *Plumeria rubra, Pseudosmodingium perniciosum, Tabebuia palmeri*. Balsas dry forest: *Agave pedunculifera, Bursera ariensis, Bursera diversifolia, Bursera hintonii, Ceiba aesculifolia, Cochlospermum vitifolium, Conzattia multiflora, Cordia elaeagnoides, Cyrtocarpa procera, Ficus cotinifolia, Ficus goldmanii, Ficus kellermanni, Ficus petiolaris, Haematoxylon brasiletto, Heliocarpus reticulatus, Lysiloma divaricatum, Pterocarpus orbiculatus, Ruprechtia fusca, Tabebuia impetiginosa* y *Vitex pyramidata*.

This dry tropical deciduous forest system is found from Jalisco south through Oaxaca, Mexico. It is found in canyons and steep slopes with thin sandy soils. These areas typically experience one distinct wet season (May-November) each year. A moderate to high diversity of tropical deciduous tree species dominate a complex multi-tiered tree canopy around 9-12 m tall. This forest has a high density of small stems and lianas. The structure and composition vary along the large distributional range of this forest system, which includes mountainous topographies that influence moisture availability and soil characteristics. The following list of species is diagnostic for this system: *Achatocarpus oaxacanus, Aphipterygium glaucum, Bombax ellipicum, Bombax palmeri, Bursera fagaroides, Bursera instabilis, Bursera longipes, Bursera morelensis, Bursera fagaroides var. elongata (= Bursera odorata), Caesalpinia coccinea, Ceiba aesculifolia, Cephalocereus* spp., *Coccoloba* spp., *Cyrtocarpa procera, Gyrocarpus mocinnoi, Hibiscus kochii, Jatropha alamani, Jatropha cordata, Leucaena esculenta, Lonchocarpus* spp., *Lysiloma* spp., *Pachycereus* spp., *Plumeria rubra, Pseudosmodingium perniciosum*, and *Tabebuia palmeri*. Balsas dry forest: *Agave pedunculifera, Bursera ariensis, Bursera diversifolia, Bursera hintonii, Ceiba aesculifolia, Cochlospermum vitifolium, Conzattia multiflora, Cordia elaeagnoides, Cyrtocarpa procera*, *Ficus cotinifolia, Ficus goldmanii, Ficus kellermanni, Ficus petiolaris, Haematoxylon brasiletto, Heliocarpus reticulatus, Lysiloma divaricatum, Pterocarpus orbiculatus, Ruprechtia fusca, Tabebuia impetiginosa*, and *Vitex pyramidata*.

CES401.289 CONCEPTUAL MODEL

Environment: Encontrado en cañones y laderas escarpadas con suelos arenosos de capacidad de retención de agua poco profundos, pobres en nutrientes y bajos, estas áreas suelen experimentar una temporada distinta húmeda (julio de noviembre) y una estación seca (diciembre a junio) cada año. Este sistema se encuentra con entre 0 a 900 msnm con precipitación media anual varía entre 400 a 1200 mm, y la temperatura media anual de alrededor de 25°C. Este sistema de transiciones en matorral espinoso en el extremo más seco de su gradiente a lo largo de las fronteras de elevación menores, y para los bosques de hoja perenne semi pendiente ascendente más o en los fondos de los valles. Régimen natural de incendios no está documentada para este sistema, sin embargo el fuego se utiliza para gestionar los pastos introducidos.

Found in canyons and steep slopes with shallow, nutrient-poor sandy soils with low water-holding capacity. These areas typically experience one distinct wet season (July-November) and one dry season (December-June) each year. This system occurs between 0-900 m asl with mean annual precipitation varying between 400-1200 mm, and mean annual temperature around 25°C. This system transitions into thornscrub at the drier end of its gradient along lower elevation borders, and to semi-evergreen forest further upslope or at the valley bottoms. Natural fire regime is not documented for this system; however, fire is used to manage the introduced pastures.

Key Processes and Interactions: Este bosque ha desarrollado mecanismos de reciclaje muy ajustados para evitar la pérdida de nutrientes del sistema. Algunos de estos mecanismos incluyen una capa de hojarasca densa de hasta 8,2 Mg ha, la inmovilización microbiana de los nutrientes durante la estación seca, la reabsorción de nutrientes antes de la abscisión de la hoja, la resistencia de los bosques a los incendios, y la estabilidad de los agregados del suelo elevado (Maass et al. 2005 y sus referencias). La dinámica natural está impulsada principalmente por el estrés y la muerte regresiva relacionados con la sequía.

This forest has evolved tight recycling mechanisms to avoid nutrient loss from the system. Some of these mechanisms include a dense leaf litter layer of up to 8.2 Mgha, microbial immobilization of nutrients during the dry season, nutrient reabsorption prior to leaf abscission, forest resistance to fires, and high soil aggregate stability (Maass et al. 2005 and references therein). Natural dynamics is mainly driven by drought-related stress and dieback.

Threats/Stressors: Conversión a la agricultura y pastos introducidos (*Urochloa maxima (= Panicum maximum), Pennisetum ciliare (= Cenchrus ciliaris)*), el pastoreo excesivo. Cuando se transforma el bosque, se modifican los mecanismos de mantenimiento de la fertilidad del sistema. Por ejemplo, incendios consumen la capa organica de la superficie hasta el 80% de la biomasa por encima del suelo. La Conversion debosque-a pasturas resulta en 77% y 82% de pérdidas de C y N, respectivamente, en la biomasa aérea. La constante presencia de una capa de hojarasca en el suelo del bosque mantiene altas tasas de infiltración en el suelo, evitando la escorrentía y la erosión del suelo y la reducción de las inundaciones durante las tormentas. Cuando el bosque se transforma hacia la agricultura y los campos de pastos, disminuye la cubierta del suelo y disminuyen las tasas de infiltración, lo que resulta en la erosión del suelo y el transporte de sedimentos vertiente abajo varios órdenes de magnitud por encima de las tasas naturales (hasta 130 Mg-1 / ha-1 / año -1) (Maass et al. 2005 y sus referencias). Todas estas perturbaciones antropogénicas genera dominancia de unas pocas especies pioneras de crecimiento rápido. Cuando el sistema agrícola permite largos períodos de barbecho suficiente, se desarrolla un bosque / matorral secundario dominado por varias leguminosas leñosas (*Acacia* spp., *Caesalpinia* spp., *Mimosa* spp., *Gliricidia sepium*).

Conversion to agriculture and introduced pastures (*Urochloa maxima (= Panicum maximum), Pennisetum ciliare (= Cenchrus ciliaris)*) and overgrazing. When the forest is transformed, the fertility maintenance mechanisms of the system are modified. For example, slash fires consume the surface litter up to 80% of the above-ground biomass. Forest-to-pasture conversion results in 77% and 82% losses of C and N, respectively, from above-ground biomass. The constant presence of a leaf litter layer in the forest floor keeps high infiltration rates in the soil, avoiding runoff and soil erosion, and reducing floods during storm events. When the forest is transformed into agriculture and pasture fields, soil cover decreases and infiltration rates diminish, resulting in soil erosion and sediment transport down the stream several orders of magnitude above the natural rates (up to 130 Mg-1 / ha-1 / yr-1) (Maass et al. 2005 and references therein). All this anthropogenic disturbance generates dominance of a few rapid-growing pioneer species. When the agricultural system allows for long enough fallow periods, a secondary forest/scrub develops dominated by several woody legumes (*Acacia* spp., *Caesalpinia* spp., *Mimosa* spp., *Gliricidia sepium*).

Ecosystem Collapse Thresholds: Uno de los trastornos más prevalentes infligidas a este bosque seco es la conversión a la agricultura de tala y quema y de pastos. Ambos tipos de uso implican la sustitución del ecosistema natural por usos de la tierra antropogénicas mantenidas con el uso periódico de fuego. La recuperación después utiliza dicha tierra es lento y requiere de varios años sin ningún tipo de uso o de fuego, con la posibilidad de no retorno para el tipo de ecosistema forestal natural, si las condiciones abióticas y bióticas críticos que controlan los procesos funcionales del sistema sufren cambios sustanciales. Los estudios sobre el efecto de borde entre este tipo de bosque seco y pastos adyacentes ha demostrado que los efectos sobre los factores abióticos como la tasa de infiltración de agua, la biomasa de hojarasca, humedad relativa, humedad del suelo, y el suelo y la temperatura atmosférica, alcanzan hasta 11-18 m en el parche de bosque, creando secadora y condiciones más cálidas en general más similares a las de los pastos (Nava Cruz 2006). El éxito de las especies de árboles en estas condiciones depende de una serie de factores, incluyendo los atributos de las especies combinadas con las condiciones del lugar abióticos específicos, y la respuesta a las perturbaciones antropogénicas como los incendios.

One of the most prevalent disturbances inflicted on this dry forest is conversion to slash-and-burn agriculture and to pastures. Both types of use result in the replacement of the natural ecosystem by anthropogenic land uses maintained with the periodic use of fire. Recovery after such land uses is slow and requires several years without any use or fire, with the possibility of no return to the natural forest ecosystem type if the critical abiotic and biotic conditions that control functional processes of the system undergo substantial changes. Studies on the edge effect between this type of dry forest and adjacent pastures has shown that effects on abiotic factors, such as rate of water infiltration, litter biomass, relative humidity, soil moisture, and soil and atmospheric temperature, reach up to 11-18 m into the forest patch, creating drier and warmer conditions overall more similar to those in the pastures (Nava Cruz 2006). The success of tree species in these conditions depends on a number of factors, including the species traits combined with site-specific abiotic conditions, and response to anthropogenic disturbance such as fire.

CES401.302 Sinaloan Dry Deciduous Forest

CES401.302 CLASSIFICATION

Concept Summary: Este sistema de bosque subtropical seco se encuentra en todo el sur de Sonora y el oeste de Sinaloa. Encontrado en cañones y laderas escarpadas con suelos delgados de arena, estas áreas tienen dos estaciones húmedas (invierno y mediados de verano) y dos estaciones secas cada año. Esto favorece a las especies de plantas de hoja caduca con sistemas de raíces de almacenamiento bien desarrollados capaces de responder rápidamente a las estaciones húmedas. Una moderada a alta diversidad de especies de árboles caducifolios tropicales dominan un complejo dosel de varios niveles. Se considera que este sistema soporta una rica fauna de aves y reptiles. La siguiente lista de especies es diagnóstica para este sistema: *Conzattia sericea, Jarilla heterophylla (= Jarilla chocola), Bursera inopinnata, Ceiba acuminata, Tabebuia cordata, Ipomoea arborescens, Lysiloma watsonii,* *Choclosperma vitifolium, Senna bicapsularis (= Cassia emarginata), Pachycereus pecten-aboriginum, Stenocereus thurberi, Mardensia edulis, Tillandsia inflata*.

This dry subtropical forest system is found throughout southern Sonora and western Sinaloa, Mexico. Found in canyons and steep slopes with thin sandy soils, these areas typically experience two wet seasons (winter and mid-summer) and two dry seasons each year. This favors deciduous plant species with well-developed root-storage systems able to rapidly respond to wet seasons. A moderate to high diversity of tropical deciduous tree species dominate a complex multi-tiered tree canopy. This system is commonly viewed as supporting a very rich fauna of songbirds and reptiles. The following list of species is diagnostic for this system: *Conzattia sericea, Jarilla heterophylla, Bursera inopinnata, Ceiba acuminata, Tabebuia cordata, Ipomoea arborescens, Lysiloma watsonii, Choclosperma vitifolium, Senna bicapsularis, Pachycereus pecten-aboriginum, Stenocereus thurberi, Mardensia edulis, Tillandsia inflata*.

CES401.302 CONCEPTUAL MODEL

Environment: Encontrado en cañones y laderas escarpadas con suelos delgados y arenosos. Estas zonas suelen experimentar dos estaciones húmedas (invierno y mediados de verano) y dos estaciones secas cada año. Esto favorece a las especies de plantas de hoja caduca con sistemas de almacenamiento de raíces bien desarrolladas, capaces de responder rápidamente a las estaciones húmedas.

Found in canyons and steep slopes with thin, sandy soils. These areas typically experience two wet seasons (winter and mid-summer) and two dry seasons each year. This favors deciduous plant species with well-developed root storage systems, able to rapidly respond to wet seasons.

Key Processes and Interactions: Este sistema es un sistema de de transición hacia el matorral espinoso Sinaloense a lo largo de las fronteras de menor elevación y hacia los bosques abiertos Madreanos a mayor altitud. Hacia el sur, es probable una transición hacia sistemas forestales semi-perennes. Régimen natural de incendios no está documentado para este sistema.

This system transitions into Sinaloan thornscrub along lower elevation borders and Madrean woodlands further upslope. To the south, there is likely a transition into more southerly semi-evergreen forest systems. Natural fire regime is not documented for this system.

Threats/Stressors:

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

CES403.606 Meso-American Premontane Semi-deciduous Forest

CES403.606 CLASSIFICATION

Concept Summary: El sistema representa las comunidades boscosas premontanas semideciduas que crecen entre los 500 m de altitud y 1000-1200 m a partir de donde empieza el bosque mixto con pinos y robles. Se encuentra en ambas vertientes y generalmente a continuación de los bosques semideciduos de tierras bajas. Posiblemente se incluyen comunidades sucesionales producto de la alteración de bosques húmedos de las vertientes más estacionales del Pacífico. La siguiente lista de las especies es de diagnóstica para este sistema: *Quercus sapotifolia, Quercus oleoides, Pinus caribaea, Guazuma ulmifolia, Acacia pennatula, Bursera bipinnata, Bursera simaruba, Cordia alliodora, Trema micrantha (= Cordia dentata), Cedrela odorata, Ceiba aesculifolia, Castilla elastica, Gliricidia sepium, Serjania, Calliandra* sp., *Crescentia alata, Tecoma stans, Coccoloba caracasana, Cochlospermum vitifolium, Trophis racemosa, Rauvolfia tetraphylla, Gyrocarpus americanus, Pseudobombax ellipticum, Vismia ferruginea, Enterolobium cyclocarpum*.

The system represents the semi-deciduous premontane forest communities growing between 500 and 1000-1200 m from where the mixed pine and oak forest begins. It lies on both Pacific and Caribbean sides and generally occurs just above semi-deciduous lowland forest. The following list of species is diagnostic for this system: *Quercus sapotifolia, Quercus oleoides, Pinus caribaea, Guazuma ulmifolia, Acacia pennatula, Bursera bipinnata, Bursera simaruba, Cordia alliodora, Trema micrantha, Cedrela odorata, Ceiba aesculifolia, Castilla elastica, Gliricidia sepium, Serjania, Calliandra* sp., *Crescentia alata, Tecoma stans, Coccoloba*

caracasana, Cochlospermum vitifolium, Trophis racemosa, Rauvolfia tetraphylla, Gyrocarpus americanus, Pseudobombax ellipticum, Vismia ferruginea, Enterolobium cyclocarpum.

CES401.298 Nayarit-Guerreran Semi-evergreen Forest

CES401.298 CLASSIFICATION

Concept Summary: Estos sistema se desarrolla en altitudes desde el nivel del mar hasta 1300 m de altitud. La precipitación media varía de 1000-1600 mm / año, y las temperaturas medias anuales están entre 20° a 28°C. Estos bosques crecen en suelos de profundidad, textura, y alcalinidad variables. Por lo general son bosques densos que alcanzan alturas de 40 m. Especies de hoja perenne son más frecuentes en las capas subdosel. Las epífitas y pteridofitas son comunes pero menos que en los bosques siempreverdes. La siguiente lista de especies es diagnóstica para este sistema: *Brosimum alicastrum, Bursera excelsa, Celtis monoica, Astronium graveolens, Bursera arborea, Enterolobium cyclocarpum, Ficus* spp., *Hura polyandra, Licania cervantesii, Tabebuia donnell-smithii (= Roseodendron donnell-smithii), Swietenia humilis, Tabebuia donnell-smithii, Tabebuia impetiginosa, Cordia elaeagnoides*.

This system occurs at elevations ranging from sea level up through 1300 m. Precipitation varies from 1000-1600 mm/year, and annual mean temperatures are between 20-28°C. These forests occur on soils of variable depth, texture, and alkalinity. These are typically dense forests reaching heights of 40 m. Evergreen species are most prevalent in subcanopy layers. Epiphytes and pteridophytes are common but less so than in evergreen forests. The following list of species is diagnostic for this system: *Brosimum alicastrum, Bursera excelsa, Celtis monoica, Astronium graveolens, Bursera arborea, Enterolobium cyclocarpum, Ficus* spp., *Hura polyandra, Licania cervantesii, Tabebuia donnell-smithii (= Roseodendron donnell-smithii), Swietenia humilis, Tabebuia donnell-smithii, Tabebuia impetiginosa, Cordia elaeagnoides*.

CES401.299 San Lucan Dry Deciduous Forest

CES401.299 CLASSIFICATION

Concept Summary: This dry tropical forest system is limited in distribution to the Cape region of southern Baja California. It is found in canyons and lowlands with thin rocky or sandy soils. A moderate to low diversity of tropical deciduous tree species dominate. These are structurally simple and of low species diversity relative to dry forests of mainland Mexico and Central America. The following list of species is diagnostic for this system: *Jatropha cinerea, Bursera microphylla, Fouquieria diguetii, Albizia occidentalis, Lysiloma candida, Lysiloma divaricata, Indigofera fruticosa, Senna bicapsularis (= Cassia emarginata), Plumeria acutifolia, Cercidium peninsulare, Ebenopsis confinis (= Pithecellobium confine)*, and *Karwinskia humboldtiana*.

CES411.439 Venezuelan Coastal Piedmontane Semi-deciduous Forest

CES411.439 CLASSIFICATION

Concept Summary: Semi-deciduous, dense forests with 2-3 strata and up to 25 m high. Its altitudinal location varies depending on the hill and the aspect, but occurs on most of the coastal ridges and highlands (500-800/1200 m or 200-600 m elevation). In the northeastern hills this forest reaches the littoral. The following list of species is diagnostic for this system: *Tabebuia chrysantha, Tabebuia serratifolia, Tabebuia heterophylla (= Tabebuia pentaphylla), Trichilia pleeana, Allophylus racemosus (= Allophylus occidentalis), Trophis racemosa, Eugenia mcvaughii, Acacia glomerosa, Lochocarpus punctatus, Coccoloba fallax, Talisia hexaphylla, Cordia panamensis, Swartzia pinnata, Ocotea glandulosa, Hura crepitans, Cedrela odorata, Carapa guianensis, Roystonea oleracea*.

CES411.439 CONCEPTUAL MODEL

Environment: Found on plains and terraces in well-drained lowlands, hills and foothills up to 500 m elevation. Average annual rainfall is 700-1500 mm with one or two dry seasons during the year. In the distribution there is a moisture gradient that goes from the coast with less precipitation and drying conditions on the sea winds, plains and hills up to more sheltered inner areas with greater precipitation.

En planicies y terrazas bien drenadas de las tierras bajas, colinas y piedemontes hasta los 500 m de altitud. Precipitación promedio anual 700-1500 mm con una o dos estaciones secas durante el año. En su distribución existe un gradiente de humedad que va desde la costa con menor precipitación y con condiciones desecantes por los vientos marinos, hasta planicies y colinas del interior mas resguardadas y con una precipitación mayor.

Key Processes and Interactions: In these forests, with limited seasonal rainfall, nutrient-cycling processes are typically very specialized and efficient and therefore soil characteristics also play a key role in the processes of forest regeneration. Because of characteristic extremes in seasonality, plant species show close relationships between certain pollinator (bees) and flowers within limited periods during rain or dry seasons. Subsequent seed dispersal is mediated by birds, small mammals, and ants. Natural herbivory is thought to be much reduced in most dry forests from historic levels, resulting in altered vegetation structure (where not then overgrazed or otherwise altered by human-induced fire). The dynamics in the surface and subsurface water system may provide critical sources of moisture during the longest dry periods, affecting plant establishment and recruitment.

Threats/Stressors: The most common anthropogenic changes in the seasonally dry tropical forests are the collection of firewood, grazing and fire, often used in the preparation of plots for shifting cultivation and to promote the development of grass. It has been found that the intensity and frequency of these alterations are directly related to the diversity of species of trees and shrubs and liana abundance. Frequent fires in these forests decrease species diversity by favoring only the selection of resistant and early-successional species and eliminating many species of shrubs and vines that are a significant part of the woody component of these forests (Gillespie et al. 2000 and references therein). Intensive firewood collection is another factor that reduces species diversity and selects for the most resistant and capable of regrowth after wood harvest. These changes in forest structure in turn favor the aggressive growth and dominance of vines that suffocate plants, especially woody shrubs, significantly retarding the natural regeneration of the forest, all of which reduces the forest diversity (Gillespie et al. 2000 and references therein).

The compaction of soil due to the presence of cattle reduces soil porosity, slowing the flow of water and air. This process reduces the possibility for some seed germination and affects the common superficial root systems in species of shrubs and trees of these forests (Maass 1995).

Ecosystem Collapse Thresholds: The combined effects of soil erosion, canopy openness, repeated burning and the effects of livestock on soil and vegetation give way to the transformation of these forests to different communities, indicating its collapse. In some cases and especially when periodic fires are introduced, they transform into savannas, which can become dominated by exotic grasses, and in extreme cases desertification processes occur. In other cases it is transformed into a wooded community but with a combination of native and exotic species, including woody trees and shrubs, which significantly changes the structure and composition of the original forest. Resilience in these novel ecosystems is not yet understood.

1.A.2.Eg. Caribbean-Mesoamerican Lowland Humid Forest

M281. Caribbean Lowland Humid Forest

CES411.500 Caribbean Lowland Moist Serpentine Woodland

CES411.500 CLASSIFICATION

Concept Summary: This system occurs below 400 m elevation on poor, acidic ferralitic soils in the serpentine areas of eastern Cuba and southwestern Puerto Rico. There are two canopy layers, mostly sclerophyllous and lauraceous trees and shrubs. The upper vegetative canopy tends to be open, with a dense lower stratum. Succulents are common. The following list of species is diagnostic for this system in Puerto Rico: *Pilosocereus royenii, Thouinia striata var. portoricensis, Plumeria alba, Croton lucidus, Pictetia aculeata*, and *Comocladia dodonaea*.

Related Concepts:

Distribution: This system is found in Cuba and Puerto Rico.

Nations: CU, PR

Concept Source: C. Josse

Description Author: C. Josse

CES411.500 CONCEPTUAL MODEL

Environment: Occurs on ferralitic soils derived from serpentine bedrock, with annual precipitation of 1800-3200 mm and mean annual temperature of 18-24°C.

Key Processes and Interactions: Diversity of above-ground plant functional groups (species that share morphological, chemical, structural or life history characteristics) determines the role of biodiversity in ecosystem functioning such as nutrient cycling, forest regeneration and successional patterns. Diversity of animal functional groups determines a number of key ecological processes such as trophic structure, nutrient cycling, and the system's resilience to disturbance. Community composition/diversity /structure affects species diversity and several ecosystem-level processes. Gap dynamics provide light, the major environmental limiting factor to plant growth in the closed-canopy humid tropical forest, and maintains the forest in shifting mosaic steady state.

Biotic interactions: pollination (bees, butterflies, beetles, moths, bats, and hummingbirds) is important for reproductive success and pollinators influence the frequency and distribution pattern of plant species; seed dispersal is executed by fruit-eating birds, mammals and ants, is important for reproductive success, and seed dispersal agents affect food webs in tropical forests by making available reproductive resources to other consumers and influencing the frequency and distribution pattern of plant species, especially woody species; seed predation is important for reproductive success and seed predation affects population recruitment and establishment of diverse plant species (e.g., palms and legumes). Seed predators occasionally act as dispersers. Seed predation is a specialized form of herbivory. Vertebrates involved are often objects of hunting by humans. Herbivores, including insects, parasitic fungi, and vertebrates, affect vigor and mortality of plants of all sizes, especially understory seedlings, and influences food chain and species composition of understory. The presence of top predators controls the populations of small mammals and herbivores. Species diversity and composition of soil biota, e.g., mycorrhizae, fungi, microbes, soil mesofauna such as leaf-cutter ants, termites, nematodes, collembola, dung beetles, etc., are fundamental for nutrient cycling and soil structure.

Disturbance regimes from catastrophic natural causes, e.g., hurricanes, rare catastrophic floods, or multiple landslides, or volcanism, or earthquakes, rare extreme cold fronts, rare extreme droughts, are rare events that can be very important for ecological dynamics. Create canopy gaps of great size allowing pioneer species to colonize and initiate successional processes, e.g., hurricanes play a major role in landscape-scale dynamics of forests on Caribbean islands. Fire due to dry spell or prolonged dry seasons or human activities: Certain species might be maintained because of this big, very rare catastrophic event. For example, mahogany thrives on fire outbreaks. Background disturbances, such as small gaps, small landslides, downbursts, normal cold fronts, and normal seasonal precipitation variability. Important for creating and maintaining habitat heterogeneity and species and structural diversity, preventing competitive exclusion. Drives regeneration.

Spatial integration and coverage (e.g., connectivity by riparian habitats) allowing migration of animals and plants outside of lowland forest: Allow to define at landscape level integrity of ecosystem. Allow to assess the extent of potential for species extinction. Spatial integration important for species to maintain contact with all habitats required for life cycles.

Biogeochemical dynamics (referring to regional and global processes such as global warming, ozone depletion, CO2 concentration, atmospheric and soil pollution, etc.): Affects basic ecosystem functioning at both global and local levels. Soil type or fertility: Affects forest primary productivity and species richness. Soil type is also relevant to tree mortality rate, treefall frequency, forest regeneration mode, and stand turnover time (Hartshorn 1990).

Threats/Stressors: The conversion of forests for the development of urban centers, agriculture and other productive activities has not only resulted in the permanent loss of significant areas of rainforest in the Caribbean islands, but also has the effect of fragmentation on forest remnants.

La conversión de bosques para el desarrollo de centros urbanos, agricultura y otras actividades productivas no solo ha ocasionado la pérdida definitiva de importantes extensiones de bosque húmedo en las islas del Caribe, sino que también produce los efectos de la fragmentación en los remanentes de bosque.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct land conversion.

Colapso ecológico tiende a ocurrir a partir de la conversión directa del bosque a otra cobertura.

CES411.426 Caribbean Seasonal Evergreen Lowland Forest

CES411.426 CLASSIFICATION

Concept Summary: This system occurs on calcareous and alluvial soils below 400 m elevation in moist climates. In Puerto Rico this system refers to the forests of the wide flatlands or valleys of the karst belt, where very little of the original extent is left. It has an open canopy, 20-25 m high, with emergents and a second denser layer, 8-15 m high. About 70% of canopy species are evergreen. Lianas are abundant. Few drought-tolerant epiphytes are present. Much of this forest has disappeared. Now open pastures and agricultural crops replace it. The following list of species is diagnostic for this system: *Andira inermis, Guettarda scabra, Guettarda odorata, Dendropanax arboreus, Guazuma ulmifolia, Hymenaea courbaril, Quararibea turbinata, Ceiba pentandra, Roystonea regia, Bucida buceras, Luehea speciosa, Lonchocarpus heptaphyllus (= Lonchocarpus latifolius), Lonchocarpus* sp., *Chamaecrista glandulosa var. mirabilis (= Cassia mirabilis), Cordia collococca, Cordia gerascanthus, Ficus stahlii, Pithecellobium cubense, Cojoba arborea (= Pithecellobium arboreum), Oxandra lanceolata, Crescentia cujete, Melicoccus bijugatus, Spondias mombin, Manilkara bidentata*, and *Margaritaria nobilis (= Phyllanthus nobilis)*.

Related Concepts:

- Lowland Rainforest Zone, Upland vegetation (Dansereau 1966) **?**

Distribution: This system occurs in the Bahamas, Cuba, Jamaica, Martinique, Puerto Rico (includes forest on white sands in the alluvial valleys within the karst belt), and the Virgin Islands.

Nations: BS, CU, JM, MQ, PR, VI

Concept Source: C. Josse

Description Author: C. Josse

CES411.426 CONCEPTUAL MODEL

Environment: Major factors that determine variation in community types within lowland tropical moist forest include precipitation, temperature, topography, edaphic conditions, and natural disturbance. The amount of rainfall and length of dry season determine the occurrences of evergreen forest or seasonally dry forest. Yearly extreme temperature fluctuations result in cold-front stressed forests in southwestern Amazonia and the southern Atlantic region and non-cold-front stressed forests in Mexico and Central America.: Zonation may occur depending on whether the forest is on a plain, or rolling hills, or foothills of a mountain range. Edaphic conditions (soil quality or fertility) can create special community types. Forests on white sand soil, on clay soil, or over limestone/ultrabasic rock differ considerably in species composition. Natural disturbance includes hurricanes and landslides. Hurricanes are the most frequent causes of landslides.

Key Processes and Interactions: Diversity of above-ground plant functional groups (species that share morphological, chemical, structural or life history characteristics) determines the role of biodiversity in ecosystem functioning such as nutrient cycling, forest regeneration and successional patterns. Diversity of animal functional groups determines a number of key ecological processes such as trophic structure, nutrient cycling, and the system's resilience to disturbance. Community composition/diversity /structure affects species diversity and several ecosystem-level processes. Gap dynamics provide light, the major environmental limiting factor to plant growth in the closed-canopy humid tropical forest, and maintains the forest in shifting mosaic steady state.

Biotic interactions: pollination (bees, butterflies, beetles, moths, bats, and hummingbirds) is important for reproductive success and pollinators influence the frequency and distribution pattern of plant species; seed dispersal is executed by fruit-eating birds, mammals and ants, is important for reproductive success, and seed dispersal agents affect food webs in tropical forests by making available reproductive resources to other consumers and influencing the frequency and distribution pattern of plant species, especially woody species; seed predation is important for reproductive success and seed predation affects population recruitment and establishment of diverse plant species (e.g., palms and legumes). Seed predators occasionally act as dispersers. Seed predation is a specialized form of herbivory. Vertebrates involved are often objects of hunting by humans. Herbivores, including insects, parasitic fungi, and vertebrates, affect vigor and mortality of plants of all sizes, especially understory seedlings, and influences food chain and species composition of understory. The presence of top predators controls the populations of small mammals and herbivores. Species diversity and composition of soil biota, e.g., mycorrhizae, fungi, microbes, soil mesofauna such as leaf-cutter ants, termites, nematodes, collembola, dung beetles, etc., are fundamental for nutrient cycling and soil structure.

CES411.427 Caribbean Seasonal Evergreen Submontane/Lowland Forest

CES411.427 CLASSIFICATION

Concept Summary: This system occurs between (200) 400 and 800 m elevation, under moist climate conditions on soils derived from volcanic and sedimentary geologies. The canopy is 20-25 m high, is not densely closed, and emergents are common. The second stratum is closed, and terrestrial ferns dominate the herb layer. Lichens and bryophytes grow on trunks. Different mountains (and islands) have different composition. This type of forest has been replaced by coffee plantations or other crops in a significant part of its original extent. The following list of species is diagnostic for this system: *Dipholis jubilla, Sideroxylon salicifolium (= Dipholis salicifolia), Cedrela odorata (= Cedrela mexicana), Calophyllum antillanum (= Calophyllum calaba), Ziziphus rhodoxylon, Calyptronoma occidentalis, Zanthoxylum martinicense, Zanthoxylum cubense, Sapium laurifolium (= Sapium jamaicense), Matayba apetala (= Matayba oppositifolia), Pseudolmedia spuria, Cupania glabra, Roystonea regia, Chrysophyllum argenteum, Oxandra lanceolata, Dendropanax arboreus, Laplacea haematoxylon*, and *Lonchocarpus heptaphyllus (= Lonchocarpus latifolius)*. The tree fern *Alsophila bryophila (= Cyathea pubescens)* can be common in the understory. In St. John in the Virgin Islands, the species assemblage for this type of forest includes *Andira inermis, Amyris elemifera, Swietenia mahagoni, Melicoccus bijugatus, Casearia guianensis, Eugenia monticola, Eugenia rhombea, Zanthoxylum monophyllum, Adenanthera pavonina*, and *Acacia muricata*.

M578. Mesoamerican Lowland Humid Forest

CES402.604 Petén Seasonal Evergreen Forest on Karstic Hills

CES402.604 CLASSIFICATION

Concept Summary: Este sistema representa las comunidades boscosas siempreverdes estacionales que crecen sobre suelos calcáreos o derivados de calizas y sobre colinas cársticas, generalmente hacia el interior, no costeros. Este tipo de sistema ocupa grandes extensiones en Honduras, Belice, Guatemala y sur de México. La topografía comprende terrenos colinados o accidentados. Por tratarse de suelos fértiles, gran parte de su distribución está dedicada a la agricultura por lo que actualmente quedan pocos remanentes en buen estado. La siguiente lista de especies es diagnóstica para este sistema: *Alseis yucatanensis, Ampelocera hottlei, Aspidosperma cruenta, Astronium graveolens, Orbignya cohune (= Attalea cohune), Bernoullia flammea, Brosimum alicastrum, Bursera simaruba, Calophyllum antillanum (= Calophyllum brasiliense), Cedrela odorata, Ceiba pentandra, Clusia salvinii, Cordia dodecandra, Cupania belicensis, Cupania prisca, Crysophila stauracantha, Chione chiapasensis, Dendropanax arboreus, Drypetes laterifolia, Drypetes brownei, Eugenia capuli, Ficus* spp., *Hirtella triandra (= Hirtella americana), Laetia thamnia, Lonchocarpus castilloi, Manilkara chicle, Matayba oppositifolia, Metopium brownei, Omphalea oleifera, Passiflora mayarum, Pimenta dioica, Pouteria amygdalina, Pouteria campechiana, Pouteria reticulata, Protium copal, Pseudobombax ellipticum, Pseudolmedia spuria, Sabal mauritiiformis, Schizolobium parahyba, Sebastiana longicuspis, Simira salvadorensis, Spondias mombin, Stemmadenia donnell-smithii, Swietenia macrophylla, Talisia olivaeformis, Terminalia amazonia, Trichilia minutiflora, Trophis racemosa, Vatairea lundellii, Vitex gaumeri, Zuelania guidonia*. Understory: *Adiantum pulverulatum, Malvaviscus arboreus, Piper jacquemontianum, Psychotria pubescens, Pteris longifolia, Tectaria heracleifolia, Ichnanthus lanceolatus*.

This system represents the seasonal evergreen forest communities growing on calcareous soils derived from limestone or karst hills and generally inland instead of coastal. This type occupies large areas in Honduras, Belize, Guatemala and southern Mexico. The topography comprises hilly or difficult terrain. Being fertile soils, much of its distribution is devoted to agriculture and there are now few remaining unaltered examples. The above list of species is diagnostic for this system.

Related Concepts:

Distribution: This type occupies large areas in Honduras, Belize, Guatemala and southern Mexico.

Nations: BZ, GT, HN, MX

Concept Source: C. Josse

Description Author: C. Josse

CES402.604 CONCEPTUAL MODEL

Environment: Ocurren en colinas cársticas sobre terreno ondulado o accidentado. Suelos fértiles, superficiales en las pendientes y por lo tanto propensos a la erosión. Clima con una estación seca de 3 a 4 meses.

Occurs in karst hills on corrugated or rough terrain. Fertile surface on slopes and therefore prone to erosion. Climate with a dry season of 3-4 months.

Key Processes and Interactions: Bosque maduro, muy afectado por las quemas y clareos para agricultura.

Threats/Stressors: Bosque maduro, muy afectado por las quemas y clareos para agricultura.

Mature forest, greatly affected by agricultural burning and thinning.

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

CES402.580 Central American Caribbean Evergreen Lowland Forest

CES402.580 CLASSIFICATION

Concept Summary: Sistema que representa los bosques altos, húmedos siempreverdes y bien drenados de la vertiente atlántica de Centroamérica y México. Crecen sobre suelos de origen sedimentario (calizo) o ígneo (cenizas o basalto), principalmente del grupo de los latosoles con textura arcillosa y buenos contenidos de materia orgánica. El relieve es generalmente colinado o accidentado en las colinas bajas de serranías costeras y estribaciones de montañas del interior. La siguiente lista de las especies es de diagnóstica para este sistema: *Anaxagorea costaricensis, Aspidosperma megalocarpon, Bursera simaruba, Calophyllum antillanum (= Calophyllum brasiliense), Capparis pittieri, Carpotroche platyptera, Cassipourea elliptica, Cordia gerascanthus, Cynometra retusa, Dalbergia tucurensis, Dendropanax arboreus, Dialium guianense, Dussia macroprophyllata, Dypterix panamensis, Eschweilera mexicana, Faramea suerrencis, Guarea rhopalocarpa, Guatteria anomala, Hernandia didymantha, Hyeronima alchorneoides, Laetia procera, Lecythis costaricensis, Licania hypoleuca, Licania platypus, Magnolia yocoronte, Manilkara zapota, Mauria sessiflora, Ocotea* sp., *Ormosia* sp., *Pentaclethra macroloba, Perebea angustifolia, Pouteria neglecta, Quararibea bracteolosa, Sloanea tuerckheimii, Socratea durissima, Socratea exorrhiza, Spondias radlkoferi, Swietenia macrophylla, Symphonia globulifera, Terminalia amazonia, Virola guatemalensis, Virola koschnyi, Vochysia guatemalensis, Welfia georgii*.

System representing the tall, moist, well-drained evergreen forests of the Atlantic slope of Central America and Mexico. It occurs on soils of sedimentary origin (limestone) or igneous (ash or basalt), mainly latosols with loamy texture and high organic matter content. The topography is generally hilly or in low coastal hills and foothills of inland mountains. The above list of species is diagnostic for this system.

Related Concepts:
Nations: CR, HN, MX, NI, PA
Concept Source: C. Josse
Description Author: C. Josse

CES402.580 CONCEPTUAL MODEL

Environment: Se encuentran sobre terrenos colinados a accidentados, de suelos bien drenados y de origen sedimentario. Alfisoles, ultisoles, latosoles e inceptisoles, pueden presentar alta concentración de materia orgánica en el horizonte superficial. Tierras bajas y piedemontes con clima húmedo, si es estacional, la estación seca es corta. La precipitación anual generalmente es >3000 mm.

They are on well-drained soils of sedimentary origin: Alfisols, Ultisols, and Inceptisols; Latosols can present high concentration of organic matter in the surface horizon. Lowlands and foothills in wet weather; if seasonal, the dry season is short. Annual rainfall is usually >3000 mm.

Key Processes and Interactions: Bosque maduro sujeto a intervención.

Threats/Stressors: Los bosques maduros son propensos a la deforestación para la producción de madera. La fragmentación resultado de la conversión de tierras para la agricultura y la infraestructura altera los procesos de sucesión y conduce a la pérdida de la diversidad nativa.

Mature forests are prone to deforestation for timber production. Fragmentation by land conversion for agriculture and infrastructure disrupts successional processes and leads to loss of native diversity.

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

CES402.597 Meso-American Pacific Evergreen Lowland Forest

CES402.597 CLASSIFICATION

Concept Summary: Este sistema que representa los bosques altos, húmedos siempreverdes y bien drenados de la vertiente pacífica de Centroamérica, México, el Chocó colombiano y la costa norte del Ecuador. Crecen sobre suelos de origen sedimentario o ígneo (cenizas o basalto), principalmente del grupo de los latosoles con textura arcillosa y buenos contenidos de materia orgánica. Generalmente en relieve colinado o accidentado, en las colinas bajas de serranías costeras y estribaciones de montañas del interior. La siguiente lista de especies es diagnóstica para este sistema: *Manilkara zapota (= Achras zapota), Alchornea costaricensis, Anacardium excelsum, Andira inermis, Apeiba aspera, Apeiba tibourbou, Ardisia cutteri, Aspidosperma megalocarpon, Brosimum utile, Brosimum utile, Carapa guianensis, Caryocar costaricense, Heisteria longipes, Huberodendron patinoi, Iriartea deltoidea, Iriartea gigantea, Minquartia guianensis, Parkia pendula, Peltogyne purpurea, Poulsenia armata, Protium copal, Qualea paraensis, Scheelea rostrata, Schizolobium parahyba, Socratea exorrhiza, Sorocea pubivena, Symphonia globulifera, Symphonia globulifera, Talisia nervosa, Terminalia lucida, Tetragastris panamensis, Vantanea barbourii, Vatairea lundellii, Welfia georgii*. Hills: *Astronium* sp., *Browneopsis* sp., *Caryodaphnopsis theobromifolia, Catoblastus* sp., *Ceiba pentandra, Coussapoa eggersii (= Coussapoa villosa ssp. eggersii), Coussapoa herthae, Daphnopsis oculta, Endlicheria* sp., *Eschweilera* sp., *Guarea pterorhachis, Guettarda* sp., *Jessenia bataua, Metteniusa nucifera, Otoba cf. novogranatensis, Perebea cf. angustifolia, Poulsenia armata, Pourouma bicolor, Protium* sp., Quararibea coloradorum, Sloanea sp., *Virola dixonii*. Palms: *Iriartea deltoidea, Oenocarpus bataua, Welfia regia, Wettinia quinaria*.

This system represents the high, moist, well-drained evergreen forests of the Pacific slope of Central America, Mexico, the Colombian Chocó and the northern coast of Ecuador. Grows on soils of sedimentary or igneous origin (ash or basalt), mainly group latosols with clay texture and good organic matter content. Usually in hilly or mountainous terrain, low hills in coastal mountains and foothills of mountains inland. The above list of species is diagnostic for this system.

CES402.581 Central American Caribbean Seasonal Evergreen Lowland Forest

CES402.581 CLASSIFICATION

Concept Summary: Bosques estacionales siempreverdes de tierras bajas y suelos bien drenados de la vertiente atlántica de Centro América. Generalmente sobre terrenos colinados o accidentados, en sustratos sedimentarios en las partes bajas y metamórficos en las partes altas, por ejemplo cuarcíticos. La siguiente lista de las especies es de diagnóstica para este sistema: *Alseis yucatanensis, Apeiba membranacea, Aphananthe monoica, Attalea butyracea, Brosimum alicastrum, Bursera simaruba, Carapa guianensis, Castilla tunu, Cedrela odorata, Chamaedorea* spp., *Coccoloba barbadensis, Cyathea* sp., *Euterpe precatoria, Ficus insipida, Guettarda combsii, Liquidambar styraciflua, Manilkara zapota, Miconia* sp., *Mouriri myrtilloides, Pimenta dioica, Podocarpus guatemalensis, Pourouma aspera, Pseudolmedia oxyphyllaria, Schippia concolor, Sloanea terniflora, Spondias mombin, Swietenia macrophylla, Symphonia globulifera, Tabebuia rosea, Terminalia amazonia, Virola brachycarpa, Vismia ferruginea, Vochysia hondurensis, Xylopia frutescens, Zuelania guidonia*.

Evergreen seasonal lowland forests and well-drained soils of the Atlantic Coast of Central America. Generally found on rugged terrain, in sedimentary or metapmorphic substrates in the lower vs. higher locations, respectively.

M873. Mesoamerican Submontane Humid Forest

CES403.323 North Meso-American Submontane Wet Forest

CES403.323 CLASSIFICATION

Concept Summary: Este sistema corresponde a los bosques humedos y muy húmedos que crecen en las estribaciones bajas y cerros del norte de Centroamérica desde los 600-800 m hasta los 1300-1500 m de altitud y con precipitación superior a 2000 mm anuales. Se tata de bosques de especies latifoliadas y siempreverdes, en algunas comunidades hay palmas y en general la estructura de los bosques es compleja, con numerosas epífitas, lianas y varios estratos leñosos, además de un dosel cerrado que alcanza los 20-40 m de alto. El tipo más húmedo ocurre sobre las vertientes del Caribe. La siguiente lista de especies es diagnóstica para este sistema: *Aspidosperma cruenta, Astrocaryum mexicanum, Calatola costaricensis, Calophyllum antillanum (= Calophyllum brasiliense), Chamaedorea tepejilote, Chamaedorea* sp., *Colpothrinax cookii, Dendropanax arboreus, Euterpe precatoria, Ficus* spp., *Hedyosmum mexicanum, Ilex guianensis, Magnolia* sp., *Myrcia splendens, Nectandra* sp., *Persea schiedeana, Pouteria* spp., *Schizolobium parahyba, Symphonia globulifera, Terminalia amazonia, Virola koschnyi, Vismia* spp., *Vochysia hondurensis*.

This system corresponds to the moist and wet forests growing on the lower slopes and hills of northern Central America to 1300-1500 m altitude and with more than 2000 mm annual precipitation. It is tata forest and evergreen broadleaf species, in some communities there are palms and overall forest structure is complex, with numerous epiphytes, woody vines and various strata, and a closed canopy reaching 20-40 m tall. The wet type occurs on the slopes of the Caribbean. The above list of species is diagnostic for this system.

Related Concepts:
Nations: BZ, GT, HN, NI
Concept Source: C. Josse
Description Author: C. Josse

CES403.323 CONCEPTUAL MODEL

Environment: Región montañosa de origen terciario con suelos molisoles, alfisoles, ultisoles, bien drenados y de alto contenido orgánico. En algunas partes puede haber afloramientos de roca, aunque no es común.

Highlands of tertiary origin with soils including Mollisols, Alfisols, Ultisols, that are well-drained and with high organic content. In some parts it may be rock outcrops, although not common.

Key Processes and Interactions:

Threats/Stressors: La conversión de tierras para la producción de café y la agricultura relacionada.

Land conversion for coffee production and related agriculture.

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

CITATIONS

Full Citation:

CES402.607 Talamancan Submontane Wet Forest

CES402.607 CLASSIFICATION

Concept Summary: Este sistema agrupa los bosques muy húmedos premontanos de la vertiente Atlántica en Costa Rica y de ambas vertientes en las montañas de la región occidental y las del área del Canal de Panamá. En Panamá constituyen una gran parte de los sistemas montanos ya que hay relativamente poco territorio sobre los 1500-1600 m de altitud, sin embargo no se cuenta con información suficiente para discriminar tipos o unidades diferentes dentro del sistema. La siguiente lista de especies es diagnóstica para este sistema: *Brosimum utile, Calophyllum longifolium, Calophyllum brasiliense var. rekoi, Micropholis crotonoides, Vochysia ferruginea, Billia columbiana, Alchornea latifolia, Hieronyma guatemalensis, Hirtella racemosa, Meliosma vernicosa, Pouteria* sp., *Podocarpus cf. oleifolius, Terminalia amazonia, Sacoglottis amazonica*, Lauraceae spp., *Euterpe macrospadix, Welfia georgii, Socratea durissima, Euterpe precatoria, Wettinia augusta*, tree ferns.

This system groups premontane wet forests of the Atlantic slope in Costa Rica and both slopes in the mountains of the western region and the area of the Panama Canal. In Panama it constitutes a large part of montane systems and there is relatively little territory about 1500-1600 m above sea level; however, there is insufficient information to discriminate different types or units within the system. The above list of species is diagnostic for this system.

CES402.614 Bosque Pluvial Premontano del Chocó-Darién

CES402.614 CLASSIFICATION

Concept Summary: Este sistema agrupa los bosques húmedos y muy húmedos de la Cordillera de Darién en Panamá y las colinas de los contrafuertes andinos occidentales en la región del Chocó colombiano, por sobre los 600 m de altitud aproximadamente. Se trata de bosques de gran estatura y alta diversidad. La siguiente lista de especies es diagnóstica para este sistema: *Alchornea polyantha, Anacardium excelsum, Billia columbiana, Brosimum guianense, Brosimum utile, Cephaelis elata, Cephaelis elata, Dipteryx panamensis, Elaeagia utilis, Eschweilera verruculosa, Guettarda chiriquense, Oenocarpus panamanus, Perebea guianensis, Pourouma aspera, Pourouma chocoana, Sorocea* sp., *Weinmannia putumayensis, Welfia regia, Wettinia radiata*.

This system groups moist and wet forests of the Cordillera de Panama and Darien in the hills of the western Andean foothills in the Chocó region of Colombia, above about 600 m altitude. These are very tall forests with high diversity. The above list of species is diagnostic for this system.

Related Concepts:

CES402.614 CONCEPTUAL MODEL

Environment: Estribaciones bajas y medias, muy húmedas y frecuentemente nubladas de las serranías de San Blas y Darién al oriente de Panamá, sobre suelos ácidos, arcillosos y generalmente bien drenados. Principalmente de origen volcánico.

Low and medium, very moist and often cloudy in the mountains of San Blas and Darien in eastern Panama, on acidic, well-drained loamy soils and generally foothills. Mainly of volcanic origin.

Key Processes and Interactions: El sistema describe al bosque maduro, aunque se ha especulado sobre el la posibilidad de que sean bosques sucesionales debido a la larga historia de ocupación humana en la zona. Se encuentran regularmente especies secundarias dominantes.

The system describes the mature forest, although it has been speculated that they may be successional forests due to the long history of human occupation in the area. They are regularly key secondary species.

Threats/Stressors:
Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

1.A.2.Ei. Guianan Lowland Humid Forest

M587. Orinoquian Humid Forest

CES404.351 Bosque Aluvial de la Guayana Oriental

CES404.351 CLASSIFICATION

Concept Summary: Ocupan partes del Delta Alto del Orinoco y se extienden por los valles de la cuenca baja de rios tributarios del Orinoco. En general se trata de planos no inundables y terrenos colinados, aunque las partes bajas pueden inundarse temporal o esporádicamente. Ombroclima húmedo. Son bosques de hasta 25-30 m de alto, siempreverdes y generalmente con tres estratos arboreos. Las palmas son abundantes y en sitios mas bajos o con menor drenaje, la especie Mora excelsa es claramente dominante. Pueden haber algunas especies deciduas en el dosel. The following list of species is diagnostic for this system: *Licania densiflora, Licania alba, Eschweilera decolorans, Gustavia poeppigiana, Gustavia augusta, Tabebuia capitata, Trichilia pleeana, Tetragastris altissima, Catostemma commune, Virola surinamensis, Alexa imperatricis, Mora excelsa, Sterculia pruriens, Peltogyne venosa, Clathrotropis brachypetala, Manilkara bidentata, Terminalia amazonia, Simarouba amara, Ceiba pentandra, Erythrina* sp., *Triplaris surinamensis*.

1.A.3.Eg. Caribbean-Mesoamerican Montane Humid Forest

M598. Caribbean Montane Humid Forest

CES411.450 Caribbean Moist Montane Mixed Pine-Broad-leaved Forest

CES411.450 CLASSIFICATION

Concept Summary: Found between 800 and 2100 m elevation on acidic yellow soils derived from sandstone and andesitic tuffs in southeastern Cuba, and on red acidic clay soils in the Cordillera Central of Hispaniola. Two canopy layers. The top canopy is formed by *Pinus maestrensis* in Cuba, and by *Pinus occidentalis* in Hispaniola. The following list of species is diagnostic for this system: *Pinus maestrensis, Myrsine coriacea, Weinmannia pinnata, Ilex macfadyenii, Clethra cubensis, Myrica punctata, Cyathea arborea, Alsophila aspera, Pinus occidentalis, Ilex microwrightioides, Ilex tuerckheimii, Eupatorium illitium, Gnaphalium eggersii, Vernonia stenophylla, Psychotria dolichocalyx, Sideroxylon repens, Buddleia domingensis, Senecio buchii, Tournefortia selleana, Magnolia pallescens, Didymopanax tremulus, Tabebuia vinosa*.

Description Author: C. Josse

CES411.450 CONCEPTUAL MODEL

Environment: Distribution is highly modified by disturbance regime. Growing under a wide range of physical parameters, soils can be volcanic, sedimentary and alluvial substrates. Most pine forests are found above 2200 m in the Cordillera Central of Hispaniola.
Key Processes and Interactions: Landslides and hurricanes are the key triggers of dynamic processes of these forests. Substrate and topography and their interaction with the vegetation are the most important factors for the survival of these forests during hurricanes - probably the single most important natural trigger of the successional dynamic. Surviving trees have their roots securely anchored in the substrate. These factors are also critical for regulating surface runoff and maintaining the water balance under very humid conditions on exposed ridges and steep slopes. Forest recovery after disturbance is slow. Monitoring of dwarf forest in Puerto Rico's Luquillo Mountains showed that it can take up to 20 years for woody species to establish and after that their growth rate is very slow. It took almost 35 years until the canopy closing decreased the grass and fern cover (Weaver 2008). Moreover, the succession process is often subjected to setbacks due to periodic hurricane disturbance. This study also showed that hurricanes cause delayed mortality, with declines in biomass and stem numbers exceeding ingrowth during 15 years after Hurricane Hugo hit. Another important finding of this study is that more than half of the arborescent species growing in dwarf forest, where they play a prominent role in post disturbance recovery, are endemic to Puerto Rico (Weaver 2008). Cloud forests are known as places of high endemism but not necessarily as areas with rich biotas (Weaver 2000, 2008).
Threats/Stressors: Clearing for agriculture, cattle ranching, logging or fuelwood collection are the most common anthropogenic stressors to these forests, as well as the direct and indirect effects of access roads. Effects of fragmentation such as increased light and changes in the hydrology close to the border of the remnants can induce changes in the composition and structure of these forests. It has been estimated that it would take 200-300 years for the recovery of the same amount of biomass of a mature cloud forest (Silver et al. 2001). Altered precipitation patterns and cloud cover as a consequence of climate change are another important stressor for cloud forest ecosystems, adapted within thresholds of a particular hydrologic cycle.
Ecosystem Collapse Thresholds: The frequency and intensity of disturbance may have an irreversible impact on these forests once soils are affected and once the pool of endemic species that play a role in the recovery process are eliminated or diminished. The thresholds for these effects are not known.

CES411.455 Caribbean Montane Wet Elfin Forest

CES411.455 CLASSIFICATION

Concept Summary: This system tends to occur above 1600 m elevation; in Puerto Rico, it is usually above 700 m, but lower elevations are possible, especially under conditions of high precipitation. Stands have a closed but irregular canopy which is typically 6-12 m high. Trees have gnarled trunks, compact crowns and small leaves. The shrub layer is almost impenetrable. Tree ferns and epiphytes are abundant. Forest floor, tree trunks and branches are covered by bryophytes. The following list of species is diagnostic for this system: *Myrsine microphylla, Nectandra reticularis, Sapium maestrense, Persea anomala, Symplocos leonis, Cyrilla racemiflora, Weinmannia pinnata, Torralbasia cuneifolia, Alsophila aspera, Didymopanax tremulus, Podocarpus aristulatus, Cyathea arborea, Cyathea balanocarpa, Vaccinium leonis, Miconia turquinensis, Tabebuia turquinensis, Tabebuia rigida, Tabebuia vinosa, Hedyosmum cubense, Henriettea ekmanii*, and *Duranta fletcheriana*. In windswept mountain ridges and summits from 500-1350 m a.s.l. in Puerto Rico and islands of the Lesser Antilles, the following species are typical: *Cyrilla racemiflora, Prestoea acuminata var. montana (= Prestoea montana), Magnolia splendens, Podocarpus coriaceus, Dacryodes excelsa, Croton poecilanthus, Ternstroemia luquillensis, Ternstroemia subsessilis, Miconia laevigata, Micropholis garciniifolia, Micropholis guyanensis, Ocotea leucoxylon, Ocotea spathulata* and stunted trees of *Sloanea* spp.

CES411.455 CONCEPTUAL MODEL

Environment: Ecosystems of this macrogroup occur above 700 m elevation in areas with mean annual precipitation >1600 mm, frequently or seasonally surrounded by clouds, and on different topographies but mostly slopes, exposed ridges, and ravines. Forests growing on exposed areas are of smaller stature and very dense. Taller forests grow on protected areas on lower slopes to the leeward of ridges or spurs. With montane forests, one of the most critical climatic factors is the frequency and duration of the cloud cover; condensation can contribute 10% or more of the precipitation amount that these forests receive. In the Caribbean, the trade winds forming clouds have saline components which have an effect on the chemistry of the ecophysiology of these forests. Cloud cover causes less solar radiation, lower temperatures, decreased transpiration and lower photosynthetic rates, resulting in lower growth rates and lower nutrient-cycling rates. The efficiency shown by these forests in the use of nutrients is high though, which is important to avoid nutrient loss due to leaching (Silver et al. 2001).

Key Processes and Interactions: Landslides and hurricanes are the key triggers of dynamic processes of these forests. Substrate and topography and their interaction with the vegetation are the most important factors for the survival of these forests during hurricanes - probably the single most important natural trigger of the successional dynamic. Surviving trees have their roots securely anchored in the substrate. These factors are also critical for regulating surface runoff and maintaining the water balance under very humid conditions on exposed ridges and steep slopes. Forest recovery after disturbance is slow. Monitoring of dwarf forest in Puerto

Rico's Luquillo Mountains showed that it can take up to 20 years for woody species to establish and after that their growth rate is very slow. It took almost 35 years until the canopy closing decreased the grass and fern cover (Weaver 2008). Moreover, the succession process is often subjected to setbacks due to periodic hurricane disturbance. This study also showed that hurricanes cause delayed mortality, with declines in biomass and stem numbers exceeding ingrowth during 15 years after Hurricane Hugo hit. Another important finding of this study is that more than half of the arborescent species growing in dwarf forest, where they play a prominent role in post disturbance recovery, are endemic to Puerto Rico (Weaver 2008). Cloud forests are known as places of high endemism but not necessarily as areas with rich biotas (Weaver 2000, 2008).

Threats/Stressors: Clearing for agriculture, cattle ranching, logging or fuelwood collection are the most common anthropogenic stressors to these forests, as well as the direct and indirect effects of access roads. Effects of fragmentation such as increased light and changes in the hydrology close to the border of the remnants can induce changes in the composition and structure of these forests. It has been estimated that it would take 200-300 years for the recovery of the same amount of biomass of a mature cloud forest (Silver et al. 2001). CES411.429 Caribbean Montane Wet Serpentine Woodland

CES411.429 CLASSIFICATION

Concept Summary: This system occurs between 400 and 900 m elevation, on poor acidic ferrallitic soils in the serpentine areas of the Crystal and Moa mountains of eastern Cuba and western Puerto Rico. It has an open canopy, 15-22 m high. The lower stratum, 5-12 m, is dense. Most of the trees and shrubs are sclerophyllous. Lianas are common, but the density and diversity of epiphytes

decrease. The following list of species is diagnostic for this system: *Calophyllum utile, Podocarpus ekmanii, Dipholis jubilla, Ocotea leucoxylon, Ocotea* spp., *Hyeronima nipensis, Tabebuia dubia, Byrsonima spicata (= Byrsonima coriacea), Byrsonima orientensis, Matayba domingensis, Bonnetia cubensis, Magnolia cubensis, Pinus cubensis, Chionanthus domingensis, Tetrazygia cristalensis, Byrsonima biflora, Ilex berteroi*. In addition, species of *Psychotria, Myrica, Eugenia, Baccharis, Ossaea, Eupatorium* and *Vernonia* are typical in the shrub layer. In Puerto Rico, the following species are typical: *Alsophila brooksii, Calyptranthes peduncularis, Calyptranthes triflora, Cordia bellonis, Crescentia portoricensis, Croton impressus, Diospyros revoluta, Eugenia glabrata, Gesneria pauciflora, Lunania ekmanii, Mikania stevensiana, Myrcia maricaensis, Phialanthus grandifolius, Phialanthus myrtilloides, Thelypteris hastata var. heterodoxa, Xylosma pachyphyllum, Xylosma* sp., *Cyathea arborea, Cnemidaria horrida, Gleichenia nervosa (= Dicanopteris nervosa), Sticherus bifidus, Magnolia splendens, Magnolia portoricensis, Schefflera gleasonii (= Didymopanax gleasonii), Micropholis guyanensis (= Micropholis chrysophylloides)*, and *Croton poecilanthus*.

CES411.451 Caribbean Montane Wet Short Shrubland

CES411.451 CLASSIFICATION

Concept Summary: This system occurs on mountain peaks or summits. In Puerto Rico, it is found on the highest peaks of Luquillo Mountains (900-1050 m elevation) and Cordillera Central; in Cuba, on steep rocky ridges of the highest peaks of Sierra Maestra, between 1800 and 1970 m. It is dominated by short scrub, 1.5-2 m high, with many thorny shrubs and herbaceous-leaved succulents. The following list of species is diagnostic for this system in Cuba: *Ilex nunezii, Ilex turquinensis, Myrica cacuminis, Lobelia cacuminis, Eupatorium* sp., *Vernonia* sp., *Weinmannia pinnata, Persea similis, Viburnum villosum, Agave pendentata, Pleurothalis* spp., *Lepanthes* spp., *Mitracarpus acunae, Cassia turquinae, Juniperus saxicola, Schoepfia stenophylla*, and *Eugenia maestrensis*. In Puerto Rico and Martinique, the following species are typical: *Eugenia borinquensis, Alsophila bryophila (= Cyathea bryophila), Tabebuia rigida, Marcgravia sintenisii, Ocotea spathulata, Henriettea squamulosa, Micropholis garciniifolia, Daphnopsis philippiana, Ardisia luquillensis, Clidemia cymosa (= Heterotrichum cymosum)*, and *Gonocalyx portoricensis*. On mountain summits of St. Kitts and Nevis *Hedyosmum arborescens, Podocarpus coriaceus, Clusia rosea, Myrsine coriacea, Cyathea arborea*, are common.

CES411.430 Caribbean Wet Montane Forest

CES411.430 CLASSIFICATION

Concept Summary: This system is found over 800 m and up to 1600 m elevation on yellowish or red ferrallitic soils or clay-loam derived from limestones. In mountains exposed to higher precipitation, it is found as low as 450 m. Remnants of these evergreen tall forests can be found in the mountains of Jamaica, Cuba, and Puerto Rico. Examples have a closed or open canopy, 15-25 m high, consisting of microphylls and notophylls. When in good condition, the upper layer is closed and has a second layer with abundant palms, tree ferns and epiphytes, all of them rich in species. *Prestoea acuminata var. montana (= Prestoea montana)* and ferns dominate areas after deforestation or hurricanes. The following list of species is diagnostic for this system: *Magnolia* spp., *Cyrilla racemiflora, Solanum acropterum, Ocotea ekmanii, Nectandra krugii (= Ocotea krugii), Ocotea cernua, Nectandra coriacea (= Ocotea coriacea), Myrsine coriacea, Clusia tetrastigma, Gomidesia lindeniana, Alchornea latifolia, Calophyllum jacquinii, Matayba apetala, Miconia punctata, Cyathea arborea, Cyathea balanocarpa, Cyathea cubensis, Torralbasia cuneifolia, Brunellia comocladiifolia, Weinmannia pinnata, Lasianthus lanceolatus, Ilex macfadyenii, Cleyera nimanimae, Clethra occidentalis, Prunus occidentalis* and *Podocarpus* spp. In Puerto Rico, the following species are typical: *Banara portoricensis, Brachionidium ciliolatum, Myrcia margarettiae (= Eugenia margarettiae), Gonocalyx concolor, Habenaria amalfitana (= Habenaria dussii), Ternstroemia luquillensis*, and *Ternstroemia subsessilis*. In Cuba: *Carapa guianensis, Calophyllum utile, Sloanea curatellifolia, Dipholis jubilla, Bactris cubensis*, and *Calyptronoma plumeriana (= Calyptronoma clementis)*.

Description Author: C. Josse

CES411.430 CONCEPTUAL MODEL

Environment: Ecosystems of this macrogroup occur above 700 m elevation in areas with mean annual precipitation >1600 mm, frequently or seasonally surrounded by clouds, and on different topographies but mostly slopes, exposed ridges, and ravines. Forests growing on exposed areas are of smaller stature and very dense. Taller forests grow on protected areas on lower slopes to the leeward of ridges or spurs. With montane forests, one of the most critical climatic factors is the frequency and duration of the cloud cover; condensation can contribute 10% or more of the precipitation amount that these forests receive. In the Caribbean, the trade winds forming clouds have saline components which have an effect on the chemistry of the ecophysiology of these forests. Cloud cover causes less solar radiation, lower temperatures, decreased transpiration and lower photosynthetic rates, resulting in lower growth rates and lower nutrient-cycling rates. The efficiency shown by these forests in the use of nutrients is high though, which is important to avoid nutrient loss due to leaching (Silver et al. 2001).

Key Processes and Interactions: Landslides and hurricanes are the key triggers of dynamic processes of these forests. Substrate and topography and their interaction with the vegetation are the most important factors for the survival of these forests during hurricanes - probably the single most important natural trigger of the successional dynamic. Surviving trees have their roots securely anchored in the substrate. These factors are also critical for regulating surface runoff and maintaining the water balance under very humid conditions on exposed ridges and steep slopes. Forest recovery after disturbance is slow. Monitoring of dwarf forest in Puerto Rico's Luquillo Mountains showed that it can take up to 20 years for woody species to establish and after that their growth rate is very slow. It took almost 35 years until the canopy closing decreased the grass and fern cover (Weaver 2008). Moreover, the succession process is often subjected to setbacks due to periodic hurricane disturbance. This study also showed that hurricanes cause delayed mortality, with declines in biomass and stem numbers exceeding ingrowth during 15 years after Hurricane Hugo hit. Another important finding of this study is that more than half of the arborescent species growing in dwarf forest, where they play a prominent role in post disturbance recovery, are endemic to Puerto Rico (Weaver 2008). Cloud forests are known as places of high endemism but not necessarily as areas with rich biotas (Weaver 2000, 2008).

Threats/Stressors: Clearing for agriculture, cattle ranching, logging or fuelwood collection are the most common anthropogenic stressors to these forests, as well as the direct and indirect effects of access roads. Effects of fragmentation such as increased light and changes in the hydrology close to the border of the remnants can induce changes in the composition and structure of these forests. It has been estimated that it would take 200-300 years for the recovery of the same amount of biomass of a mature cloud forest (Silver et al. 2001). Altered precipitation patterns and cloud cover as a consequence of climate change are another important stressor for cloud forest ecosystems, adapted within thresholds of a particular hydrologic cycle.

Ecosystem Collapse Thresholds: The frequency and intensity of disturbance may have an irreversible impact on these forests once soils are affected and once the pool of endemic species that play a role in the recovery process are eliminated or diminished. The thresholds for these effects are not known.

CES411.470 Hispaniola Montane and Upper Montane Pine Forest

CES411.470 CLASSIFICATION

Concept Summary: This system is found above 2200 m elevation in the Cordillera Central of Hispaniola and in Massif du Nord in Haiti. Forests are characterized by a fairly open and monospecific canopy of *Pinus occidentalis*, with many endemic shrubs and ferns in the understory or an herbaceous layer dominated by the tussock grass *Danthonia domingensis*. The following list of species is diagnostic for this system: *Pinus occidentalis, Lyonia urbaniana, Lyonia tuerkheimii, Gaultheria domingensis, Fadyenia hookeri (= Garrya fadyenii), Senecio* spp., *Oxandra lanceolata, Hypericum pycnophyllum, Weinmannia pinnata, Vaccinium cubense, Cojoba arborea (= Pithecellobium arboreum), Juniperus gracilior, Juniperus eckmanii, Podocarpus buchii, Pteridium aquilinum, Calamagrostis leonardii, Agrostis hyemalis, Danthonia domingensis, Verbena domingensis*.

Description Author: C. Josse

CES411.470 CONCEPTUAL MODEL

Environment: Occurs on elevations above 1900 m and up to 3000 m, with a dry season of 3-5 months.

Key Processes and Interactions: In these seasonal, open forests fire is a natural disturbance factor triggering dynamic processes, originally caused by lightning and then intensified by human intervention (Horn et al. 2000). Given their distribution on mountain slopes, landslides and hurricanes also play a role in the dynamic processes of these forests.

Threats/Stressors: Clearing for agriculture, cattle ranching, logging or fuelwood collection are the most common anthropogenic stressors to these forests, as well as the direct and indirect effects of access roads. Effects of fragmentation such as increased light

and changes in the hydrology close to the border of the remnants can induce changes in the composition and structure of these forests. It has been estimated that it would take 200-300 years for the recovery of the same amount of biomass of a mature cloud forest (Silver et al. 2001). Altered precipitation patterns and cloud cover as a consequence of climate change are another important stressor for cloud forest ecosystems, adapted within thresholds of a particular hydrologic cycle.
Ecosystem Collapse Thresholds: The frequency and intensity of disturbance may have an irreversible impact on these forests once soils are affected and once the pool of endemic species that play a role in the recovery process are eliminated or diminished. The thresholds for these effects are not known.

M600. Mesoamerican Montane Humid Forest

CES403.315 Mexican Deciduous Cloud Forest

CES403.315 CLASSIFICATION

Concept Summary: Cloud forests in Mexico are transitional forest communities occurring in tropical and subtropical humid mountains located south of the 25°N parallel, at elevations mostly between 1250 and 2500 m. They are located in areas of high relative humidity, on steep or irregular topography, often in protected ravines. These areas are more humid than pine, pine-oak and oak forests, warmer than high-elevation conifer forests, and cooler than those that support the development of tropical plant formations (González-Espinosa et al. 2011). Floristically, this forest type is one of the ecosystems that better expresses transitional conditions between tropical and temperate biogeographic realms. It shows close floristic affinities to deciduous forests of North America, equivalent forests of eastern Asia, and montane forests in the Andean region of South America (Alcántara et al. 2002). They are easily distinguishable from other forest systems by the abundance of epiphytes and reduction in woody climbers. The distribution of cloud forests in Mexico is archipelago-like; this, the great variety of habitats and the wide contact between Holartic and Neotropical floras, make this forest floristically very rich. It is considered that 10% of the vascular plant species of Mexico are found in the country's cloud forests, which only cover between 0.5-1.0% of the national territory. Plant species endemism is also extremely high in these forests. the following list of species is diagnostic for this system: *Carpinus caroliniana, Chiranthodendron pentadactylon, Liquidambar styraciflua, Oreomunnea mexicana, Oreopanax echinops*, and *Podocarpus matudae*, although none of these species occurs throughout the distribution of this ecological system (González-Espinosa et al. 2011). Genera with most of their species better distributed in Mexican cloud forest than in any other type of Mexican vegetation are *Clethra, Magnolia, Meliosma, Styrax, Symplocos*, and *Ternstroemia* (Alcántara et al. 2002). Also *Cyathea* (tree fern) and many moss species are characteristic.

Nations: GT, MX
Concept Source: C. Josse
Description Author: C. Josse

CES403.315 CONCEPTUAL MODEL

Environment: En México, los bosques nubosos en general, aparecen como parches aislados dentro de elevación oscila entre 600 y 2900 m (en su mayoría por encima de 1.500 m) y están rodeadas de vegetación xerofítica, bosques de *Quercus* o pino, o bosques mixtos. La topografía es abrupta, con pendientes bastante pronunciadas. La temperatura media anual es de 13-14°C (hasta 18°C en las partes inferiores del cinturón altitudinal), y la media de precipitación anual es de 1200 a 1500 mm, aunque también se encuentran en lugares donde la precipitación media anual supera los 5.000 mm. Por lo general ocurren en suelos profundos, bien drenados, se originó a partir de piedra caliza o rocas metamórficas, a menudo afloran. Las extensiones de bosque nuboso más grandes de México se encuentran en la Sierra Madre Oriental, la Sierra Norte de Oaxaca (Northern Range Oaxaca), la Sierra Madre del Sur, las montañas del norte de Chiapas y la Sierra Madre de Chiapas (González-Espinosa et al. 2011). Al igual que en otras regiones del mundo donde se producen estos bosques, su hábitat se considera único entre los ecosistemas terrestres: está fuertemente ligada a los procesos de formación de nubes y un resultantes cerca de la saturación atmosférica constante.

In Mexico, cloud forests generally appear as isolated patches within elevation ranges from 600-2900 m (mostly above 1500 m) and are surrounded by xeric vegetation, *Quercus* or *Pinus* forests, or mixed forests. The topography is abrupt with fairly steep slopes. Mean annual temperature is 13-14°C (up to 18°C in the lower portions of the altitudinal belt), and mean annual rainfall is 1200-1500 mm, though they are also found in places where the average annual precipitation exceeds 5000 mm. They usually occur on deep, well-drained soils, originated from limestone or metamorphic rocks, often outcropping. The largest cloud forest tracts in Mexico are located in the Sierra Madre Oriental, the Sierra Norte de Oaxaca (Northern Oaxaca Range), the Sierra Madre del Sur, the Northern Mountains of Chiapas and the Sierra Madre de Chiapas (González-Espinosa et al. 2011). As in other regions of the world where these forests occur, their habitat is considered unique among terrestrial ecosystems; it is strongly linked to processes of cloud formation and a resulting near constant atmospheric saturation.

Key Processes and Interactions: La perturbación natural es causada principalmente por los deslizamientos de tierra, por lo que la sucesión secundaria es un proceso clave que define los aspectos estructurales y de composición de los bosques de niebla. Perturbación de bosque nublado y húmedo tiende a conducir a las comunidades de roble dominado.

Natural disturbance is primarily caused by landslides, so secondary succession is a key process defining structural and compositional aspects of cloud forests. Disturbance of humid cloud forest tends to lead to oak-dominated communities.

Threats/Stressors: La principal amenaza para estos bosques es el uso del suelo, sobre todo debido a la ampliación de las actividades agrícolas y de pastoreo en su distribución naturalmente dispersa a lo largo de un cinturón altitudinal estrecho. Algunos estudios estiman que el 90% de la distribución de los bosques nubosos México se ha perdido ya (Cayuela et al. 2006). Durante el último medio siglo, las tasas más altas de deforestación se han reportado en los bosques de niebla en México y bosques de neblina en otros lugares (González-Espinosa 2011). La mayoría de remanentes forestales están sujetos a perturbaciones continuas tales como la recolección de leña, la tala selectiva, el pastoreo de ganado, y la recolección de plantas epífitas como PFNM. Además de perturbación antropogénica actual y en el pasado, los bosques nublados se encuentran entre los ecosistemas predichos a ser los más afectados por el cambio climático.

The main threat to these forests is land-use change, mostly due to encroaching agricultural and grazing activities into their naturally scattered distribution along a narrow elevational belt. Some studies consider that 90% of the distribution of Mexico cloud forest has been lost already (Cayuela et al. 2006). During the last half-century the highest deforestation rates have been reported in cloud forests in Mexico and elsewhere (González-Espinosa 2011). Most forest remanants are subject to continuous disturbance, such as firewood collection, selective logging, livestock grazing, and harvesting of epiphytes as NTFP. In addition to past and current antropogenic disturbances, cloud forests are among the ecosystems predicted to be most affected by climate change.

Ecosystem Collapse Thresholds: La distribución fragmentada de este ecosistema ocurriendo junto a otros tipos de bosques montanos, como los bosques de roble o de pino-encino crea una dinámica sucesional compleja que no ha sido bien estudiada y clarificada. Los estudios en una de las zonas de distribución con extensiones grandes de bosque nublado en México indican que, dado el tamaño y la forma de parches remanentes (el más grande de 550 ha y hasta unas pocas hectáreas), las áreas centrales representan sólo la mitad o menos de los fragmentos, los índices de fragmentación mejoran sólo si se contabilizan los bosques de roble y pino-encino que rodean a los remanentes de bosque nublado. Sin embargo, estos parches más grandes de bosques combinados a menudo tienen formas muy complejas debido a la perturbación humana que opera en el interior del bosque, probablemente debido al uso para la agricultura a una escala muy local (Ochoa-Gaona y González-Espinosa 2000). Por lo tanto, las áreas centrales del bosque nuboso incrustados en parches de mosaicos boscosos también están expuestos a un cierto grado de perturbación humana (Cayuela et al. 2006). La dispersión de algunos organismos y la permeabilidad a los procesos ecológicos entre los parches de bosque nublado que se producen dentro de un grupo pueden ser favorecidas por los hábitats forestales intermedios (Gascon et al. 1999 en Cayuela et al. 2006). Una nota positiva es que no hay pruebas todavía de que se haya producido la reciente extinción de especies vegetales (Cayuela et al. 2006). Parches aislados y pequeños pueden mantener gran número de especies (por ejemplo,>50 especies de árboles / ha, Cayuela et al. 2006). Sin embargo, esta tendencia puede estar cambiando, ya que las aves y los mamíferos son especialmente vulnerables a las altas tasas de fragmentación MCF (Pattanavibool y Dearden 2002). Otros estudios han reiterado la importancia de incluso muy pequeños fragmentos (2- 10 ha) como reservorios de bosques de elementos maduros y diversidad de árboles en general. En muchos casos, la alta diversidad de árboles en estos parches es el resultado de la presencia de varias especies pioneras, sin embargo, las especies de bosque maduro se producen dentro de los parches pequeños también. La presión continua sobre el bosque y los parches de bosque cada vez más pequeñas y aisladas, puede causar la extinción retardada de especies forestales claves (Toledo-Aceves et al. 2014).

The fragmented distribution of this ecosystem occurring adjacent to other types of montane forests, such as oak or pine-oak forests, creates complex successional dynamics which have not been well-studied and clarified. Studies in one of the distribution areas with larger extents of cloud forest in Mexico indicate that given the size and shape of remnant patches (the largest of 550 ha and down to a few hectares), the core areas represent only half or less of the fragments; fragmentation indexes improve only if oak and pine-oak forest buffering the cloud forest remnants are accounted for. However, these larger assorted forest patches often have very intricate shapes due to human disturbance operating inside the forest, in addition to disruption from the patch border inward, probably due to clearance for agriculture at a very local scale (Ochoa-Gaona and González-Espinosa 2000). Thus, cloud forest core areas embedded within assorted forest patches are also exposed to some degree of human disturbance (Cayuela et al. 2006). Dispersal of some organisms and permeability to ecological processes between the cloud forest patches occurring within a cluster may be favored by the intervening forest habitats (Gascon et al. 1999, as cited in Cayuela et al. 2006). A positive note is that no evidence has yet been produced of recent extinction of plant species (Cayuela et al. 2006). Isolated and small patches may maintain large number of species (e.g., >50 tree species/ha) (Cayuela et al. 2006). Yet this trend may be changing, as birds and mammals are especially vulnerable to high rates of MCF fragmentation (Pattanavibool and Dearden 2002). Other studies have reiterated the importance of even very small fragments (2-10 ha) as reservoirs of mature forest elements and tree diversity in general. In many cases the high tree diversity in these patches is the result of the presence of several pioneer species; nevertheless species of mature forest do occur within small patches as well. Continued pressure on the forest and increasingly small and isolated forest patches can cause time-delayed extinction of keystone forest species (Toledo-Aceves et al. 2014).

CES403.324 North Meso-American Upper Montane Conifer and Mixed Forest

CES403.324 CLASSIFICATION

Concept Summary: En las partes más altas de montañas de Guatemala y Honduras, crecen comunidades dominadas por coníferas. Un ejemplo típico de este sistema se encuentra sobre los 1500 m en Sierra de las Minas, en Guatemala. En Honduras también se conoce de bosques mixtos y rodales puros de pinos entre los 1800 y 2800 m. Generalmente los rodales puros se encuentran en pendientes que reciben poca precipitación y además experimentan quemas cada cierto tiempo. En estos casos el sotobosque es muy pobre y está dominado por especies de gramíneas. La siguiente lista de especies es diagnóstica para este sistema: *Abies guatemalensis, Alnus jorulensis, Alsophila salvinii, Culcita coniifolia, Cyathea divergens, Dicksonia sellowiana, Ilex* spp., *Juglans guatemalensis, Juniperus standleyi, Lophosoria quadripinnata, Pinus strobiformis (= Pinus ayacahuite), Podocarpus oleifolius, Quercus sapotifolia, Quercus* spp., *Taxus globosa, Weinmannia pinnata, Weinmannia tuerckheimii*.

In the higher parts of the mountains of Guatemala and Honduras are located communities dominated by conifers. A typical example of this system is found at about 1500 m in the Sierra de las Minas in Guatemala. In Honduras mixed and pure stands of pine forests are known between 1800 and 2800 m. Generally pure stands are found on slopes that receive little precipitation and also experience burning every so often. In these cases the understory is very poor and is dominated by grasses. The above list of species is diagnostic for this system.

CES403.319 North Meso-American Evergreen Cloud Forest

CES403.319 CLASSIFICATION

Concept Summary: Los bosques nubosos se encuentran en zonas de alta humedad relativa, ambientes montanos, topografía irregular, una capa de humus profunda, y el clima relativamente templado. En México y en otros lugares que se distribuyen entre los 600 y 3000 m de altitud, pero se encuentran de manera óptima entre 1250 y 2450 m. Son fácilmente distinguibles de otros sistemas forestales por la abundancia de epífitas y la reducción en la densidad de trepadoras leñosas. Con el aumento de la elevación, la altura del dosel de los bosques nubosos es inferior a la de los bosques de tierras bajas; los árboles exhiben coronas compactas y troncos retorcidos; contrafuertes, lianas, palmas y hojas tienden a ser más pequeños, más gruesos y más duros, al parecer una adaptación a la transpiración suprimida debido a la alta humedad atmosférica. Generos característicos de los bosques de niebla mexicanos son: *Clethra, Magnolia, Meliosma, Styrax, Symplocos* y *Ternstroemia* con varias especies cada uno. Otras especies comunes en México, Guatemala y Honduras son: *Quercus crispifolia, Quercus bumelioides, Quercus insignis, Quercus cortesii, Quercus lancifolia, Quercus laurina, Quercus xalapensis, Oreopanax xalapensis, Oreopanax* spp., *Phoebe helicterifolia, Alsophila salvinii, Persea donnell-smithii, Persea sessilis, Persea schiedeana, Podocarpus oleifolius, Podocarpus guatemalensis, Weinmannia pinnata, Magnolia hondurensis, Alfaroa costaricensis, Alfaroa hondurensis, Billia hippocastanum, Brunellia mexicana, Prunus brachybotrya, Olmediella betschleriana, Amphitecna montana, Pithecellobium vulcanorum*.

Cloud forests are located in areas of high relative humidity, montane environments, irregular topography, a deep litter layer, and relatively temperate climate. In Mexico and elsewhere they are distributed between 600 and 3000 m elevation but are found optimally between 1250 and 2450 m. They are easily distinguishable from other forest systems by the abundance of epiphytes and reduction in woody climbers. With increasing elevation, the canopy height of cloud forests is lower than that of lowland forests; trees exhibit compact crowns and gnarled trunks; buttresses, lianas, palms, and leaves tend to be smaller, thicker, and harder, apparently an adaptation to suppressed transpiration due to high atmospheric moisture. Genera characteristic of Mexican cloud forests are *Clethra, Magnolia, Meliosma, Styrax, Symplocos*, and *Ternstroemia* with several species each. Other common species in Mexico, Guatemala and Honduras are listed above.
Related Concepts:
Distribution: Neotropical cloud forests extend from 23°N to 25°S latitude, roughly from mid-Mexico to northeastern Argentina.

CES403.319 CONCEPTUAL MODEL

Environment: Bosques nublados neotropicales se extienden desde 23°N a 25°S, aproximadamente desde el centro de México hasta el noreste de Argentina. El típico bosque nublado, húmedo y denso, generalmente se encuentra en las cordilleras, de 1.000 a 3.000 m, con nubes relativamente continuas, cubriendo el bosque. El parche más septentrional del bosque nuboso parece ser el Rancho del Cielo, a 23°N, en la Sierra Madre Oriental de México, entre 1000 y 1500 m. En Mesoamérica, los bosques nubosos en general, aparecen como parches aislados rodeados de diferentes tipos de vegetación. Por lo general, la precipitación anual es de más de 1500 mm y la temperatura media inferior a 18°C. Los suelos son poco profundos, pero con alto contenido de materia orgánica.

Neotropical cloud forests extend from 23°N to 25°S latitude, roughly from mid-Mexico to northeastern Argentina. The typical cloud forest, humid and dense, is generally found on mountain ranges, from 1000 to 3000 m, with relatively continuous cloud cover at the vegetation level, blanketing the forest. The northernmost stand of cloud forest appears to be the Rancho del Cielo, at 23°N latitude in the Sierra Madre Oriental of Mexico, between 1000 and 1500 m. In Meso-America, cloud forests generally appear as isolated patches surrounded by different types of vegetation. Usually anual precipitation is more than 1500 mm and mean temperature lower than 18°C. Soils are shallow but with high organic matter content.

Key Processes and Interactions: La perturbación natural es causada principalmente por los deslizamientos de tierra, por lo que la sucesión secundaria es un proceso clave que define los aspectos estructurales y de composición de los bosques de niebla.

Disturbance is primarily caused by landslides, so secondary succession is a key process defining structural and compositional aspects of cloud forests.

Threats/Stressors: [de M600] Conversión para el café y otros productos agrícolas.

[from M600] Conversion for coffee and other agricultural production.

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

M601. Mesoamerican Pine-Oak Forest

CES403.318 Mexican Upper Montane Pine-Oak Forest and Woodland

CES403.318 CLASSIFICATION

Concept Summary: This system occurs on mountain slopes in the southern Sierra Madre Occidental, Transvolcanic ranges, and mountain slopes of Mexico, extending south into Central America. These forests and woodlands are composed of Madrean pines and evergreen oaks intermingled with patchy shrublands on most mid-elevation slopes (2300-2400 m elevation). The following list of species is diagnositc for this system: *Cleyera theaoides, Solanum nigricans, Litsea glaucescens, Pinus oaxacana, Pinus oocarpa, Prunus serotina, Quercus crassifolia, Quercus laurina, Quercus rugosa, Rapanea juergensenii*.

Description Author: C. Josse

CES403.318 CONCEPTUAL MODEL

Environment: Encontrado en suelos moderadamente profundos que a menudo son calcáreos y de textura franco arcillosa. Ocurren en elevaciones entre 2.300 y 2.400 m, donde las temperaturas de congelación casi nunca, o nunca, se producen.

Found on moderately deep soils that are often calcareous and of clay loam texture. They occur at elevations between 2300 and 2400 m where freezing temperatures seldom, if ever, occur.

Key Processes and Interactions: La frecuencia de incendios de superficie: ~20 años. Lafrecuencia de incendios del dosel: ~150-250 años. Estabilidad de taludes determina la frecuencia de deslizamientos de tierra provocados por terremotos y altas precipitaciones. La frecuencia de deslizamientos a su vez determina los patrones de perturbación y crea heterogeneidad en el paisaje.

Surface fire frequency is ~20 years. Crown fire frequency is ~150-250 years. Slope stability determines the frequency of landslides triggered by earthquakes and high rainfalls. Landslide regime in turn determines landslide disturbance patterns and creates landscape heterogeneity.

Threats/Stressors:

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

CES403.321 North Meso-American Upper Montane Pine-Oak Cloud Forest

CES403.321 CLASSIFICATION

Concept Summary: Este sistema agrupa los bosques nublados mixtos de montañas del norte de Centro América caracterizados por la asociación de especies de pino y encino (roble), y representa el límite de la influencia de la flora boreal en el Neotrópico caracterizada por una alta diversidad de coníferas. Se trata de un sistema transicional entre el templado de pino encino o mesófilo de montaña y los robledales tropicales montanos de Costa Rica hasta Colombia y se distribuye desde el sur de Chiapas, México hasta el noroeste de Nicaragua. La diversidad de coníferas y de robles es una de las mas altas del mundo porque se trata del centro de especiación del genero *Pinus*. Es un sistema influenciado por la neblina y por lo tanto con humedad ambiental casi constante a pesar de la estacionalidad que pudiera tener. Esta es una de las principales diferencias con el sistema de Bosque de pino-encino montano de la zona templada de México, que se desarrolla en un ambiente más seco. El bosque montano nublado de pino encino se encuentra generalmente entre los 1500 y 2300 m y ocurre en ambas vertientes: Pacífica y Caribe. Se han registrado hasta 36 especies de Encino (roble) y 11 especies de Pino en comunidades de bosque maduro. La siguiente lista de especies es diagnóstica para este sistema: *Abies guatemalensis, Acer skutchii, Alnus jorulensis, Arbutus xalapensis, Bocconia glaucifolia, Cornus disciflora, Culcita coniifolia, Hesperocyparis lusitanica (= Cupressus lusitanica), Drimys tuerckheimii, Juglans guatemalensis, Juniperus comitana, Liquidambar styraciflua, Miconia theaezans, Morella cerifera (= Myrica cerifera), Nectandra* spp., *Persea* spp., *Phoebe acuminatissima, Pinus strobiformis (= Pinus ayacahuite), Pinus chiapensis, Pinus hartwegii, Pinus maximinoi, Pinus patula ssp. tecunumanii, Pinus pseudostrobus, Podocarpus maturai, Podocarpus montana, Podocarpus oleifolius, Quercus benthamii, Quercus corrugata, Quercus cortesii, Quercus lancifolia, Quercus laurina, Quercus ovandensis, Quercus rugosa, Quercus sapotaefolia, Saurauia kegeliana, Saurauia scabrida, Weinmannia tuerckheimii*.

This system groups the mixed mountain cloud forests of northern Central America characterized by the association of pine and encinal (oak), and represents the limit of the influence of boreal flora in the Neotropics characterized by a high diversity of conifers. This is a transitional system between the temperate pine-oak or cloud forests and the tropical montane oak forests of Costa Rica to Colombia, and is distributed from southern Chiapas, Mexico, to northwestern Nicaragua. The diversity of conifers and oaks is one of the highest in the world because it is the center of speciation of the genus *Pinus*. It is a system influenced by the mist and therefore almost constant, although it may have seasonal humidity. This is one of the main differences with the system of forest montane pine-oak forests of the temperate zone of Mexico, which develops in a dry environment. Cloudy montane pine-oak forest is generally between 1500 and 2300 m and occurs in both strands: Pacific and Caribbean. Up to 36 species of encinal (oak) and 11 species of pine have been recorded in mature forest communities. The above list of species is diagnostic for this system.

Related Concepts:

Distribution: Se distribuye sobre los 1500 m y hasta los 2300 m de altitud desde el sur de Chiapas, Mexico hasta el noroeste de Nicaragua, sobre la Sierra Madre de Chiapas, las montañas del sur de Guatemala, una importante porción en el centro de Honduras, ocurrencias menores en el norte del Salvador y el noroccidente de Nicaragua.

Found between about 1500-2300 m elevation from southern Chiapas, Mexico, to northwestern Nicaragua, on the Sierra Madre de Chiapas, the southern mountains of Guatemala, a large portion in central Honduras, and minor occurrences in northern El Salvador and northwestern Nicaragua.

Nations: GT, HN, MX, NI, SV

Concept Source: C. Josse

Description Author: C. Josse

CES403.321 CONCEPTUAL MODEL

Environment: Pendientes de media y alta montaña a menudo de origen volcánico, con precipitación de 1500-3000 mm anuales, aunque generalmente más de 2000 mm y además con influencia de la neblina. Las lluvias ocurren principalemnte en el verano y normalmente los periodos secos van de 0-4 meses al año. Se ubica a mayor altitud en el lado Pacífico que en el Atlántico. La temperatura media de estos bosques varía entre 12°C y 20°C dependiendo de la altitud. Estos bosques se presentan en condiciones de temperaturas moderadas y de alta humedad atmosférica. La nubosidad es un factor importante para mantener la humedad atmosférica ya que reduce la incidencia de la radiación solar y la intensidad lumínica, provocando un descenso en la temperatura. Al ubicarse en las partes medias y altas de las cuencas hidrográficas, con capacidad para recibir y conservar gran cantidad de humedad gracias a la vegetación y los suelos, cumplen un papel importante en la regulación del sistema hídrico aguas abajo (Luna et al. 2001).

Moderate slopes and high elevation often volcanic, with annual rainfall of 1500-3000 mm, but generally more than 2000 mm and also influenced by fog. Principally rainfall occurs in the summer and dry periods are usually 0-4 months a year. It is located at the highest altitude in the Pacific than in the Atlantic side. The average temperature of these forests varies from 12°C and 20°C depending on the altitude. These forests occur under moderate temperatures and high humidity. The cloudiness is an important factor to maintain the atmospheric humidity and to reduce the incidence of solar radiation and the light intensity, causing a drop in temperature. Being located in the middle and upper parts of watersheds, with capacity to receive and store a considerable amount of moisture through vegetation and soils plays an important role in regulating the water systems downstream (Luna et al. 2001) .

Key Processes and Interactions: La cantidad de materia orgánica que se acumula en el horizonte superior generalmente es mucha y forma una capa gruesa que detiene el drenaje con lo que el proceso de mineralización está limitado por condiciones de saturación y anaerobismo. Estos suelos en general son ácidos, poco fértiles y sujetos a fuertes problemas de erosión si se transforma la cobertura vegetal. Las condiciones de humedad atmosférica también se alteran significativamente al remover la cubierta boscosa.

The amount of organic matter that accumulates in the upper horizon is generally very thick and forms a layer that stops thereby draining the mineralization process is limited by saturation conditions and anaerobismo. These soils are generally acidic, infertile and subject to severe erosion problems if the vegetation becomes. Humidity conditions were also significantly altered by removing forest cover.

Threats/Stressors: Las amenazas principales son los altos niveles de fragmentación de los bosques remanentes, incendios, prácticas de manejo incompatibles con la conservación del bosque y extracción de madera. La tasa de deforestacion de estos bosques en décadas recientes ha sido de 60,000 ha/año, que de continuar, eliminaría todo el bosque montano remanante en 45 años (Pérez et al. 2007). La incidencia de incendios es alta debido a que la población local a menudo utiliza la forma de roza, tumba y quema para la producción agrícola. Niveles de fragmentación altos y los cambios concomitantes en las condiciones microclimáticas, vuelven estos ecosistemas mas susceptibles a incendios forestales y generan cambios en la composición y estructura. A su vez, estas alteraciones pueden hacer que estos bosques se vuelvan mas vulnerables a las plagas que se conocen para la región, tanto de insectos (*Dendroctonus* spp.) como de plantas parásitas (*Psittacanthus* spp., *Arceuthobium aureum*) (Pérez et al. 2007).

The main threats are high levels of fragmentation of the remaining forest and fire management practices incompatible with forest conservation and logging. The rate of deforestation of these forests in recent decades has been 60,000 ha / year, which if it continues, will eliminate all remnant montane forest in 45 years (Pérez et al. 2007). The incidence of fires is high because local people often use slash-and-burn agricultural practices. With high levels of fragmentation and concomitant changes in microclimatic conditions, these ecosystems become more susceptible to forest fires which cause changes in the composition and structure. In turn, these changes can make these forests more vulnerable to pests that are known to the region, both insect (*Dendroctonus* spp.) and parasitic plants (*Psittacanthus* spp., *Arceuthobium aureum*) (Pérez et al. 2007).

Ecosystem Collapse Thresholds: Variabialidad climática provocando más fuegos y más intensos, eliminación de los bancos de semillas, eliminación de microrizas en encinos. Ascenso del nivel de formación de nubes y cambios en el número de días con nubosidad, con lo que se alteran las condiciones de humedad de estos bosques llevando en casos extremos a la alteración de la composición y estructura a niveles de cambio de estado.

Climate variability causes more and more intense fires which result in the removal of seed banks and mycorrhizae in oak. Rise of cloud formation level and changes in the number of days with cloud cover could change the humidity of these forests leading in extreme cases to the alteration of the composition and structure beyond the forest resilience capacity.

CES403.320 North Meso-American Lower Montane Pine-Oak Cloud Forest

CES403.320 CLASSIFICATION

Concept Summary: Este sistema representa los bosques mixtos de las estribaciones bajas de las montañas del norte de Centro América, entre 900 y 1500 m de altitud aproximadamente. Agrupa las comunidades que están en el límite superior de los bosques húmedos latifoliados premontanos y bajo los bosques nublados. Posiblemente más característico de las estribaciones del Caribe que reciben los vientos alisios húmedos. La siguiente lista de especies es diagnóstica para este sistema: *Acer negundo var. mexicana, Arbutus xalapensis, Calyptranthes hondurensis, Carpinus caroliniana, Cedrela oaxacensis, Clethra macrophylla, Cleyera theanoides, Ficus* spp., *Inga* spp., *Liquidambar styraciflua, Morella cerifera (= Myrica cerifera), Persea* spp., *Pinus maximinoi, Pinus oocarpa, Pinus patula ssp. tecunumanii, Pinus pseudostrobus, Prunus* spp., *Quercus elliptica (= Quercus hondurensis), Quercus oleoides, Quercus segoviensis (= Quercus peduncularis)*.

This system represents the mixed forests of the lower foothills of the northern mountains of Central America, between 900 and 1500 m altitude. It brings together communities that are at the upper limit of premontane moist broadleaf forests and below cloud forest. Perhaps most characteristic of the Caribbean slopes due to higher moisture brough by the moist trade winds. The above list of species is diagnostic for this system.

M602. Southern Mesoamerican Montane Humid Forest

CES402.609 Talamancan Upper Montane Oak Cloud Forest

CES402.609 CLASSIFICATION

Concept Summary: Las montañas de Costa Rica hacia el sur son diferentes de las del norte de Centroamérica gracias a la barrera que representa la depresión nicaraguense con sus llanuras y lagos y también debido a la presencia de un clima más lluvioso y menos estacional hacia el sur. La Cordillera de Talamanca representa en el sur de Centroamérica la distribución típica de los bosques de robles, que alcanzan su límite sur de distribución en los andes colombianos. Este sistema agrupa los bosques de roble sobre los 2500 m aproximadamente y hasta los 3100-3200 m snm. Estos bosques son muy húmedos y también tienen una estructura compleja y gran estatura, hacia su límite superior la estatura disminuye y los robles alternan principalmente con especies de Ericaceae. La siguiente lista de especies es diagnóstica para este sistema: *Quercus costaricensis, Ilex lamprophylla, Quercus copeyensis, Myrsine pittieri, Brunellia costaricensis, Drimys granadensis, Clethra gelida, Magnolia* spp., *Ilex vulcanicola, Weinmannia pinnata, Weinmannia* spp., *Schefflera rodriguesiana, Alnus, Buddleia, Escallonia, Miconia, Oreopanax, Prumnopitys standleyi, Podocarpus macrostachys, Cinnamomum* spp., Lauraceae, *Chusquea* spp.

1.A.4.Ed. Caribbean-Central American Flooded & Swamp Forest

M618. Caribbean Floodplain Forest

CES411.420 Caribbean Floodplain Forest

CES411.420 CLASSIFICATION

Concept Summary: This system occurs in basins and plains along the coast, in the wide valleys of lowland rivers, or on rich, black alluvial soils. It can also occur right behind the mangrove communities in high rainfall and/or abundant river runoff locations. Depending on the duration of the flooding period, forests can have one or more tree layers. The canopy can be 10-15 m, 15-18 m, or 20-25 m high. The following list of species is diagnostic for this system: *Pterocarpus officinalis, Roystonea regia, Roystonea borinquena, Tabebuia angustata, Bucida buceras, Sideroxylon portoricense (= Bucida subinermis), Calophyllum antillanum (= Calophyllum brasiliense), Swietenia mahagoni, Tabernaemontana amblyocarpa, Sabal parviflora, Sabal yapa, Acoelorraphe wrightii, Ficus* spp., *Myrsine cubana, Prestoea acuminata var. montana (= Prestoea montana), Symphonia globulifera, Melicoccus bijugatus, Cladium mariscus ssp. jamaicense (= Cladium jamaicense)*, and *Nephrolepis biserrata*.

Related Concepts:

Distribution: This system is found in Cuba, the Dominican Republic, Puerto Rico, and Trinidad and Tobago.

Nations: CU, DO, PR, TT

Concept Source: C. Josse

Description Author: C. Josse

CES411.420 CONCEPTUAL MODEL

Environment: [from M618] Located on alluvial plains in climates that vary from very humid to seasonal.

Key Processes and Interactions: In the Caribbean, hurricanes constitute a trigger of periodic disturbance that provides long-term opportunities for species invasions and long-term ecosystem response in floodplain forests. A study about the effects of a hurricane in a Puerto Rican floodplain palm forest (Frangi and Lugo 1998), showed that the dominant species became more dominant and created low instantaneous tree mortality (1% of stems) and reductions in tree biomass (-16 Mg/ha/yr) and density, although not in basal area. Five years after the hurricane, the palm floodplain forest had exceeded its pre-hurricane above-ground tree biomass, tree density, and basal area. Delayed tree mortality was twice as high as instantaneous tree mortality after the storm and affected dicotyledonous trees more than it did palms. Regeneration of dicotyledonous trees, palms, and tree ferns was influenced by a combination of factors including hydroperiod, light, and space (Frangi and Lugo 1998).

Threats/Stressors: Key hydrodynamics are easily affected by infrastructure for roads, agriculture, and urban development.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct conversion by draining, damming (permanent inundation), or disruption of hydrodynamics that results in loss of characteristic biotic composition.

CES402.579 Caribbean Seasonal Evergreen Gallery Forest

CES402.579 CLASSIFICATION

Concept Summary: El sistema integra las comunidades boscosas de las planicies aluviales de cauces fluviales largos y caudalosos que tienen crecidas esporádicas según la cantidad de lluvia en las cuencas altas (arroyo washes). De igual forma, en la estación seca, estos cauces pueden permanecer totalmente secos. En este tipo de sistema los suelos pedregosos o rocosos son comunes y generalmente son ultisoles arcillosos. Los bosques son relativamente abiertos y de estatura media. En algunas partes de su distribución se encuentran rodeados por sabanas de pinos, por lo que los márgenes pueden verse afectados por las quemas. The following list of species is diagnostic for this system: *Aristolochia grandiflora, Bactris major, Bactris mexicana, Belotia campbellii, Bucida buceras, Cassia grandis, Cordia gerascanthus, Balizia leucocalyx, Lonchocarpus guatemalensis, Muntingia calabura, Pachira aquatica, Pterocarpus officinalis, Roystonea regia, Samanea saman, Schizolobium parahyba, Tabebuia rosea, Guadua longifolia, Calophyllum brasiliense var. rekoi, Vochysia hondurensis, Xilopia frutescens, Xilopia aromatica, Alchornea latifolia, Apeiba membranacea, Bactris gassipaeas, Bellucia costaricensis, Guadua macclurei, Quassia amara, Vismia macrophylla, Pera arborea, Zygia longifolia, Chrysobalanus icaco, Eugenia acapulcensis, Eugenia monticola, Tibouchina aspera, Amanoa guianensis, Myrsine coriacea, Croton trinitatis, Alibertia edulis*.

M617. Caribbean Swamp Forest

CES411.453 Caribbean Coastal Palm Swamp

CES411.453 CLASSIFICATION

Concept Summary: Coastal plain semipermanently or tidally flooded. Fen woods are 8-15 m high, on peat or limestone soil. Freshwater and transitional halophilic communities. The following list of species is diagnostic for this system: *Acoelorraphe wrightii, Leucothrinax morrisii (= Thrinax morrisii), Coccothrinax argentata, Chrysobalanus icaco, Annona glabra, Sabal parviflora, Bucida palustris, Tabebuia angustata, Fraxinus caroliniana, Guettarda combsii, Ilex cassine, Salix caroliniana (= Salix longipes), Copernicia* spp., and mangrove species. The herbaceous stratum is well-developed, and consists of *Eleocharis* spp. and *Cladium mariscus ssp. jamaicense*. Communities dominated by the clumping palm species *Acoelorraphe wrightii* occur also in the humid sites of white-sand areas, usually along or near the drainage network surrounding shallow oligotrophic lakes. The fern *Blechnum serrulatum* often gives substantial coverage to the ground.

Nations: BS, CU, MQ, PR, TT

Concept Source: C. Josse

Description Author: C. Josse

CES411.453 CONCEPTUAL MODEL

Environment: Coastal plain in seasonally flooded and semipermanently saturated situations, on peat or limestone soil. Freshwater and transitional halophilic communities. Some of these communities occur associated with *Cladium* marsh.

Key Processes and Interactions: Based on the length of the hydroperiod, flooded forests can be grouped into permanently inundated swamp forest and periodically inundated swamp forest. Swamp forest is usually found on soils that a have high water table, e.g., *Mauritia flexuosa* (palm) swamp in Trinidad grows on land perpetually inundated with 30 to 100 cm of water, while periodically-inundated swamp occurs in areas subjected to inundation during rainy season. Species richness generally decreases with increasing hydroperiod. Based on the type of dominant species, swamp forests can be conveniently divided into two types: forests dominated by hardwood species and those dominated by palms. Dominance by palms becomes stronger with increasing hydroperiod or soil moisture conditions (Bacon 1990, Lugo et al. 1990).
Threats/Stressors: Key Factors for evaluating integrity include hydrodynamics that are frequently altered by human uses. Flood Regime: duration, magnitude and return interval of flooding should fall within historical ranges for the type, and is easily affected by infrastructure for roads, agriculture, and urban development. Channel Dynamics: the rate of change and/or lateral migration in riverine portions of swamps create habitat mosaics such as oxbow lakes, levees, seasonal lakes, canals, forested terraces, and associated successional patterns in vegetation. Water Quality: chemistry (pH, salinity gradient, N, C, P), transparency (suspended sediment, phytoplankton count, fish composition)
Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct conversion by draining, damming (permanent inundation), or disruption of hydro dynamics that results in loss of characteristic biotic composition.

CES411.366 South Florida Bayhead Swamp

CES411.366 CLASSIFICATION

Concept Summary: This ecological system consists of stands of predominately broad-leaved hardwoods which are emergent amidst marshes of the south Florida Everglades region. These areas are often called "tree islands" as they occur on slightly elevated sites above the low-relief marshes. Loveless, writing in 1959, considered them to be "perhaps the most striking botanical feature in the Everglades." Individual islands often have a characteristic shape depending upon the size; large islands are often teardrop-shaped, smaller islands are circular. Patches range in size from one-quarter acre to 300 acres or more. These islands often form an abrupt ecotone with adjacent fire-prone marshes. Fires enter bayhead swamps only under extreme drought conditions and may kill much of the bayhead vegetation and heavily reduce peat accumulation. If left long unburned, bayheads may succeed to hardwood hammocks.

- Sweetbay - Swamp Tupelo - Redbay: 104 (Eyre 1980) **<**
- Tropical Hardwoods: 105 (Eyre 1980) **<**

Distribution: Endemic to south Florida.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, M. Pyne and C. Nordman

CES411.366 CONCEPTUAL MODEL

Environment: This system occurs on sites elevated above surrounding marshes; they are inundated 2-6 months during the year, and often found on Gandy Peat soils (Gunderson and Loftus 1993). Tree islands in the northern Everglades occur on acidic, deep peat sites, while southern examples are higher in pH, and shallower peat. Individual islands often have a characteristic shape depending upon the size; large islands are often teardrop-shaped, smaller islands are circular (Loveless 1959, Gunderson and Loftus 1993). Patches range in size from one-quarter acre to 300 acres or more.

Key Processes and Interactions: These islands often form an abrupt ecotone with adjacent marshes. Although fires often burn through the marshes, they enter bayhead swamps only under extreme drought conditions. Under these conditions, fires may kill much of the bayhead vegetation and heavily reduce peat accumulation. If left long unburned, bayheads may succeed to hardwood hammocks. Bayheads in some areas are inundated 2-6 months during the year (Gunderson and Loftus 1993), but hydroperiods may vary from 1-4 months in the northern to middle part of Taylor Slough; small, higher areas within a bayhead may never be under water (Olmstead et al. 1980b).
Threats/Stressors: Threats include hurricanes and invasive exotic plants, such as *Lygodium microphyllum* and/or *Melaleuca quinquenervia*. The open canopies which result from hurricanes provide opportunities for these invasive exotic plants to increase and spread (Brandt et al. 2003, Ugarte et al. 2006). Changes to hydrology and fire frequency are also threats. While the bayhead swamps are slightly higher than the surrounding sawgrass marsh, sea-level rise may also threaten the bayhead swamps. During dry conditions, because they are slightly higher than the surrounding wetlands and contain organic soils, severe fires can consume the organic soils and completely eliminate a tree island or hammock. The result frequently is development of a willow thicket (Wade et al. 1980, Landfire 2007a).
Ecosystem Collapse Thresholds: Ecosystem collapse is characterized by dominance of the vegetation by invasive exotic plants (Ugarte et al. 2006) such as *Lygodium microphyllum* and/or *Melaleuca quinquenervia*, succession of the vegetation to hardwood hammock, or dramatic vegetation change due to alteration of hydrology, or a combination of factors including altered fire regime, such as the development of a willow thicket (Wade et al. 1980, Landfire 2007a).

M619. Mesoamerican Coastal Plain Swamp Forest

CES402.586 Meso-American Coastal Swamp Forest

CES402.586 CLASSIFICATION

Concept Summary: Este sistema representa las comunidades costeras sobre suelos saturados debido a lo alto del nivel freático, o que soportan inundación durante buena parte del año. Pueden encontrarse en los márgenes de un yolillal y se caracterizan por ser más diversas y presentar una mezcla de palmas y especies de hoja ancha, aunque algunas de las asociaciones son dominadas por palmas (*Manicaria, Acoelorrhaphe*). El agua es dulce o salobre de baja salinidad. Generalmente están hacia la costa pero en algunas partes llegan hasta más de 300 m de altitud. La siguiente lista de especies es diagnóstica para este sistema: Isthmian Atlantic and Choco-Darien: *Camnosperma panamensis* (orey, sajales), *Raphia taedigera* (yolillo, matomba), *Euterpe precatoria, Carapa guianensis, Dialyanthera gordoniifolia* (guandales), *Prioria copaifera, Symphonia globulifera, Grias fendleri, Sacoglottis trichogyna, Conocarpus erectus, Cassipourea* sp., *Calophyllum antillanum (= Calophyllum brasiliense)*. Peten and CA Atlantic: *Manicaria saccifera* (manacal), *Roystonea dunlapiana, Roystonea regia, Acoelorraphe wrightii* (tique), *Astrocaryum mexicanum, Astrocaryum alatum,*

Dialium guianense, Symphonia globulifera, Orbignya cohune (= Attalea cohune), Pentaclethra macroloba, Sabal mauritiiformis, Bactris spp., *Euterpe aff. oleracea, Crysophila stauracantha*.

Nations: BZ, CO, CR, EC, GT, HN, NI, PA
Concept Source: C. Josse
Description Author: C. Josse

CES402.586 CONCEPTUAL MODEL

Environment: Ocurre a lo largo de canales de estuarios y de ríos de la planicie costera, puede crecer adyacente a los manglares e incluso avanzar hasta la playa, así como avanzar tierra adentro a lo largo del recorrido de ríos. Los suelos son hidromórficos de textura arcillosa -aunque es común una capa arenosa superficial, el drenaje es defectuoso y puede haber acumulación de turba.

It occurs along channels and river estuaries of the coastal plain. It can grow adjacent to mangroves and even advance to the beach and move inland along the course of rivers. The soil is clayey hydromorphic though it is commonly a shallow sandy layer; drainage is poor and there may be an accumulation of peat.

Key Processes and Interactions: La dinámica de las mareas y fluviales moderado.

Moderate tidal and fluvial dynamics.

Threats/Stressors: [de M619] Factores clave para la evaluación de la integridad incluyen hidrodinámica que con frecuencia son alterados por usos humanos: Régimen de inundación: la duración, la magnitud y el intervalo de retorno de las inundaciones debe caer dentro de los rangos históricos para el tipo, y es fácilmente afectada por la infraestructura de carreteras, construcción de drenajes y canales, la agricultura y el desarrollo urbano. Canal Dinámico: la tasa de cambio y / o migración lateral en porciones ribereñas de pantanos crea mosaicos de hábitats tales como madreviejas, diques, lagos estacionales, canales, terrazas boscosas, y los patrones de sucesión asociados en la vegetación. Calidad del Agua: la química (pH, gradiente de salinidad, N, C, P), transparencia (sedimentos en suspensión, recuento de fitoplancton, la composición de los peces).

[from M619] Key factors for evaluating integrity include hydrodynamics that are frequently altered by human uses: Flood Regime: duration, magnitude and return interval of flooding should fall within historical ranges for the type, and is easily affected by infrastructure for roads, agriculture, and urban development. Channel Dynamics: the rate of change and/or lateral migration in riverine portions of swamps create habitat mosaics such as oxbow lakes, levees, seasonal lakes, canals, forested terraces, and associated successional patterns in vegetation. Water Quality: chemistry (pH, salinity gradient, N, C, P), transparency (suspended sediment, phytoplankton count, fish composition)

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa mediante el drenaje, la construcción de presas (inundación permanente), o la interrupción de la dinámica de hidroeléctricas que se traduce en la pérdida de la composición biótica característica.

Ecological collapse tends to occur from direct conversion by draining, damming (permanent inundation), or disruption of hydro dynamics that results in loss of characteristic biotic composition.

CES402.603 Petén Lowland Alluvial Seasonal Forest on Calcareous Soil

CES402.603 CLASSIFICATION

Concept Summary: Sistema que agrupa las comunidades boscosas siempreverdes que crecen en depresiones del terreno u hondonadas, en suelos ricos en calcio de textura arcillosa y que se inundan estacionalmente alternando con periodos de extrema sequía de varios meses debido al clima estacional. La inundabilidad está asociada al balance entre el escurrimiento, la infiltración y las precipitaciones. Son bosques de unos 10 m de alto, con alta densidad de árboles de diámetros pequeños y con numerosos árboles de troncos retorcidos y/o espinosos. Se encuentran en situaciones heterogéneas inmersos en la matriz de bosque siempreverde estacional de suelos calcáreos y colinas cársticas (Tun Dzul 2007). Principalmente en el sur de la península de Yucatán en México, el Petén en Guatemala y Belice, en Honduras se encuentra muy alterado. La siguiente lista de especies es diagnóstica para este sistema: *Croton nitens, Cameraria latifolia, Haematoxylum campechianum, Bucida buceras, Diospyros anisandra, Metopium brownei, Manilkara zapota, Coccoloba cozumelensis, Coccoloba spicata, Coccoloba diversifolia, Myrcianthes fragrans, Eugenia winzerlingii, Syderoxylon celastrinum, Calophyllum antillanum (= Calophyllum brasiliense), Acacia gaumeri, Lonchocarpus yucatanensis, Vitex gaumeri, Byrsonima bucidaefolia, Hippocratea excelsa, Krugiodendron ferreum, Manilkara zapota* y *Swietenia macrophylla*. *Cladium mariscus ssp. jamaicense (= Cladium jamaicense)* es abundante en el estrato herbáceo.
Related Concepts:
Distribution: En los bosques del Petén y sur de la Península de Yucatán.

Description Author: C. Josse

CES402.603 CONCEPTUAL MODEL

Environment: Ocurre en suelos compuestos por residuales de las fracciones insolubles de las rocas carbonatadas y con un alto contenido de arcilla (58%) por lo que tienen poco drenaje tanto interno como superficial, llegando a anegarse hasta 50 cm o mas en la época de lluvias, la alternabilidad entre el anegamiento y el secado del suelo arcilloso hace que se formen pequeños montículos conocidos como relieve gilgai. En los bosques del Petén y sur de la Península de Yucatán este sistema se encuentra en zonas inundables que forman parte de la variada geomorfología de la altiplanicie cárstica que forma la espina dorsal de la península, con áreas de planicie con lomeríos de cimas redondeadas, separados por zonas bajas inundables y mesetas niveladas. La altitud varía de 250 a 340 msnm. Bajo estas depresiones u hondonadas limitadas por las elevaciones calcáreas, pueden haber cavidades con flujo subterráneo vertical u horizontal o disponerse una capa impermeable de terrenos muy planos, que a causa de la poca permeabilidad del suelo, pueden anegarse durante algunos meses con aguas salobres o no, originadas en el nivel freático e inundaciones temporales en época lluviosa, luego de lo cual los suelos se secan. La precipitación anual fluctúa en un rango de 900-1400 mm y se concentra entre mayo y octubre. La temperatura promedio mensual es >21°C.

Key Processes and Interactions: Bosques sujetos a intervención y fuegos.
Threats/Stressors: Estos bosques han sufrido pérdidas significativas en extensión por deforestación y conversion a campos de arroz y pastos para ganadería. Las políticas de acceso a la tierra y desarrollo agrícola han generado sucesivas etapas de fragmentación de estos bosques con usos colindantes de agricultura de milpa o tumba y quema para autoconsumo y para comercio. La apertura de nuevas redes viales también presenta amenazas para este ecosistema. Estudios de cambio de uso del suelo (Turner et al. 2001) han encontrado que las tasas de deforestación anual de 0.3-0.4% previas al año 2000, han disminuido considerablemente y en los últimos años el uso agrícola se ha enfocado mas en usar las áreas de rebrote y bosque secundario joven. Además este uso se concentra ahora en las tierras altas y no en las áreas sujetas a inundación.
Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra. Sin embargo las áreas de bosque que ya han sufrido alteraciones, especialmente si fueron drenadas, no llegan a recuperarse porque vuelven a ser utilizadas antes de los 25-30 años que necesitarían para alcanzar una estructura de bosque maduro.

Ecological collapse tends to occur from direct land conversion.However, forest areas that have already been altered, especially if they were drained, do not recover because they tend to be disrupted again within 25-30 years before they achieve a mature forest structure.

CES401.295 Meso-American Semi-deciduous Gallery Forest and Shrubland

CES401.295 CLASSIFICATION

Concept Summary: Este sistema reune las comunidades que ocurren a lo largo de ríos que atraviesan zonas de bosque deciduo o semideciduo y sabanas (naturales o antrópicas). Se trata de complejos de vegetación herbácea, arbustiva y boscosa en diferentes posiciones a lo largo de los bancos del río y terrazas, con diferentes niveles de disturbio natural propios de la dinámica de inundación del río, o debidos a la alteración antrópica. Generalmente la composición de las especies leñosas asemeja la de un bosque más húmedo que el del entorno, debido a la mayor disponibilidad de humedad. El regimen de humedad y anegamiento del sustrato también juegan un papel fundamental. Si se encuentra en terrenos con pendiente, la inundación puede ser muy corta porque los ríos tienen un curso rápido y hay posibilidad de drenaje, en planicies la inundación puede durar varios días o semanas. La siguiente lista de especies es diagnóstica para este sistema: *Cecropia obtusifolia, Salix humboldtiana, Cordia alliodora, Cedrela odorata, Schizolobium parahyba, Castilla elastica, Castilla tunu, Calliandra emarginata, Inga vera, Inga affinis, Vismia* sp., *Ficus insipida, Anacardium excelsum, Annona glabra, Annona reticulata, Astronium graveolens, Brosimum alicastrum, Spondias mombin, Trichilia pittieri, Hernandia didymantha, Caryocar costaricense, Couroupita nicaraguarensis, Chrysophila guaguara, Albizia caribaea, Calophyllum antillanum (= Calophyllum brasiliense), Ochroma, Miconia, Heliconia, Canna, Calathea, Isertia*.

1.A.5.Ua. Atlantic-Caribbean & East Pacific Mangrove

M004. Eastern Pacific Mangrove

CES402.599 Pacific Coast and Estuarine Mangrove

CES402.599 CLASSIFICATION

Concept Summary: Es un sistema de zonas mareales con fluctuaciones de hasta más de 5 m. Según su ubicación puede estar permanentemente inundados o soportar dos inundaciones diarias, este gradiente del nivel de inundación del suelo y de salinidad influye en las características estructurales y de composición de la vegetación. En el Pacífico la amplitud de la marea es mayor que en el Caribe, y por tanto los manglares se extienden muy adentro por los deltas de los ríos. Esta dinámica intensa produce un proceso de sucesión con el resultado de que se forman comunidades casi monoespecíficas de Rizophora en las zonas de influencia mareal más directa. En sustratos más estables se encuentran las poblaciones de Avicennia, Laguncularia y Pelliciera y finalmente, Mora megistosperma y Euterpe que están en la transición con los terrenos aluviales. La siguiente lista de las especies es de diagnóstica para este sistema: *Rhizophora mangle, Rhizophora racemosa, Rhizophora x harrisonii, Laguncularia racemosa, Avicennia germinans, Avicennia bicolor, Conocarpus erectus, Pelliciera rhizophorae, Acrostichum aureum*.

Concept Source: C. Josse

Description Author: C. Josse

CES402.599 CONCEPTUAL MODEL

Environment: Los manglares ocurren en una planicie fluvial marina con sedimentos aluviales. Los suelos son inceptisoles higromórficos arcillosos. Se trata de un sistema en el ecotono entre los sistemas continentales y marinos y por tanto las especies se distribuyen de acuerdo a sus adpataciones, en un gradiente del nivel de inundación del suelo y de salinidad.

Key Processes and Interactions: Active tidal and fluvial dynamics.

Threats/Stressors: [de M004] Las principales amenazas incluyen la conversión para la acuicultura y el desarrollo del turismo costero. Durante la cosecha de madera de mangle para carbón, leña y forraje se producen impactos en la composición de las especies y la estabilidad del parche. La contaminación del agua y la alteración de la hidrología de fuentes interiores de agua dulce afecta la salinidad del agua y la hidrodinámica. La sobrepesca altera cadenas tróficas acuáticas en los manglares. El cambio climático y la degradación de los arrecifes adyacentes pueden exponer a los manglares a la onda destructiva y lavado por tierra derivada de la subida del nivel del mar y las tormentas extremas.

[from M004] Key threats include conversion for aquaculture and coastal tourism development. Over harvest for mangrove wood for charcoal, fuelwood, and fodder impacts species composition and patch stability. Water pollution and alteration to hydrology from inland freshwater sources affects water salinity and hydrodynamics. Overfishing alters aquatic foodwebs in mangroves. Climate change and adjacent reef degradation can expose mangroves to destructive wave and overland wash stemming from sea level rise and extreme storm events.

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

Description Author: C. Josse

CES402.596 CONCEPTUAL MODEL

Environment: [de M004] Hogarth (1999) reconoce los siguientes tipos de sistemas de manglares basado en el entorno ambiental. Manglares de franja (dominado por mareas): se caracteriza por un alto rango de mareas en una zona intermareal de poca profundidad a menudo colonizada por manglares. La marea tiene típicamente toda la fuerza oceánica, pero acción la de las olas se difunde rápidamente por el paso a través de una zona intermareal escalonada. Sedimentos y suelos de manglares es probable que sean más dinámicos ya que las mareas depositan y remueven sedimentos de los estuarios y de los ríos interiores. Reciben menos escurrimiento de nutrientes terrestres en comparación con los bosques ribereños. Manglares de cuenca: adyacentes a los manglares de franja hacia el lado interior (hacia tierra). Protegidos de la acción del oleaje, e inundados con poca frecuencia. Con salinidad altamente variable en función de la precipitación, el flujo de las aguas subterráneas, y el aumento de marea local. A menudo exhiben altas tasas de evaporación, lo cual puede resultar en suelos hipersalinos. Debido a las corrientes bajas y poca turbulencia, los manglares de cuenca pueden ser sumideros de nutrientes y sedimentos. Los manglares ribereños: grandes extensiones de manglares se encuentran en los deltas de los ríos, donde los suelos y la salinidad son adecuadas para el desarrollo de manglares (por ejemplo, el delta del Amazonas). Tienen una baj amplitud de mareas y un fuerte flujo de agua dulce que transporta cargas sustanciales de sedimentos, gran parte del cual se deposita en las comunidades de manglar. Se caracterizan por desplazamientos de los canales del río, y por lo una dinámica de expansión hacia el interior, así como hacia el exterior gracias a la sedimentación cambiante en el delta. Manglares arbustivos: se encuentran en ambientes extremos donde los nutrientes y el agua dulce pueden ser limitantes. Los manglares elevados (hammock): el aislamiento relativo de los ríos o el mar lleva a una acumulación en forma de cúpula de turba orgánica sobre depresiones, donde se arraigan los manglares. Manglares en sustratos carbonatados: En las costas de baja energía, donde el carbonato ha acumulado de la descomposición de arrecifes de coral, lo que resulta en los sedimentos de cal y la acumulación de sedimentos. Manglares del interior: Las zonas donde los manglares se encuentran totalmente separadas del mar, a menudo en agujeros de geología cársica u otras depresiones.

[from M004] Hogarth (1999) recognizes the following types of mangrove systems based on environmental setting. Fringe Mangroves (tide-dominated): characterized by a high tidal range over a shallow intertidal zone that is often colonized by mangrove trees. Tidal water is typically full strength seawater, but wave action is diffused quickly by passage over a stepped intertidal zone. Sediment and mangrove soils are likely to be more dynamic as tides deposit and remove sediments from the sea and from inland river estuaries. Receive less runoff of terrestrial nutrients compared to riverine forests. Basin Mangroves: On the landward side of fringing mangroves in estuaries. Sheltered from wave action, and inundated infrequently. Highly variable salinity depending on rainfall, groundwater flow, and local tidal surges. Often exhibit high evaporation rates, which can result in hypersaline soils. Due to low currents and little turbulence, basin mangroves can be sinks for nutrients and sediment. Riverine Mangroves: Many large expanses of mangroves are located at river deltas where soils and salinity are amenable to mangrove community development (e.g., Amazon delta). Have low tidal ranges, and strong freshwater flow carrying substantial sediment loads, much of which is deposited within the mangrove communities. Characterized by shifting river channels, and typically mangal expanding inland as well as outward in the shifting, sediment-driven river deltas. Scrub Mangroves: Found in extreme environments where nutrients and freshwater may be limiting. Hammock Mangroves: Relative isolation from rivers or the sea leads to a domed accumulation of organic peat over depressions, where mangroves take root. Carbonate Setting Mangroves: On low-energy coasts where carbonate has accumulated from coral reef breakdown, resulting in lime sediment and silt accumulation. Inland Mangroves: Areas where the mangroves are completely cut-off from the sea, often in sink holes or other depressions.

Key Processes and Interactions: [de M004] Condicion: Los manglares presentan vivipary, o el crecimiento precoz de plántulas mientras permanecen pegadas al árbol madre. Cuando se desperenden, los propágulos son fuertes, flotantes, y fácilmente dispersados por el agua. La competencia entre los manglares y especies de árboles que nos son de manglar no es un factor clave en el manglar porque las condiciones hidrológicas y edáficas únicas de los ecosistemas de manglar hacen que sea difícil invadir para otras especies. Los lodos de turba típicos de los manglares tienen un alto contenido de limo y tienden a ser bastante inhóspitos para los invertebrados filtradores. Sin embargo, cangrejos especializados de los grupos sesarmid, portunuid, and ocupodid son extremadamente comunes.

Conectividad y Paisaje Contexto: Los manglares son naturalmente hábitats disyuntos que ocurren a lo largo de las costas y ríos. Ellos tienden a tener distrbutions lineales o de parche pequeño, y por lo tanto no suelen ocurrir como grandes hábitats de matriz. También se dispersan bien con propágulos transmitidas por el agua (a menudo vivíparos). Tienden, por tanto, a no ser tan sensibles a la fragmentación del hábitat como muchos otros hábitats forestales costeros, siempre y cuando los principales procesos ecológicos continúen intactos. Sin embargo, los manglares de franja en particular, pueden verse afectados por el aumento del nivel del mar, ya que su contexto paisajístico es extremadamente limitado y lineal. Estos tipos de sistemas de manglares estarán limitados por la geología y por la fragmentación humana, con la pérdida in-situ de los sistemas de franja restantes debido a los efectos fisiológicos de la subida del nivel del mar.

[from M004] Condition: Mangroves exhibit vivipary, or the precocious growth of seedlings while still attached to the parent tree. When abscised, the propagules are tough, buoyant, and readily water-dispersed. Competition between mangrove and non-mangrove tree species is rarely a key factor in mangal because the unique hydrologic and edaphic conditions of mangrove ecosystems make it difficult for non-mangrove species to invade. The peaty muds typical of mangroves have a very high silt content and tend to be fairly inhospitable to most suspension and filter-feeding invertebrates. However, mud-dwelling sesarmid, portunuid, and ocupodid crabs are extremely common.

Connectivity and Landscape Context: Mangroves are naturally disjunct habitats occurring along coastlines and rivers. They tend to have linear or small-patch distributions, and therefore do not generally occur as large matrix habitats. They also disperse well with waterborne propagules (often viviparous). They tend therefore not to be as sensitive to habitat fragmentation as many other coastal forest habitats, as long as major ecological processes are intact. However, fringing mangroves in particular may be affected by rising sea level, as their landscape context is extremely limited and linear. These types of mangrove systems will be limited by geology, and by human fragmentation, with *in situ* loss of the remaining fringing systems from physiological effects of rising sea levels.

Threats/Stressors: [de M004] Las principales amenazas incluyen la conversión para la acuicultura y el desarrollo del turismo costero. Durante la cosecha de madera de mangle para carbón, leña y forraje se producen impactos en la composición de las especies y la estabilidad del parche. La contaminación del agua y la alteración de la hidrología de fuentes interiores de agua dulce afecta la salinidad del agua y la hidrodinámica. La sobrepesca altera cadenas tróficas acuáticas en los manglares. El cambio climático y la degradación de los arrecifes adyacentes pueden exponer a los manglares a la onda destructiva y lavado por tierra derivada de la subida del nivel del mar y las tormentas extremas.

[from M004] Key threats include conversion for aquaculture and coastal tourism development. Over harvest for mangrove wood for charcoal, fuelwood, and fodder impacts species composition and patch stability. Water pollution and alteration to hydrology from inland freshwater sources affects water salinity and hydrodynamics. Overfishing alters aquatic foodwebs in mangroves. Climate change and adjacent reef degradation can expose mangroves to destructive wave and overland wash stemming from sea level rise and extreme storm events.

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

M005. Western Atlantic & Caribbean Mangrove

CES402.578 Caribbean Maritime Shore/Estuarine Mangrove

CES402.578 CLASSIFICATION

Concept Summary: Es un sistema de zonas mareales que en la costa atlántica sufre fluctuaciones muy bajas ya que la amplitud mareal es menor a 1 m. Según su ubicación puede estar permanentemente inundado o soportar dos inundaciones diarias, este gradiente del nivel de inundación del suelo y de salinidad influye en las características estructurales y de composición de la vegetación. Forman franjas estrechas a lo largo de la costa. La siguiente lista de las especies es de diagnóstica para este sistema: *Rhizophora mangle, Avicennia germinans, Laguncularia racemosa, Conocarpus erectus, Morella cerifera (= Myrica cerifera), Raphia taedigera, Acoelorraphe wrightii*.

CES402.578 CONCEPTUAL MODEL

Environment: Los manglares ocurren en una planicie fluvial marina con sedimentos aluviales. Los suelos son inceptisoles higromórficos arcillosos. Se trata de un sistema en el ecotono entre los sistemas continentales y marinos y por tanto las especies se distribuyen de acuerdo a sus adpataciones, en un gradiente del nivel de inundación del suelo y de salinidad.

Key Processes and Interactions: Disturbance in mangrove forests may be caused by large-scale events such as hurricanes, frost damage or clearcutting, but also by small-scale events such as lightning, causing mangrove trees to die in small areas around lightning strikes, or attack by wood-boring beetles. The relative importance of these different types of disturbance varies with geography, with some localities more often subjected to the impact of hurricanes or lightning. Mangroves are considered pioneer species because of their ability to establish on otherwise unvegetated substrates. Once individuals begin to colonize a disturbed area, even-aged stands are established with little variation in the structure because new development of successive colonizers is arrested by the closed canopy. On shorter time scales, the pulses of the tides and freshwater runoff are very important factors in the dynamics of mangroves because these control the rates of sedimentation and vertical accretion and thus determine their intertidal position.

Threats/Stressors: Key threats include conversion for aquaculture and coastal tourism development. Over-harvest of mangrove wood for charcoal, fuelwood, and fodder impacts species composition and patch stability. Water pollution and alteration to hydrology from inland freshwater sources affect water salinity and hydrodynamics. Overfishing alters aquatic foodwebs in mangroves. Climate change and adjacent reef degradation can expose mangroves to destructive wave and overland wash stemming from sea-level rise and extreme storm events.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct conversion. However, alterations to hydrodynamics in areas supporting mangroves can directly affect reproductive success in mangrove trees and other characteristic biota. *Environmental Degradation:* Hydrologic regime alterations, either those effecting broader patterns of coastal circulation, or more locally with freshwater inputs from inland sources, directly influence salinity, aeration, and sedimentation rates, in turn altering food webs and reproductive success of mangrove species. *Severity:* Where inland and coastal margins of mangrove locations are converted to intensive land uses, measurable departure in expected sedimentation rates, salinity, and water oxygen levels.

CES411.289 South Florida Mangrove Swamp

CES411.289 CLASSIFICATION

Concept Summary: This swamp ecological system of southern Florida occurs along intertidal and supratidal shorelines. The primary species comprising this system are *Rhizophora mangle, Avicennia germinans, Laguncularia racemosa*, and *Conocarpus erectus*, each with essentially tropical affinities and poor survival in cold temperatures. This system attains best development in low wave-energy, depositional environments. Examples occur on soils generally saturated with brackish water at all times and which become inundated during high tides. The brackish environment tends to limit competition from other species. At least three broad variants of this system can be recognized: riverine mangrove forests, fringe mangrove forests, and basin mangrove forests; all are included here.

Related Concepts:

- Mangrove: 106 (Eyre 1980) **<**

Distribution: This system is best developed in southern Florida, extending north to approximately 29°N latitude on both coasts.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans

CES411.289 CONCEPTUAL MODEL

Environment: Mangroves are essentially tropical species that occur only infrequently in areas where the average annual temperature is below 19°C; fluctuations greater than 10°C and short-duration freezes are detrimental to all species. Low-temperature stress leads to decreased height, leaf area, and increased tree density (Odum and McIvor 1990). *Avicennia* is apparently the most cold hardy species, extending as far north as the Gulf Coast (Sherrod and McMillan 1985) and on the Atlantic Coast nearly to the Florida stateline (30°N latitude) (Savage 1972, Odum et al. 1982). *Rhizophora* and *Laguncularia* reach approximately 29°N latitude on both coasts of Florida (Rehm 1976, Teas 1977, Odum et al. 1982). However, the northern limits of all species fluctuate due to short-term climatic swings making exact delineations impossible. Mangroves are also affected by substrate type and wave energy, with best development in low wave-energy, depositional environments; high wave energy prevents establishment and may destroy their shallow root systems (Odum and McIvor 1990). Examples occur on soils generally saturated with brackish water at all times, and which become inundated during high tides (FNAI 2010a). The species sometimes sort along salinity gradients, with *Rhizophora* limited to salinities below 60-65 ppt, while *Avicennia* and *Laguncularia* tolerate levels above 80-95 ppt [see references in Odum and McIvor (1990)]. The species employ different strategies to cope with fluctuations and extremes in salinity. Red mangroves exclude salt by a reverse osmosis process, while black and white mangroves use salt glands to excrete excess salts. However, most species may use combined strategies of salt exclusion and excretion (Albert 1975).

M007. Longleaf Pine Woodland

CES203.254 Atlantic Coastal Plain Fall-line Sandhills Longleaf Pine Woodland

CES203.254 CLASSIFICATION

Concept Summary: This system occurs in the Fall-line Sandhills region of central North Carolina south and west into central Georgia. It is the predominant system in its range, covering most of the natural landscape of the region. It occurs on upland sites ranging from gently rolling, broad ridgetops to steeper sideslopes, as well as locally in mesic swales and terraces. Most soils are well-drained to excessively-drained. The vegetation is naturally dominated by *Pinus palustris*. Most associations have an understory of scrub oaks (*Quercus laevis, Quercus marilandica, Quercus incana*, and *Quercus margarettae*). The herb layer is generally well-developed and dominated by grasses. Wiregrasses (*Aristida stricta* in the north, *Aristida beyrichiana* in the south) dominate in most of the range, but other grasses dominate where these are absent. Forbs, including many legumes and composites, are also abundant. Frequent, low-intensity fire is the dominant natural ecological force.

- Southern Scrub Oak: 72 (Eyre 1980) **<**
- Xeric Sandhill Scrub (Schafale and Weakley 1990) **<**

Distribution: This system ranges from central North Carolina to central Georgia, in the Fall-line Sandhills region (Ecoregion 65c of EPA (2004); 232Bq of Keys et al. (1995)).

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, C. Nordman

CES203.254 CONCEPTUAL MODEL

Environment: This system occurs on upland sites in the Fall-line Sandhills region (Ecoregion 65c of EPA (2004); 232Bq of Keys et al. (1995)). It covers the gently rolling, ancient eolian sands and the steeper side slopes in older formations that make up most of the dissected landscape in this region. Shallow swales, drier stream terraces, and rock outcrops also may support this system. Substrates include interbedded sands and clays, deep sands, and occasional loamy sediments. Soils are generally well- to excessively drained and infertile, though local richer, mesic sites occur. All soil types are underlain by a thick clay layer that impedes drainage and creates innumerable headwater creeks; the depth from the surface to this clay layer is very variable. Non-wetland conditions and frequent fire unify this system within the Fall-line Sandhills region. Soil texture appears to be the most important driver of differences among associations within the system, with biogeography also important.

Key Processes and Interactions: Frequent fire is the predominant natural disturbance in this system. Component communities naturally burned every few years, many averaging as often as every 3 years. Fires are naturally low to moderate in intensity. They burn above-ground parts of herbs and shrubs, but have little effect on the fire-tolerant *Pinus palustris* trees. Vegetation recovers very quickly from fires, with live herbaceous biomass often restored in just a few weeks during the growing season. Many plants have their flowering triggered by burning. Fire is important in creating the structure of the vegetation. In the absence of fire, less fire-tolerant species increase and others invade the system. The scrub oaks and shrubs, kept to low density and mostly reduced to shrub size, become tall and dense and can suppress *Pinus palustris* tree regeneration. Herb layer density and diversity decline. Only on the most excessively drained coarse sands does the vegetation not undergo substantial structural alteration and reduction in species richness after just a few years without burning. The often patchy nature of natural fires (and controlled burns) results in part from the abundance of streamheads that lace the Sandhills region and which tend to restrict fires from sweeping across large acreages.

Canopies are believed to naturally be multi-aged, consisting of a fine mosaic of small even-aged groves driven by gap-phase regeneration. *Pinus palustris* is shade-intolerant and slow to reach reproductive age, but is very long-lived. Most plants in these systems appear to be conservative, living a long time and only rarely sexually reproducing or colonizing new sites. Similar conservatism is shown by some of the vertebrates, such as red-cockaded woodpecker (*Picoides borealis)*. Different dynamics occur in many insect populations, whose individuals are not resilient to fire and must recolonize burned areas from nearby unburned patches.

Threats/Stressors: Lack of fire is a big threat for all *Pinus palustris* ecosystems, even on conservation lands. The development of a closed forest canopy and lack of fire can lead to declines, and eventual loss, of the native herbaceous ground cover vegetation. For unprotected examples, the greatest threat is destruction by commercial and residential development, conversion to intensively managed pine plantation, and other land uses. Logging without deliberate conversion (such as high grading) is also a serious threat, because it can destroy the natural vegetation structure, and because *Pinus palustris* often fails to regenerate at all if not carefully managed, for instance by retaining enough *Pinus palustris* seed trees, and using prescribed fire to prepare the seed bed for *Pinus palustris* regeneration. The collecting of snakes by putting gasoline or kerosene in gopher tortoise burrows is a real threat, as it pollutes the tortoise burrow which is habitat for many species. Fragmentation of habitat by roads and commercial or residential development is also a serious threat, because the ability to manage remaining *Pinus palustris* sites with fire is limited in urban interface areas and near roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Invasive exotic species are threats, including *Imperata cylindrica* (Brewer 2008), *Lespedeza bicolor* or *Lespedeza cuneata*, and feral pigs (*Sus scrofa)*, which root up *Pinus palustris* seedlings (Wahlenberg 1946) and herbaceous plants with thick roots. *Pinus palustris* woodlands have declined due to conversion to intensively managed pine plantations.

Ecosystem Collapse Thresholds: In the absence of deliberate conversion to other land uses, ecological collapse tends to result from long-term lack of fire, cutting of *Pinus palustris* without managing for its regeneration on the site, or invasion of exotic plants such as *Imperata cylindrica, Lespedeza bicolor*, or *Lespedeza cuneata*. Ecological collapse is characterized by the loss of the appropriate native herbaceous ground cover or by loss of the *Pinus palustris* canopy. Degraded examples may have a canopy dominated by trees other than *Pinus palustris*. *Pinus taeda, Pinus clausa* or *Pinus elliottii*, or hardwoods may be dominant, with few *Pinus palustris* remaining, or the site may be treeless. Specifications for degraded examples include: *Pinus palustris* basal area <10 ft2/acre or hardwood (not including *Quercus laevis*) plus *Pinus taeda* or *Pinus clausa* basal area >70 ft2/acre, a stand with both tall and dense midstory, shrubs average >75% cover and average >2.1 m tall. The cover of invasive exotic plant species >10%, lichen or moss cover >5%. Native warm-season grasses such as *Andropogon ternarius, Aristida beyrichiana, Aristida stricta, Schizachyrium scoparium, Schizachyrium tenerum*, or *Sporobolus junceus* have <5% cover, site may be an old field or where intensive forestry site preparation was used in the past. There may be a significant amount of weedy plants, especially on more open sites. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus palustris* trees is >10 cm (>4") deep. None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus palustris* tree crowns, or snags (NatureServe 2011).

CES203.281 Atlantic Coastal Plain Upland Longleaf Pine Woodland

CES203.281 CLASSIFICATION

Concept Summary: This system of upland *Pinus palustris*-dominated vegetation is found in the Atlantic Coastal Plain of the United States, where it ranges from southern Virginia (where it is nearly extirpated and of very limited extent) to northeastern Florida. This system does not include *Pinus palustris* stands found in the Fall-line Sandhills, which are accommodated by another ecological system. Examples and associations share the common feature of upland (non-wetland) moisture regimes and natural exposure to frequent fire. They occur on a variety of well- to excessively drained soils, and on the higher parts of upland-wetland mosaics. The vegetation is naturally dominated by *Pinus palustris*. Most associations have an understory of scrub oaks. The herb layer is generally well-developed and dominated by grasses, with legumes and composites. *Aristida stricta* primarily dominates in the northern part of its range, and *Aristida beyrichiana* in the southern part. Frequent, low-intensity fire is the dominant natural ecological force.

Description Author: R. Evans, M. Pyne and C. Nordman

CES203.281 CONCEPTUAL MODEL

Environment: This system occurs on upland sites of the Middle to Outer Atlantic Coastal Plain, on landforms that include loamy to sandy flats, relict beach system deposits, eolian sand deposits, Carolina bay rims (Bennett and Nelson 1991), and occasional low rolling hills. Soils range from mesic to xeric and from sandy to loamy or occasionally clayey. Most natural remnants are on coarse sands, but most examples probably once occurred on loamy soils but have subsequently been converted to agricultural uses since the time of European settlement. Soils are largely acidic and infertile, and the coarsest sands are excessively drained and sterile. The unifying feature of this system is non-wetland sites that naturally supported frequent fire. As such, it once covered much of the landscape of the Coastal Plain. Variations in soil texture and drainage appear to be a primary driver of differences between associations within the system, with biogeography also important as there is considerable floristic turnover along a northeast-to-southwest gradient paralleling the coast. In addition, soil texture varies dramatically along this gradient with finer-textured soils predominating north of the Neuse River (in North Carolina), and again south of the Great Pee Dee River and north of the Savanna River (in South Carolina).

Key Processes and Interactions: Frequent fire is the predominant natural disturbance in this ecological system, except on the most excessively drained coarse sands, where the sparse ground cover vegetation limits low intensity fire. Component communities naturally burned every few years, many averaging as often as every 3 years. Fires are naturally low to moderate in intensity. They burn above-ground parts of herbs and shrubs but have little effect on the fire-tolerant trees. Vegetation recovers very quickly from fire, with live herbaceous biomass often restored in just a few weeks. Many plants have their flowering triggered by burning. In the absence of fire, less fire-tolerant species increase and others invade the system. The scrub oaks and shrubs, kept to low density and mostly reduced to shrub size by fire, become tall and dense and can suppress *Pinus palustris* regeneration as well as dramatically reducing the herbaceous layer. Only on the most excessively drained coarse sands does the vegetation not undergo substantial structural alteration and reduction in species richness after just a few years without burning.

Canopies are believed to naturally be multi-aged, consisting of a fine mosaic of small even-aged patches driven by gap-phase regeneration. *Pinus palustris* is shade-intolerant and slow to reach reproductive age but is very long-lived.

Threats/Stressors: Reduced fire frequency is a major threat for all *Pinus palustris* ecosystems, even those on conserved lands. The development of a closed forest canopy and lack of fire can lead to declines, and eventual loss, of the native herbaceous ground cover vegetation. For unprotected examples, the greatest threat is destruction by commercial and residential development, and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Logging without deliberate conversion (such as high grading) is also a serious threat, because it can destroy the natural vegetation structure, and because *Pinus palustris* often fails to regenerate at all if not carefully managed, for instance by retaining enough *Pinus palustris* seed trees, and using prescribed fire to prepare the seed bed for *Pinus palustris* regeneration. Invasive exotic plant species are generally not major threats, with certain exceptions. Invasive exotic species threats include *Imperata cylindrica* (Brewer 2008), *Lespedeza bicolor, Lespedeza cuneata, Lonicera japonica*, or *Triadica sebifera* and feral pigs (*Sus scrofa*), which root up *Pinus palustris* seedlings (Wahlenberg 1946) and in the process numerous herbaceous plant species with thick roots. *Pinus palustris* woodlands have also declined due to conversion to intensively managed pine plantations.
Ecosystem Collapse Thresholds: Ecological collapse tends to result from long-term lack of fire, cutting of *Pinus palustris* without managing for its regeneration on the site, or invasion of exotic plants such as *Imperata cylindrica, Lespedeza bicolor, Lespedeza cuneata, Lonicera japonica*, and *Triadica sebifera*. Ecological collapse is characterized by the loss of the appropriate native herbaceous ground cover or by loss of the *Pinus palustris* canopy. Degraded examples may have a canopy dominated by trees other than *Pinus palustris*. *Pinus taeda, Pinus clausa*, or *Pinus elliottii*, or hardwoods may be dominant, with few *Pinus palustris* remaining, or the site may be treeless. Specifications for degraded communities include: *Pinus palustris* basal area <10 ft2/acre or hardwood (not including *Quercus laevis*) plus *Pinus taeda* or *Pinus clausa* basal area >70 ft2/acre, a stand with both tall and dense midstory, shrubs average >75% cover and average >2.1 m tall, cover of invasive exotic plant species >10%, lichen or moss cover >5%. Native warm-season grasses such as *Andropogon ternarius, Aristida beyrichiana, Aristida stricta, Schizachyrium scoparium, Schizachyrium tenerum*, or *Sporobolus junceus* have <5% cover, site may be an old field or where intensive forestry site preparation was used in the past. There may be a significant amount of weedy plants, especially on more open sites. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus palustris* trees is >10 cm (>4") deep. None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus palustris* tree crowns, or snags (NatureServe 2011).

CES203.265 Central Atlantic Coastal Plain Wet Longleaf Pine Savanna and Flatwoods

CES203.265 CLASSIFICATION

Concept Summary: This ecological system of wet *Pinus palustris*-dominated savannas and flatwoods ranges from southern Virginia to central South Carolina. It was once one of the most extensive systems in the coastward part of its range. Examples and associations share the common features of wet, seasonally saturated, mineral soils and exposure to frequent fire. They occur on a wide range of soil textures, which is an important factor in distinguishing different associations. The vegetation is naturally dominated by *Pinus palustris* or, less frequently, *Pinus serotina*. There is a dense ground cover of herbs and low shrubs; grasses dominate but there is often a large diversity of other herbs. Frequent, low-intensity fire is the dominant natural ecological force.

Related Concepts:

- Longleaf Pine: 70 (Eyre 1980) **<**
- Pond Pine: 98 (Eyre 1980) **<**

Distribution: This system ranges from southern Virginia to central South Carolina. To the south, the equivalent system is ~Southern Atlantic Coastal Plain Wet Pine Savanna and Flatwoods (CES203.536)$$, the range of which includes Georgia and northern Florida.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, C. Nordman

CES203.265 CONCEPTUAL MODEL

Environment: This system occurs on wet mineral soil sites, primarily in the Middle and Outer Coastal Plain but occasionally in the Fall-line Sandhills. Landforms include low areas in relict beach ridge systems and eolian sand deposits, and poorly drained clayey, loamy, or sandy flats. They occasionally occur on river terraces above current flood levels. Soils range from clayey to sandy, with no accumulated organic surface layer. Soils are seasonally saturated, due to high water table or poor soil drainage. The unifying feature of this system is wet mineral soils associated with a high frequency of fire. Variation in soil texture appears to be a primary driver of differences between associations within the system, with biogeography also important.

Key Processes and Interactions: Frequent fire is the predominant natural disturbance in this system. Communities naturally burned every few years, many averaging as often as every 3 years. Fires are naturally low to moderate in intensity. They burn above-ground parts of herbs and shrubs but have little effect on the fire-tolerant trees. Vegetation recovers very quickly from fire, with live herbaceous biomass often restored in just a few weeks during the growing season. Many plants have their flowering triggered by burning, the effects on subsequent establishment are not well-documented. In the absence of fire, the shrubs increase and hardwoods may invade the system. Herb layer density and diversity decline after a number of years without fire. In time, unburned examples may become nearly indistinguishable from the drier associations of ~Atlantic Coastal Plain Peatland Pocosin and Canebrake (CES203.267)$$.

Canopies are believed to naturally be multi-aged, consisting of a mosaic of even-aged patches driven by gap-phase regeneration. *Pinus palustris* is shade-intolerant and slow to reach reproductive age but is very long-lived, and healthy trees continue to produce more cones as they age beyond 100 years.

Threats/Stressors: Lack of fire is a big threat for all *Pinus palustris* ecosystems. Threats also include the loss of habitat from commercial and residential development, and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Invasive exotic species are threats, including *Imperata cylindrica* (Brewer 2008), *Lespedeza bicolor, Lespedeza cuneata, Lonicera japonica*, and feral pigs (*Sus scrofa*), which root up *Pinus palustris* seedlings (Wahlenberg 1946) and herbaceous plants with thick roots. *Pinus palustris* woodlands have declined due to conversion to intensively managed pine plantations. Today, conversion for development is greater than conversion to intensively managed pine plantations.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from long-term lack of fire, cutting of *Pinus palustris* without managing for its regeneration on the site, or invasion of exotic plants such as *Imperata cylindrica* (Brewer 2008), *Lespedeza bicolor, Lespedeza cuneata, Lonicera japonica*, or *Triadica sebifera*. Minor drainage for pine forestry often is combined with bedding the soil into rows to facilitate planting and rapid growth of *Pinus taeda* or *Pinus elliottii var. elliottii*. These forestry practices contribute to ecological collapse. Ecological collapse is characterized by canopy dominated by trees other than *Pinus palustris*. *Pinus taeda* or *Pinus elliottii var. elliottii*, or hardwoods may be dominant, with few *Pinus palustris* remaining, but site is suitable for *Pinus palustris*. *Pinus palustris* basal area is <10 ft2/acre or hardwood plus *Pinus taeda* or *Pinus elliottii var. elliottii* basal area >60 ft2/acre. It is a stand with both tall and dense midstory, shrubs average >75% cover and average >2.1 m tall. The cover of invasive exotic plant species is >10%. Native warm-season grasses such as *Andropogon ternarius, Aristida beyrichiana, Aristida stricta, Schizachyrium scoparium, Schizachyrium tenerum*, or *Sporobolus junceus* have <=5% cover, site may be an old field or where intensive forestry site preparation was used in the past. There may be a significant amount of weedy plants, especially on more open sites. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus palustris* trees is >10 cm (>4 inches). None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus palustris* tree crowns, or snags (NatureServe 2011).

CES203.382 Central Florida Pine Flatwoods

CES203.382 CLASSIFICATION

Concept Summary: This system is endemic to Florida, ranging from Levy and St. Johns counties in the north (ca. 30°N latitude) southward to Hillsborough, Osceola and Polk counties. It was once an extensive system within its historic range. As currently conceived, this system includes both "scrubby flatwoods" that occur on well-drained soils and typical flatwoods that occur on more poorly drained soils. The vegetation is naturally dominated by either *Pinus palustris* or *Pinus elliottii var. elliottii*, and less frequently includes *Pinus serotina*. Examples vary in aspect from well-developed understory layers or scrub species to more herbaceous, savanna-like conditions. There is a dense ground cover of low shrubs, grasses, and herbs. Frequent, low-intensity fire is the dominant natural ecological force.

Related Concepts:

- Longleaf Pine - Slash Pine: 83 (Eyre 1980) **<**
- Longleaf Pine: 70 (Eyre 1980) **<**
- Pond Pine: 98 (Eyre 1980) **<**
- Slash Pine: 84 (Eyre 1980) **<**

Distribution: Endemic to Florida, ranging in the north from Levy and St. Johns counties southward to Hillsborough and Polk counties. It was once an extensive ecological system within its historic range (Stout and Marion 1993).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and C. Nordman

CES203.382 CONCEPTUAL MODEL

Environment: As currently conceived, this system includes both "scrubby flatwoods" that occur on well-drained soils and typical mesic and wet flatwoods that occur on more poorly drained soils. Wetter pine flatwoods sites with an herbaceous ground cover are included, these are sometimes called wet pine savannas.

Key Processes and Interactions: Fire is naturally frequent, with a fire-return time of from one to four years. Disturbances are an important part of the natural functions of this system. In order for these habitats to burn frequently there needs to be enough fine fuel, such as needles from *Pinus palustris* trees, healthy populations of native warm-season grasses, and evergreen shrubs with volatile oils in their leaves, such as *Ilex glabra, Lyonia* spp., *Morella cerifera, Quercus geminata, Quercus minima, Serenoa repens*, and *Vaccinium* spp. The frequent fires promote flowering, seed production, and seed germination of many plants and provide open areas in patches (Van Lear et al. 2005).

Threats/Stressors: Lack of fire and drainage or alteration of the natural hydrology are big threats for all *Pinus palustris* ecosystems. Threats also include the loss of habitat from commercial and residential development, and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Invasive exotic species are threats, including *Imperata cylindrica* (Brewer 2008), *Lespedeza bicolor*, and feral pigs (*Sus scrofa*), which root up *Pinus palustris* seedlings (Wahlenberg 1946) and herbaceous plants with thick roots. *Pinus palustris* woodlands have declined due to conversion to intensively managed pine plantations.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from long-term lack of fire, cutting of *Pinus palustris* or *Pinus elliottii var. densa* without managing for its regeneration on the site, or invasion of exotic plants such as *Imperata cylindrica* or *Lespedeza bicolor*. Minor drainage for pine forestry often is combined with bedding the soil into rows to facilitate machine planting and rapid growth of *Pinus elliottii var. elliottii*. These forestry practices contribute to ecological collapse. Ecological collapse is characterized by canopy dominated by trees other than *Pinus palustris* or *Pinus elliottii var. densa*. Hardwood trees and tall shrubs are dominant, with few *Pinus palustris* or *Pinus elliottii var. densa* remaining, but the site is suitable for *Pinus palustris* or *Pinus elliottii var. densa*. *Pinus palustris* basal area <10 ft2/acre or hardwood basal area >60 ft2/acre. None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus palustris* or *Pinus elliottii var. densa* tree crowns, or snags. It is a stand with both tall and dense midstory. Shrubs average >75% cover and average >2.1 m tall. Cover of invasive exotic plant species >10%. *Aristida beyrichiana, Schizachyrium scoparium var. stoloniferum, Sorghastrum secundum*, or *Andropogon ternarius* ?5% cover, site may be an old field or where intensive forestry site preparation was used in the past. There may be a significant amount of weedy plants, especially on more open sites. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus palustris* or *Pinus elliottii var. densa* trees is >10 cm (>4") deep. (NatureServe 2011).

CES203.496 East Gulf Coastal Plain Interior Upland Longleaf Pine Woodland

CES203.496 CLASSIFICATION

Concept Summary: This ecological system represents *Pinus palustris* forests of rolling, dissected to relatively flat uplands of the East Gulf Coastal Plain. These stands occur primarily in the Southeastern Plains (EPA Ecoregion 65). It is found inland of the Gulf Coast Flatwoods (EPA Ecoregion 75a) and extends landward into the Upper East Gulf Coastal Plain Ecoregion by about 80 km (50 miles). It potentially occupies a much larger geographic area than the related *Pinus palustris* woodlands of the outer coastal area. The characteristic species is *Pinus palustris*, although many stands may support only relictual individuals following a long history of exploitation, harvest, and stand conversion, primarily to agriculture or to planted stands of *Pinus elliottii var. elliottii* or *Pinus taeda*. This system includes stands with a range of soil and moisture conditions. Mesic stands on medium- to fine-textured soils are more typical of the system, although limited xeric areas on deep sands are also present. In natural condition, fire is believed to have been frequent enough to limit development of fire-intolerant hardwood species as well as *Pinus taeda* and *Pinus echinata*. Although such species may be present or even common in the most mesic stands, they generally do not share dominance in the overstory unless fire has been absent from the stand.

Related Concepts:

- Longleaf Pine - Scrub Oak: 71 (Eyre 1980) **<**
- Longleaf Pine: 70 (Eyre 1980) **<**

Distribution: This system formerly occupied an extensive range across the southern parts of Alabama, northern Panhandle of Florida (north of the Cody Scarp), southern Mississippi, and southwestern Georgia and was also present in limited areas of Louisiana. It has been greatly reduced in its extent, with much of its range now occupied by agriculture or by planted stands of *Pinus taeda*. In southwestern Mississippi, this system is apparently absent (or very rare and limited) west of 91°W longitude to the limits of the alluvial plain and northwest of a line running approximately from the intersection of 31°N latitude and 91°W longitude, northeastward to the city of Jackson, Mississippi. This is consistent with the ranges of "Oak-Pine" vegetation versus "Longleaf-Loblolly-Slash Pines" (generally equivalent to this system) in Shantz and Zon (1924). In southwest Georgia, this ecological system occurs in Coastal Plain areas which drain to the Gulf of Mexico.

Nations: US

Concept Source: R. Evans, A. Schotz, M. Pyne

Description Author: R. Evans, A. Schotz, M. Pyne, C. Nordman

CES203.496 CONCEPTUAL MODEL

Environment: This system once occupied extensive areas of the East Gulf Coastal Plain from the northern range limits of *Pinus palustris* southward to the inland terminus of the Coastal Flatlands (sensu Peet and Allard (1993); Ecoregion 75a (EPA 2004)). In its natural condition, this system occupied a range of upland soils from clays and loams to deep sands, including weathered and older Ultisols. Due to locally distinctive understory, shrub and herbaceous vegetation associated with differing soil textures, "sandhills" and "loamhills" are generally recognizable as distinctive components of this system. However, they are generally interspersed to such an extent that differentiating them as separate systems is not practical. The topography of this system is generally more rolling than ~East Gulf Coastal Plain Near-Coast Pine Flatwoods (CES203.375)$$ to the south. The largest and best examples occupy landscapes where prescribed fire is an active management practice. Localized soil characteristics will determine the specific composition of the lower strata. Ultisols are the dominant soil order and cover most of the range of the system. Ultisols most commonly associated with *Pinus palustris* are the Typic Paleudults and Plinthic Paleudults. More limited areas are occupied by Psamments and other coarser-textured materials. *Pinus palustris* grows in warm, wet temperate climates characterized by hot summers and mild winters. The annual mean temperatures range from 16-23°C (60-74°F), and the annual precipitation ranges from 1090 to 1750 mm (43-69 inches) (Boyer 1990). Fall is the driest season of the year, although periods of drought during the growing season are not unusual (Boyer 1990).

Key Processes and Interactions: Frequent fire was the predominant natural disturbance in this system, which is now dependent on management with prescribed fire. Component communities naturally burned every few years, many averaging as often as every 3 years. Fires are naturally low to moderate in intensity. They burn above-ground parts of herbs and shrubs but have little effect on the fire-tolerant trees. Vegetation recovers very quickly from fire; the perennial species resprout quickly. Many herbaceous plants have their flowering triggered by burning. Frequent fires help maintain more species richness at small sample scales, compared to pinelands of the other regions (Carr et al. 2010). In the absence of fire, hardwoods increase. *Quercus* spp. and shrubs, kept to low density and mostly reduced to shrub size by fire, become tall and dense and can suppress *Pinus palustris* regeneration. Herb layer density and diversity decline without occasional fire. Frequent fire requires a mix of fine fuels composed both of herbaceous (primarily grasses) fine fuels and *Pinus palustris* leaf litter. Consequently, thinning the *Pinus palustris* canopy to low basal area or opening too large gaps, particularly in absence of *Aristida beyrichiana*, can lead to rapid hardwood encroachment due to lack of abundant and continuous fuels necessary for frequent fire (K. Kirkman pers. comm.). Only on the most excessively drained coarse sands does the vegetation not undergo substantial structural alteration and reduction in species richness after a number of years without burning. This is due to the infertile soils. This structural alteration occurs more slowly on these infertile soils, but due to the slow accumulation of fuels, lack of fire can become more pronounced.

Canopies are believed to naturally be multi-aged, consisting of a fine mosaic of small even-aged groves driven by gap-phase regeneration. *Pinus palustris* is shade-intolerant and slow to reach reproductive age but is very long-lived. *Pinus palustris* seedlings can survive under a gap opening in canopy >35%. However, they will not move out of grass stage unless the gap fraction is >60%. Because these canopy gaps have less needle fall, the frequent fires which burn there are less intense, which permits *Pinus palustris* seedlings to survive. *Pinus palustris* can also stay in the sapling stage for decades and still take advantage of a gap opening to move into the canopy (Kirkman and Mitchell 2006).

Threats/Stressors: Lack of fire is a big threat for all *Pinus palustris* ecosystems. Threats also include the loss of habitat from commercial and residential development, and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Invasive exotic species are threats, including *Imperata cylindrica* (Brewer 2008), *Lespedeza bicolor, Lespedeza cuneata, Ligustrum sinense, Lonicera japonica, Lygodium japonicum*, and feral pigs (*Sus scrofa*), which root up *Pinus palustris* seedlings (Wahlenberg 1946) and herbaceous plants with thick roots. *Pinus palustris* woodlands have declined due to conversion to intensively managed pine plantations. The collecting of snakes by putting gasoline or kerosene in gopher tortoise burrows is a real threat, as it pollutes the tortoise burrow which is habitat for many species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from long-term lack of fire, cutting of *Pinus palustris* without managing for its regeneration on the site, or invasion of exotic plants such as *Imperata cylindrica, Lespedeza bicolor, Lespedeza cuneata, Ligustrum sinense, Lonicera japonica*, or *Lygodium japonicum*. Ecological collapse is characterized by canopy dominated by trees other than *Pinus palustris*. *Pinus taeda, Pinus clausa* or *Pinus elliottii var. elliottii*, or hardwoods are dominant, with few *Pinus palustris* remaining, but site is suitable for *Pinus palustris*. *Pinus palustris* basal area is <10 ft2/acre or hardwood (not including *Quercus laevis*) plus *Pinus taeda, Pinus elliottii var. elliottii* or *Pinus clausa* basal area >70 ft2/acre. None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus palustris* tree crowns, or snags. It is a stand with both tall and dense midstory, shrubs average >75% cover and average >2.1 m tall. The cover of invasive exotic plant species is >10%, lichen or moss cover is >5%. Native warm-season grasses such as *Andropogon ternarius, Aristida beyrichiana, Schizachyrium scoparium, Schizachyrium tenerum*, or *Sporobolus junceus* have <5% cover, the site may be a recent old field or where intensive forestry site preparation was used in the past. There may be a significant amount of weedy plants, especially on more open sites. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus palustris* trees is >10 cm (>4") deep (NatureServe 2011).

CES203.375 East Gulf Coastal Plain Near-Coast Pine Flatwoods

CES203.375 CLASSIFICATION

Concept Summary: This ecological system of open forests or woodlands occupies broad, sandy flatlands in a relatively narrow band along the northern Gulf of Mexico coast east of the Mississippi River. This range corresponds roughly to the Gulf Coast Flatwoods (EPA Ecoregion 75a). These areas predominantly occur on poorly drained acidic Spodosol soils, which are subject to seasonal inundation as well as droughty conditions. Often called "flatwoods" or "flatlands," they are subject to short fire-return intervals and seasonally high water tables. Overstory vegetation is characterized by *Pinus palustris* and, to a lesser degree, by *Pinus elliottii var. elliottii*. Understory structure ranges from densely shrubby to open and herbaceous-dominated, with variation in soils and drainage. The variation includes Scrubby Flatwoods, Mesic Flatwoods, Wet Flatwoods, and Maritime Flatwoods. Fire is naturally frequent; many sites have a fire-return time of from one to four years.

Related Concepts:

- Longleaf Pine - Slash Pine: 83 (Eyre 1980) **<**
- Longleaf Pine: 70 (Eyre 1980) **<**
- Pond Pine: 98 (Eyre 1980) **<**
- Pondcypress: 100 (Eyre 1980) **<**
- Slash Pine: 84 (Eyre 1980) **<**

Distribution: This system is conceived of as including wet and dry pine flatwoods of the near-coastal zone of the East Gulf Coastal Plain, mainly south of the Cody Scarp (Peet and Allard 1993). It corresponds roughly to the Gulf Coast Flatwoods, Ecoregion 75a (EPA 2004).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and C. Nordman

CES203.375 CONCEPTUAL MODEL

Environment: This system occupies broad, sandy flatlands which are subject to short fire-return intervals even though they are subject to seasonally high water tables. Spodosols encourage seasonal saturation, acidity, and high soil iron and aluminum concentrations. These areas are often called "flatwoods" or "flatlands."

Key Processes and Interactions: Fire is naturally frequent, with a fire-return time of from one to four years. Disturbances are an important part of the natural functions of wet pine savanna and flatwoods. In order for these habitats to burn frequently (every 2-3 years), there needs to be enough fine fuel, such as needles from *Pinus palustris* trees, healthy populations of native warm-season grasses, and evergreen shrubs with volatile oils in their leaves, such as *Gaylussacia frondosa, Ilex coriacea, Ilex glabra, Lyonia* spp., *Serenoa repens*, and *Vaccinium* spp. The frequent fires promote flowering, seed production, and seed germination of many plants and provide open areas in patches (Van Lear et al. 2005).

Threats/Stressors: Lack of fire and hydrological alteration are big threats for these *Pinus palustris* ecosystems. Ditches and bedding can alter the hydrology of sites, but also when the midstory becomes dominated by shrubs due to lack of fire, increased transpiration reduces water availability to the herbaceous ground cover plants. Threats also include the loss of habitat from commercial and residential development, and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Invasive exotic species are threats, including *Imperata cylindrica* (Brewer 2008), *Lespedeza bicolor* or *Lespedeza cuneata, Lonicera japonica*, and feral pigs (*Sus scrofa*), which root up *Pinus palustris* seedlings (Wahlenberg 1946) and herbaceous plants with thick roots. *Pinus palustris* woodlands have declined due to conversion to intensively managed pine plantations, usually of *Pinus elliottii var. elliottii*.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from long-term lack of fire, cutting of *Pinus palustris* without managing for its regeneration on the site, or invasion of exotic plants such as *Imperata cylindrica, Lespedeza bicolor, Lespedeza cuneata*, or *Lonicera japonica*. Minor drainage for pine forestry often is combined with bedding the soil into rows to facilitate planting and rapid growth of *Pinus elliottii var. elliottii*. These forestry practices contribute to ecological collapse. Ecological collapse is characterized by canopy dominated by trees other than *Pinus palustris*. *Pinus taeda* or *Pinus elliottii var. elliottii*, or hardwoods are dominant, with few *Pinus palustris* remaining, but site is suitable for *Pinus palustris*. *Pinus palustris* basal area is <10 ft2/acre or hardwood plus *Pinus taeda* or *Pinus elliottii var. elliottii* basal area >60 ft2/acre. None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus palustris* tree crowns, or snags. It is a stand with both tall and dense midstory. The shrubs average >75% cover and average >2.1 m tall. The cover of invasive exotic plant species is >10%. Native warm-season grasses such as *Aristida beyrichiana, Schizachyrium scoparium, Schizachyrium tenerum*, or *Andropogon ternarius* have <5% cover, the site may be an old field or where intensive forestry site preparation was used in the past. There may be a significant amount of weedy plants, especially on more open sites. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus palustris* trees is >10 cm (>4") deep (NatureServe 2011).

CES203.284 Florida Longleaf Pine Sandhill

CES203.284 CLASSIFICATION

Concept Summary: This system represents stands of *Pinus palustris* on excessively well-drained, sandy soils in the Outer Coastal Plain and adjacent Inner Coastal Plain of Florida. This includes the "high pine islands" of central Florida, as well as vegetation of extensive areas of sand in the Florida Panhandle, north of the Cody Scarp, including at Eglin Air Force Base (with greater than 100,000 hectares of this ecological system). In central Florida on the Ocala National Forest, these stands are found in relation with sand pine scrub vegetation. This system is represented by larger patches of *Pinus palustris* sandhills, generally ranging from 60 to 4000 hectares in size and larger. In addition to the largest extent at Eglin Air Force Base, examples also occur on the Ocala National Forest, the southern end of the Lake Wales Ridge, the Brooksville Ridge, and in other parts of the Florida Peninsula. Fire is absolutely essential to maintain this system, without which it may be almost completely replaced by scrub vegetation, hardwood trees, *Pinus taeda*, or other non-*Pinus palustris*-dominated vegetation.

Related Concepts:
- Longleaf Pine: 70 (Eyre 1980) **<**

Distribution: This ecological system is found in the Outer Coastal Plain and adjacent Inner Coastal Plain of Florida, including the central Florida Peninsula (Ocala National Forest, Brooksville Ridge, southern end of the Lake Wales Ridge) (Abrahamson et al. 1984) and the Florida Panhandle, mainly north of the Cody Scarp (e.g., Eglin Air Force Base).

Nations: US

Concept Source: R. Evans and C. Nordman

Description Author: R. Evans, C. Nordman, M. Pyne

CES203.284 CONCEPTUAL MODEL

Environment: Surface soils tend to be coarse, with <5% composition of finer-textured particles (silt and clay), and very low organic content and low moisture-holding capacity. Soils are typically Entisols (Psamments), with very limited profile development. In the Florida Panhandle soils can be Ultisols. Some soil series associated with this system include the Astatula series (Kalisz 1982), as well as the Lakeland, Tavares, and Orsino series (Abrahamson et al. 1984). Candler is the most extensive soil on sandhills on the ridges of Central Florida (S. Carr pers. comm.) In some cases on the Ocala National Forest the soils may be unusually dark in color at the surface, which has been attributed, in part, to the presence of charcoal. Soils are strongly acidic (pH 4.7-5.0). Some Central Florida sites have silt or clay in the subsoil contributing to significantly higher extractable bases at the surface when compared to nearby scrub sites (Kalisz 1982). Excluded are areas with a "shallow sand cap" (K. Outcault pers. comm.). On Eglin Air Force Base in the western Florida Panhandle, this ecological system occurs on deep sands on the Citronelle Formation. Psamments are the dominant soil suborder in the areas of Florida where this system is found (NRCS n.d.).

Key Processes and Interactions: Fire is absolutely essential to maintain this system, without which it may be almost completely replaced by scrub vegetation (in the Florida Peninsula), hardwood trees, *Pinus clausa, Pinus taeda*, or other non-*Pinus palustris*-dominated vegetation.

Threats/Stressors: Lack of fire is a big threat for all *Pinus palustris* ecosystems. Threats also include the loss of habitat from commercial and residential development (especially on the highlands of central Florida), and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Invasive exotic species are threats, including the plants *Imperata cylindrica* (Brewer 2008), *Lantana camara, Lespedeza bicolor, Lespedeza cuneata, Melinis repens*, and *Urena lobata* and animals such as feral pigs (*Sus scrofa*), which root up *Pinus palustris* seedlings (Wahlenberg 1946) and herbaceous plants with thick roots. *Pinus palustris* woodlands have declined due to conversion to intensively managed pine plantations, citrus and other agricultural cropland, and improved pasture. In the absence of fire, stands will be replaced by scrub vegetation or other non-*Pinus palustris*-dominated vegetation.

Ecosystem Collapse Thresholds: This system is represented by larger patches of *Pinus palustris* Sandhills, ranging from 60 to 4000 hectares in size and larger. Ecological collapse tends to result from long-term lack of fire, cutting of *Pinus palustris* without managing for its regeneration on the site, or invasion of exotic plants such as *Imperata cylindrica* (Brewer 2008), *Lantana camara, Lespedeza bicolor, Lespedeza cuneata, Melinis repens*, and *Urena lobata*. Ecological collapse is characterized by canopy dominated by trees other than *Pinus palustris*. *Pinus taeda, Pinus clausa*, or *Pinus elliottii var. elliottii*, or hardwoods are dominant, with few *Pinus palustris* remaining, but site is suitable for *Pinus palustris*. *Pinus palustris* basal area is <10 ft2/acre or hardwood (not including *Quercus laevis*) plus *Pinus taeda* or *Pinus clausa* basal area >70 ft2/acre. None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus palustris* tree crowns, or snags. The stand has both tall and dense midstory, shrubs average >75% cover and average >2.1 m tall. The cover of invasive exotic plant species is >10%, lichen or moss cover is >5%. Native sandhill grasses such as *Andropogon floridanus, Andropogon ternarius, Aristida beyrichiana, Schizachyrium scoparium var. stoloniferum, Schizachyrium tenerum, Sorghastrum secundum*, and *Sporobolus junceus* are <5% cover, site may be an old field or where intensive forestry site preparation was used in the past. There may be a significant amount of weedy plants, especially on more open sites. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus palustris* trees is >10 cm (>4") deep (NatureServe 2011).

CES411.381 South Florida Pine Flatwoods

CES411.381 CLASSIFICATION

Concept Summary: This system is endemic to Florida, ranging from Lee, Desoto, Highlands, and Okeechobee counties southward. It was once an extensive system within its historic range. The vegetation is naturally dominated by *Pinus elliottii var. densa*, being largely outside the natural range of *Pinus serotina, Pinus elliottii var. elliottii*, and *Pinus palustris*. In natural condition, examples are generally open with a variety of low shrub and grass species forming a dense ground cover. Frequent, low-intensity fire was the dominant natural ecological force, but most areas have undergone long periods without fire, resulting in greater dominance of shrubs and saw palmetto, as well as denser canopies of slash pine.

Related Concepts:

- Pine Forest (Duever et al. 1986) **<**

Distribution: This system is found in southern Florida, extending north to mid-peninsula (e.g., Lee, Desoto, Highlands, and Okeechobee counties).

Nations: US

Concept Source: R. Evans and C. Nordman

Description Author: R. Evans and C. Nordman

CES411.381 CONCEPTUAL MODEL

Environment: This system occurs on sandy soils, including Spodosols, which are prone to some saturation or short periods of flooding after summer rains. These flatwoods occur in areas which have some creeks, which provide some natural firebreaks. Similar areas which are very extensive without creeks tend to be ~Florida Dry Prairie (CES203.380), which naturally burns more frequently.

Key Processes and Interactions: Frequent, low-intensity fire was the dominant natural ecological force, but most areas have undergone long periods without fire, resulting in greater dominance of shrubs and saw palmetto, as well as denser canopies of slash pine (Huffman and Judd 1998, Noel et al. 1998). Disturbances are an important part of the natural functions of pine flatwoods. In order for these habitats to burn frequently (every 2-3 years), there needs to be enough fine fuel, such as needles from *Pinus elliottii var. densa* or *Pinus palustris* trees, healthy populations of native warm-season grasses, and evergreen shrubs with volatile oils in their leaves, such as *Gaylussacia frondosa, Hypericum tenuifolium, Ilex glabra, Lyonia ferruginea, Lyonia fruticosa, Serenoa repens*, and *Vaccinium myrsinites*. The frequent fires promote flowering, seed production, and seed germination of many plants and provide open areas in patches (Van Lear et al. 2005).

Threats/Stressors: Lack of fire is a big threat for all *Pinus elliottii var. densa* or *Pinus palustris* ecosystems. Threats also include the loss of habitat from commercial and residential development, and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Invasive exotic species are threats, including *Imperata cylindrica* (Brewer 2008) or *Melinis repens* and feral pigs (*Sus scrofa)*, which root up *Pinus palustris* seedlings (Wahlenberg 1946) and herbaceous plants with thick roots *Pinus elliottii var. densa* or *Pinus palustris* woodlands have declined due to conversion to intensively managed pine plantations.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from long-term lack of fire, cutting of *Pinus elliottii var. densa* or *Pinus palustris* without managing for its regeneration on the site, or invasion of exotic plants such as *Imperata cylindrica* or *Melinis repens*. Minor drainage for pine forestry often is combined with bedding the soil into rows to facilitate planting and rapid growth of *Pinus elliottii var. elliottii*. These forestry practices contribute to ecological collapse. Ecological collapse is characterized by canopy dominated by trees other than *Pinus elliottii var. densa* or *Pinus palustris*. *Pinus taeda* or *Pinus elliottii var. elliottii*, or hardwoods are dominant, with few *Pinus elliottii var. densa* or *Pinus palustris* remaining, but site is suitable for *Pinus elliottii var. densa* or *Pinus palustris*. *Pinus elliottii var. densa* or *Pinus palustris* basal area <10 ft2/acre or hardwood plus *Pinus taeda* or *Pinus elliottii var. elliottii* basal area >60 ft2/acre. None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus elliottii var. densa* or *Pinus palustris* tree crowns, or snags. It is a stand with both tall and dense midstory. Shrubs average >75% cover and average >2.1 m tall. Cover of invasive exotic plant species >10%. *Andropogon ternarius, Aristida beyrichiana, Schizachyrium scoparium, Schizachyrium tenerum*, and *Sporobolus junceus* ?5% cover, site may be an old field or where intensive forestry site preparation was used in the past. There may be a significant amount of weedy plants, especially on more open sites. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus elliottii var. densa* or *Pinus palustris* trees is >10 cm (>4") deep. (NatureServe 2011).

CES411.367 South Florida Pine Rockland

CES411.367 CLASSIFICATION

Concept Summary: This system includes pinelands of extreme south Florida growing on limestone. The uniqueness of the flora associated with this type has long been recognized, including the number of endemic and West Indian species. Many plant and animal taxa found in this system are restricted to it, including many of south Florida's endemic plants. Unlike pinelands elsewhere in the southeastern coastal plain, *Pinus elliottii var. densa* is the only native pine species in this system. Understory vegetation consists of many hardwood species, including a number with tropical origins, and the herbaceous flora is species-rich and fire-adapted.

Related Concepts:
- Pine Forest (Duever et al. 1986) **>**
- South Florida Slash Pine: 111 (Eyre 1980) **?**

Distribution: Davis (1943) mapped this system, which occurred primarily on the Miami ridge bordering the Everglades, with disjunct examples found in the Big Cypress Swamp. Davis estimated there once was 180,000 acres of "Miami region pine" (Davis 1943). McPherson's (1986) map of Big Cypress shows "pine forest," which includes both pine rocklands and pine flatwoods, scattered across the unit. It may be possible to differentiate based on soil type or geology, the pine rockland being in the southeast part of Big Cypress. In the Florida Keys it is found on Big Pine Key, No Name Key, Little Pine Key, Cudjoe Key, and Upper Sugarloaf Key. The Miami Rockridge extends from around downtown Miami southwest to Long Pine Key in Everglades National Park (Miami-Dade County). Big Pine Key is in Monroe County, and the Big Cypress National Preserve is in Monroe and Collier counties. In addition, pine rockland historically occurred in the upper Florida Keys; pine stumps and remnant species characteristic of pine rockland have been found in one area of Key Largo (Alexander 1953). There has been an estimated 98% decline in the amount of pine rockland habitat on the Miami Rock Ridge in southern Florida, outside of the Everglades National Park where Long Pine Key is protected (Noss et al. 1995, Enge et al. 2002). About 6200 ha (15,000 acres) of pine rockland remain (Enge et al. 2002).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and C. Nordman

CES411.367 CONCEPTUAL MODEL

Environment: Pine rockland occurs on relatively flat, moderately to well-drained terrain from 2-7 m above sea level (Snyder et al. 1990). Along the southeastern coast of Florida this system occurs on Miami Oolitic Limestone, while in the Big Cypress region (southwest Florida) it is found on outcrops of Tamiami Limestone. Outcrops of weathered oolitic limestone, known locally as pinnacle rock, are common, and solution holes may be present (FNAI 2010a). The oolitic limestone is at or very near the surface, and there is very little soil development. Soils are generally composed of small accumulations of nutrient-poor sand, marl, clayey loam, and organic debris in depressions and crevices in the rock surface. Organic acids occasionally dissolve the surface limestone causing

collapsed depressions in the surface rock called solution holes (Outcalt 1997b). Drainage varies according to the porosity of the limestone substrate, but is generally rapid. Consequently, most sites are wet for only short periods following heavy rains. During the rainy season, however, some sites may be shallowly inundated by slow-flowing surface water for up to 60 days each year.
Key Processes and Interactions: Historical accounts show that fire has been frequent over the past several hundred years, perhaps as often as every 1-4 years (Wade et al. 1980, Bergh and Wisby 1996, Slocum et al. 2003). Without fire, after 15-20 years, hardwoods will be numerous and quite large (Wade et al. 1980). In the absence of fire, this system may be replaced by hardwoods species within several decades (Stout and Marion 1993). High winds from hurricanes are an infrequent, natural disturbance. Pine rockland in the Florida Keys can be subjected to storm surge associated with hurricanes (Saha et al. 2011).
Threats/Stressors: Fragmentation is a threat, especially in the Miami area. Lack of fire is a threat, which allows the encroachment of hardwood trees. Invasive exotic plants are also a threat, such as *Melinis repens, Neyraudia reynaudiana*, and *Schinus terebinthifolius* (Landfire 2007a, FNAI 2010a). Habitat loss due to development pressure is a threat to remaining pine rockland on private lands, such as in the Florida Keys. Storm surge associated with hurricanes is a threat to pine rockland areas at less than 2 m elevation (Saha et al. 2011).
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from the lack of fire, failure of *Pinus elliottii var. densa* reproduction and recruitment, and the encroachment of hardwood trees. Ecosystem collapse is characterized by forests dominated by hardwood trees and/or exotic plants. Lack of fire can allow the succession of this system to ~South Florida Hardwood Hammock (CES411.287)$$.

CES203.536 Southern Atlantic Coastal Plain Wet Pine Savanna and Flatwoods

CES203.536 CLASSIFICATION

Concept Summary: This ecological system of pine-dominated savannas and/or flatwoods ranges from central South Carolina to northeastern Florida, centered near the coast in southeastern Georgia. It was the former matrix system in this region. This general area has been referred to as the Longleaf Pine Wiregrass Savannas region and the Sea Island Flatwoods Ecoregion (75f). Examples of this system and component community associations share the common features of wet, seasonally saturated, mineral soils and historic exposure to frequent low-intensity fire. They occur on a wide range of soil textures, which is an important factor in distinguishing different associations. The vegetation is naturally dominated by *Pinus palustris* or, on wetter sites, *Pinus elliottii* or less commonly *Pinus serotina*. Understory conditions may be dramatically altered by fire frequency and seasonality. In natural condition (with frequent fires, including some growing-season fire), there tends to be a dense ground cover of herbs and low shrubs; grasses can dominate, but there is often a large diversity of other herbs and shrubs.

Related Concepts:

- Longleaf Pine - Slash Pine: 83 (Eyre 1980) **<**
- Longleaf Pine: 70 (Eyre 1980) **<**
- Pond Pine: 98 (Eyre 1980) **<**
- Pondcypress: 100 (Eyre 1980) **<**
- Savannas (Christensen 2000) **<**
- Slash Pine: 84 (Eyre 1980) **<**

Distribution: This system is restricted to the Atlantic Coastal Plain from central South Carolina to northeastern Florida. This general area has been referred to as the Longleaf Pine Wiregrass Savannas region (Platt 1999) and the Sea Island Flatwoods (EPA Ecoregion 75f) (Griffith et al. 2001, 2002).

Nations: US

Concept Source: R. Evans and C. Nordman

Description Author: R. Evans and C. Nordman

CES203.536 CONCEPTUAL MODEL

Environment: This system occurs on wet mineral soil sites, in the middle and outer Coastal Plain. Landforms include low areas in relict beach ridge systems and eolian sand deposits, and poorly drained clayey, loamy, or sandy flats.

Key Processes and Interactions: Frequent low-intensity fire is important. Lightning has been an important source of ignition for these fires, especially historically. Disturbances are an important part of the natural functions of wet pine savanna and flatwoods. In order for these habitats to burn frequently (every 2-3 years), there needs to be enough fine fuel, such as needles from *Pinus palustris* trees, healthy populations of native warm-season grasses, and evergreen shrubs with volatile oils in their leaves, such as *Gaylussacia frondosa, Ilex coriacea, Ilex glabra, Lyonia* spp., *Serenoa repens*, and *Vaccinium* spp. The frequent fires promote flowering, seed production, and seed germination of many plants and provide open areas in patches (Van Lear et al. 2005).

In the past, wildland fires were started by lightning strikes and deliberately by people, including Native Americans prior to the 1700s. The wet pine savanna may have burned as frequently as every 2-3 years. Hurricane-force winds can knock down and break trees, including *Pinus palustris*, but in frequently burned savannas, weakened hardwood midstory trees could be especially prone to blowdown.

Threats/Stressors: Lack of fire is the primary threat to *Pinus palustris* ecosystems. Other threats include the loss of habitat from commercial and residential development, and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Invasive exotic species are threats, including *Imperata cylindrica* (Brewer 2008), *Lespedeza bicolor, Lespedeza cuneata, Lonicera japonica, Triadica sebifera*, and feral pigs (*Sus scrofa*), which root up herbaceous plants with thick roots as well as *Pinus palustris* seedings (Wahlenberg 1946). *Pinus palustris* woodlands have declined due to their conversion into intensively managed pine plantations.

Ecosystem Collapse Thresholds: Frequent fires promote flowering, seed production, and seed germination of many plants and provide open areas in patches (Van Lear et al. 2005). Fuels include native grasses and *Pinus palustris* needles.

Landscape Context: Historically these habitats were very common and covered large areas of the lower coastal plain. They occupied broad wet or seasonally wet flats and extended between streams across the flat landscape, where occasional ponds were found within the extensive areas of savanna and flatwoods. Today the habitat remains in isolated areas where it is deliberately managed with prescribed fire; these areas include private quail hunting plantations, public and private conservation lands, as well as other federal and state lands.

Size: Size is important for retaining populations of component species, many of which occur at low densities, as well as for natural disturbance dynamics. Fire needs a sizeable area to assume its characteristic behavior, even under the best management. Size interacts with fire behavior to determine the likelihood and abundance of unburned patches that serve as refugia for fire-sensitive insect species. Size is important for area-sensitive characteristic vertebrates. Excellent sites based on size are very large (>4000 ha [10,000 acres]) (NatureServe 2006).

Condition: In the absence of fire, the successional trend is toward forest with a mixed canopy of *Acer rubrum, Liquidambar styraciflua, Pinus elliottii var. elliottii, Pinus palustris*, and *Pinus taeda*. Shrubs such as *Acer rubrum, Cliftonia monophylla, Ilex coriacea, Ilex glabra*, and *Liquidambar styraciflua* grow tall and develop into a midstory which shades out and suppresses the herbaceous ground cover. The herbaceous ground cover can decline as shade reduces sunlight and woody plants compete with the herbaceous species.

Ecological collapse tends to result from long-term lack of fire, cutting of *Pinus palustris* without managing for its regeneration on the site, or invasion of exotic plants such as *Imperata cylindrica, Lespedeza bicolor, Lespedeza cuneata, Lonicera japonica*, or *Triadica sebifera*. Minor drainage for pine forestry often is combined with bedding the soil into rows to facilitate planting and rapid growth of *Pinus elliottii var. elliottii*. These forestry practices contribute to ecological collapse. Ecological collapse is characterized by canopy dominated by trees other than *Pinus palustris*. *Pinus taeda* or *Pinus elliottii var. elliottii*, or hardwoods are dominant, with few *Pinus palustris* remaining, but site is suitable for *Pinus palustris*. *Pinus palustris* basal area is <10 ft2/acre or hardwood plus *Pinus taeda* or *Pinus elliottii var. elliottii* basal area is >60 ft2/acre. None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus palustris* tree crowns, or snags. It is a stand with both tall and dense midstory, shrubs average >75% cover and average >2.1 m tall. Cover of invasive exotic plant species is >10%. Native warm-season grasses such as *Andropogon ternarius, Aristida beyrichiana, Schizachyrium scoparium, Schizachyrium tenerum*, and *Sporobolus junceus* have <5% cover, site may be an old field or where intensive forestry site preparation was used in the past. There may be a significant amount of weedy plants, especially on more open sites. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus palustris* trees is >10 cm (>4") deep (NatureServe 2011).

CES203.497 Southern Atlantic Coastal Plain Xeric River Dune

CES203.497 CLASSIFICATION

Concept Summary: This system encompasses a range of vegetation present on inland sand dunes of the Atlantic Coastal Plain of Georgia. These dunes are associated with certain rivers such as the Ohoopee and Canoochee and are apparently eolian in origin, formed of riverine alluvial sands. The sandy soils are deep, coarse, and xeric in nature. The vegetation consists of an assemblage of xeric communities that also occur in other xeric habitats in the Coastal Plain. These include *Pinus palustris - Quercus laevis* communities and a scrub community akin to Inland Florida Scrub, but lacking *Pinus clausa*. This system is distinguished from more typical xeric sandhills of the Coastal Plain by its occurrence on the deep sands of river dunes. Xeric river dunes have a similar fire-return interval to other upland systems of which *Pinus palustris* is a component, but the fuels are fires tend to be patchy, leaving some unburned areas.

Related Concepts:

- Longleaf Pine: 70 (Eyre 1980) **<**
- Southern Scrub Oak: 72 (Eyre 1980) **<**

Distribution: This system is endemic to river-associated dunes in the South Atlantic Coastal Plain of Georgia, such as along the Ohoopee and Canoochee rivers (Wharton 1978), as well as other watersheds. Reports of similar or related vegetation from North and South Carolina are being investigated.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, C.W. Nordman and M. Pyne

CES203.497 CONCEPTUAL MODEL

Environment: These dunes are apparently eolian in origin, formed of reworked riverine alluvial sands. The sandy soils are deep, coarse, and xeric in nature. These deep coarse sand dunes have formed from winds blowing exposed sand from the riverbars in the Pleistocene (Edwards et al. 2013). They occur on the east and northeast sides of rivers which flow southeast (Bozeman 1971) in south Georgia, such as the Altamaha, Ohoopee, Flint, Satilla and Canoochee (Edwards et al. 2013). The dune system is most developed along the east side of the Ohoopee River, which is 35 miles long and about 40,000 acres (Edwards et al. 2013).

Key Processes and Interactions: About half of the woody species are evergreen, but there is greater cover of deciduous shrubs, and there are more shrubs than herbs (Harper 1906). This contrasts with other *Pinus palustris* habitats, which tend to be grass-dominated with a high diversity of herbs. Both *Ceratiola ericoides* and *Chrysoma pauciflosculosa* are evergreen shrubs and are fire-sensitive. *Chrysoma pauciflosculosa* seeds are able to spread to newly available open sandy and unburned habitat in local areas where they occur, but *Ceratiola ericoides* seeds are heavy, landing mostly near the mother plant, are inhibited by allelopathy, and generally start germinating after death of mother shrub, in same vicinity (M. Hodges pers. comm.). These shrubs may persist with the sparse *Pinus palustris* due to their metapopulation dynamics; certain subpopulations may be lost to occasional wildland fires, but new subpopulations also form where seeds germinate. While *Ceratiola ericoides* will generally not persist if burned more frequently than every 20 years (Johnson 1982), in some Florida habitats, population models of *Ceratiola ericoides* on Georgia xeric river dune sandhills suggest that burns at least as frequently as every 10 years may be important for maintaining open habitat and promoting recruitment of new shrubs (Schmidt 2006). These river dune habitats are naturally topographically isolated by a river on one (west or southwest) side and typically are adjacent to pine flatwoods on the other (east or northeast) side. Consequently, they have been partially protected from large wildland fires and may have a similar or lower fire-return interval than typical dry *Pinus palustris* habitats. The accumulation of fuel in these xeric river dune habitats is slow and does not support the frequent continuous fires that can occur in *Pinus palustris* habitats which have higher nutrient availability. The natural fire-return interval may have varied from 5 to 10 years depending on the fertility of the site and accumulation of fuels (Edwards et al. 2013). Where xeric river dunes are connected to pine flatwoods, fires would have been more frequent, and fires were patchy, leaving many unburned patches (M. Hodges pers. comm.). Fuels include *Pinus palustris* needles and dead leaves of *Aristida purpurascens, Aristida beyrichiana, Quercus laevis, Triplasis americana*, and other plants. Small areas along the Altamaha River sand ridge have broadleaf evergreen tall-shrub and small-tree vegetation, called the Georgia River Dune Myrtle Oak Scrub NVC Association (Bozeman 1971). These areas apparently burn only rarely (perhaps at high intensity), if at all, and are somewhat similar to oak scrub found in Florida.

Threats/Stressors: Lack of fire is a big threat for all *Pinus palustris* ecosystems. Threats also include the loss of habitat to residential development, and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Invasive exotic species are threats, such as feral pigs (*Sus scrofa)*, which root up *Pinus palustris* seedlings (Wahlenberg 1946) and herbaceous plants with thick roots. Xeric river dune habitats have declined due to conversion to intensively managed *Pinus* spp. plantations or *Cynodon dactylon* pastures.

Logging of *Pinus palustris* is a threat. Areas where *Pinus palustris* has been logged in the past may now be more difficult to burn with prescribed fire due to the lack of *Pinus palustris* needles, which are a very important fine fuel, naturally replenished by seasonal and fire-related needle drop. These sites may become more dominated by *Quercus laevis*. *Quercus laevis* leaves do burn (mixed with grassy fine fuels), but more patchily than *Pinus palustris* needles (M. Hodges pers. comm.). Sites have been replanted with *Pinus taeda* and are then no longer burned for forest management. Off-road vehicles are detrimental to the habitat for burrowing animals and rare plants that occur in these habitats (Edwards et al. 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from cutting of this habitat's characteristic trees, including *Pinus palustris*, without managing for regeneration on the site, or invasion of exotic plants such as *Imperata cylindrica, Lespedeza bicolor, Lespedeza cuneata, Lonicera japonica, Lygodium japonicum*, and *Microstegium vimineum*. A long period without fire (30-50 years) would lead to ecological collapse due to dense *Quercus laevis* shading out low shrubs and herbaceous plants, and deep duff accumulation around *Pinus palustris* trees (M. Hodges pers. comm.). Ecological collapse is characterized by canopy dominated by *Pinus taeda* or other off-site trees, such as planted *Pinus clausa, Pinus elliottii var. elliottii*, or *Pinus taeda*. *Pinus taeda* or *Pinus clausa* basal area is >70 ft2/acre. None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus palustris* tree crowns, or snags. Cover of invasive exotic plant species is >10%. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus palustris* trees is >10 cm (>4") deep (NatureServe 2011). Some areas of this ecological system naturally have no *Pinus palustris* and are dominated by native evergreen shrubs and small trees. The criteria for ecological collapse pertaining to *Pinus palustris* do not apply to those habitats. However, even where *Pinus palustris* is present, sites that have become dominated by *Quercus laevis* may be difficult to return to a more open condition with an herbaceous layer dominated by *Aristida beyrichiana* because large-diameter *Quercus laevis* trees are very fire-resistant. In such cases, mechanical removal may be required to create high-quality habitat for the gopher tortoise.

CES203.891 West Gulf Coastal Plain Stream Terrace Sandyland Longleaf Pine Woodland

CES203.891 CLASSIFICATION

Concept Summary: These sandhills are dry longleaf pine-dominated woodlands or savannas found on excessively drained, xeric soils of alluvial origin in the West Gulf Coastal Plain (South Central Plains of EPA) of Texas and formerly Louisiana. They occur on areas of deep sand (ranging in texture from coarse to fine) which are present in quaternary alluvial deposits. The general habitat is on low terraces adjacent to stream floodplains, and adjacent communities may include baygalls and ponds. Precipitation rapidly dissipates via percolation due to the character of the soil. Soils include fine sands, such as fluvial terraces of Bienville-Alaga soils developed in the Deweyville Formation, and the Tonkawa fine sand, as well as other coarse sands. *Pinus palustris* historically dominated the vegetation of this region across nearly all uplands regardless of soil type or moisture. The importance of frequent fire has been well-documented for the perpetuation of this and related systems throughout the coastal plains. Stands are dominated by *Pinus palustris*, which often occurs in mixed stands with *Quercus incana, Pinus echinata*, and *Carya texana*. Some small isolated terraces (inclusions) may be dominated by oaks and hickories, with little or no *Pinus palustris*. The oaks generally become denser with fire exclusion, particularly on the small isolated areas. Mesophytic oak species are absent or extremely rare. This type, and other longleaf communities and systems of the West Gulf Coastal Plain, lie outside the range of *Aristida beyrichiana* (wiregrass). Other grasses (*Andropogon* spp., other *Aristida* spp., and *Schizachyrium* spp.) dominate understories which are rich in species diversity.

Related Concepts:

- Upland Pine Forest (Marks and Harcombe 1981) **?**
- Xeric stream terrace sand ridge subtype (of Upland Longleaf Pine Savanna) (Bridges and Orzell 1989a) **=**

Distribution: This upland ecological system occurs mainly in the Southern Loam Hills Subsection (232Fa) of Texas and formerly Louisiana, apparently ranging south into the Southwest Flatwoods Subsection (232Fb) (Hardin County, Texas). West Gulf Coastal Plain longleaf sandhills are distinctive from those in the East Gulf Coastal Plain because they occur beyond the limits of where wiregrass and sand post oak are dominant.

Nations: US

Concept Source: M. Pyne, after I. McWhorter, W. Ledbetter et al.

Description Author: M. Pyne and J. Teague

CES203.891 CONCEPTUAL MODEL

Environment: This system is relatively xeric vegetation, even though it occurs on terraces adjacent to, or within, floodplains. This is because the soils are deep and well-drained sands (often alluvial deposits), with low moisture retention and high permeability. This system usually occurs in deep, well-drained sandy soils on stream terraces, occurring above medium-sized perennial creeks that are typically clear and have sandy bottoms. These sites have very fine sands on ridgetops or slightly higher rises in the sandhill terraces. The flat areas with broad sandhills are slightly coarser and hold a little more water. A site for this system can have both fine and coarse sands. The landscape profile starts out with some bottomland hardwoods type with braided bald-cypress - tupelo, then a slight slope with a wide baygall edge against the sandhill. Sometimes there is a small ribbon of American beech slope forest just above the baygall, then going into the upland sandhill; sometimes it is just a baygall to sandhill transition (J. Singhurst pers. comm.). It represents a distinctive subset of longleaf pine-dominated vegetation in the inner (landward) portions of the West Gulf Coastal Plain in eastern Texas (and Louisiana).

Key Processes and Interactions: The importance of frequent fire has been widely-accepted for the perpetuation of *Pinus palustris* systems (Stambaugh et al. 2011a), but fires may actually be less frequent, more patchy and discontinuous than in other related longleaf pine-dominated systems. The oaks generally become denser with fire exclusion, particularly in small, isolated examples. Lichens (e.g., *Cladonia* spp.) and *Selaginella arenicola ssp. riddellii* also occur along with patches of bare sand. Canopy trees are patchy in distribution, with regeneration in canopy gaps of a quarter acre or less in size, mid-successional clumps in similar sized patches, and the oldest trees occurring as isolated individuals. The reference condition classes are aggregates of numerous patches well-dispersed over the landscape. Canopy gaps are created by fire mortality, pest outbreaks, lightning, and windthrow at the scale of individual trees or several trees. Because of the irregular seed production of longleaf pine, canopy gaps may lack regeneration for several years. Uncharacteristic vegetation types include even-aged canopy stands in which age structure has been homogenized by logging or clearing. Examples include where *Pinus taeda* or *Pinus elliottii* have replaced some or all of the longleaf pine, where midstory oaks and/or low shrubs have become dense due to fire suppression, and where the grass-dominated ground cover has been lost due to soil disturbance or canopy closure.

Threats/Stressors: A primary threat to this ecological system is alteration of the natural fire regime. With longer fire-return intervals, this system can become invaded by fire-sensitive woody species common in the nearby forest systems. An increase in cover of off-site woody species can suppress the regeneration and growth of species typical of this system in its natural state. Threats also include the loss of habitat from commercial and residential development, and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. *Pinus palustris* woodlands have also declined due to conversion to intensively managed pine plantations. Longleaf pine forests were among the most valuable economic resources in the region at the turn of the twentieth century (Bray 1906). Overall losses of longleaf pine in Texas have exceeded those of all other southern states (Outcalt 1997); less than 16,200 hectares of mostly second-growth stands remain (McWilliams and Lord 1988). Land-use practices continue to degrade remaining examples of longleaf pine communities (Bridges and Orzell 1989a).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from long-term alteration of the natural fire regime, logging, conversion to forest plantations, and other land-use conversion. Collapse of the ecological system is characterized by habitat loss and fragmentation and a conversion to uncharacteristic vegetation types. These include even-aged canopy stands in which age structure has been homogenized by logging or clearing, stands where *Pinus taeda* or *Pinus elliottii* have replaced some or all of the *Pinus palustris*, where midstory oaks and/or low shrubs have become dense due to fire suppression, and where the grass-dominated ground cover has been lost due to soil disturbance or canopy closure. *Ilex vomitoria* and *Quercus incana* are native species that, although present at low levels historically, have now become a significant part of the midstory, and may require a combination of intensive management, which includes chemical and mechanical treatments, to increase the effectiveness of fire to restore the historical conditions of the sandhill sites. Collapse is also characterized by the absence of the many animal and plant species of conservation concern that inhabit this system (Van Lear et al. 2005).

CES203.293 West Gulf Coastal Plain Upland Longleaf Pine Forest and Woodland

CES203.293 CLASSIFICATION

Concept Summary: The common and unifying feature of this system is vegetation naturally dominated by *Pinus palustris*. This was formerly the most extensive system within its natural range in western Louisiana and eastern Texas. In most of the region, longleaf pine is (presently) a distinctive, but rarely dominant, element of existing vegetation. However, this tree historically dominated the vegetation across nearly all uplands regardless of soil type or moisture (excluding wetlands), and longleaf pine forests were among the most valuable economic resources in the region at the turn of the century. Typical sites include sandhills on well-drained to excessively drained soils, but the type is also found on loamy and clayey upland soils. The importance of frequent fire has been well documented for the perpetuation of this system. This type lies outside the ranges of *Aristida stricta* and *Aristida beyrichiana*, unlike comparable systems east of the Mississippi River, but most stands at least formerly supported open grass-dominated understories rich in species diversity.

Distribution: The natural range of this system is in the coastal plains of western Louisiana and eastern Texas. Its boundary follows TNC Ecoregion 41 (West Gulf Coastal Plain) closely in western Louisiana, but extends slightly into Ecoregion 40 (Upper West Gulf Coastal Plain) in eastern Texas.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, M. Pyne, L. Elliott and J. Teague

CES203.293 CONCEPTUAL MODEL

Environment: This system represents the presumed matrix vegetation type of the inner (landward) portions of the West Gulf Coastal Plain in Louisiana and eastern Texas within the range of *Pinus palustris*. In Louisiana, these are mapped as the Upper Terrace and some smaller landward units (Snead and McCulloh 1984). The system is bounded on the outer (seaward) side by ~West Gulf Coastal Plain Wet Longleaf Pine Savanna and Flatwoods (CES203.191)$$ and on the inner (landward) side primarily by ~West Gulf Coastal Plain Pine-Hardwood Forest (CES203.378)$$ and other hardwood or hardwood-pine systems. Stands are found on sedimentary Pleistocene formations (particularly the Bentley Formation), to formations of the Tertiary period (particularly the Catahoula and Wilcox formations). Historically, this system was more widely distributed on older, more inland formations of the Eocene and Paleocene epochs. They occupy topography ranging from rolling uplands, to hills and ridges such as those associated with the Kisatchie Wold (or Kisatchie Cuesta) and the Sabine Uplift, and are usually associated with coarse-textured, well-drained Ultisols and

Alfisols, including loams, sandy loams, loamy sands, and sands, though occurrences may also be found to a lesser extent on tighter soils such as clay loams (Elliott 2011). It is characteristically dissected by small to large streams.

Key Processes and Interactions: Frequent fire was the predominant natural disturbance in this system, which is now dependent on management with prescribed fire. The importance of frequent surface fire (every 1-5 years) has been widely accepted for the perpetuation of this system (Stambaugh et al. 2011a and others). Fires are usually low in intensity overall, consuming only shrubs and herbs, but will occasionally kill patches of young pine regeneration and rarely kill individual older trees. Historically, individual fires covered extensive areas. This high fire frequency is dependent on the presence of fine fuels in the form of grasses and pine leaf litter. This ecological system is also affected by hurricane and tornado occurrences every 200 +/- years. In mature stands, competition between pine and hardwood trees is also a factor in maintaining species composition.

Threats/Stressors: This ecological system is much reduced form its original extent. Today, only 10 to 25% of this system remains in Louisiana (Smith 1993). The primary historic threat was conversion to other forest types or agriculture including forest plantations (LDWF 2005). A primary threat to current occurrences of this ecological system is alteration of the natural fire regime. With longer fire-return intervals, this system quickly becomes invaded by fire-sensitive woody species common in the nearby forest systems. An increase in cover of off-site woody species can suppress the regeneration and growth of species typical of this system in its natural state. Threats also include the loss of habitat from commercial and residential development, and fragmentation of habitat by roads. These threats limit prescribed burning due to urban interface, safety and smoke management concerns. *Pinus palustris* woodlands have also declined due to conversion to intensively managed pine plantations. Longleaf pine forests were among the most valuable economic resources in the region at the turn of the twentieth century (Bray 1906). Overall losses of longleaf pine in Texas have exceeded those of all other southern states (Outcalt 1997); less than 16,200 hectares of mostly second-growth stands remain (McWilliams and Lord 1988). Land use practices continue to degrade remaining examples of longleaf pine communities (Bridges and Orzell 1989a).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from long-term lack of fire and conversion of the ecological system to other land uses, e.g., forest plantations, and commercial, residential, and infrastructure development. Ecological collapse is characterized by canopy dominated by trees other than *Pinus palustris*, a tall and dense woody midstory, a dense shrub layer, absence of native ground flora, especially those that provide fine fuel to carry frequent fires, and presence of deep duff and litter. None of these old growth characteristics are present: medium sized canopy gaps, flat-topped *Pinus palustris* tree crowns, or snags. Collapse is also characterized by the absence of the many animal and plant species of conservation concern that inhabit this system (Van Lear et al. 2005).

CES203.191 West Gulf Coastal Plain Wet Longleaf Pine Savanna and Flatwoods

CES203.191 CLASSIFICATION

Concept Summary: This system was the historical matrix vegetation of the outer (seaward) portions of the West Gulf Coastal Plain between the coastal prairies and the inner coastal plain in Louisiana and eastern Texas within the range of longleaf pine. These areas are characterized by poorly drained upland soils with high and highly fluctuating water tables. In natural condition, monospecific stands of *Pinus palustris* and species-rich herbaceous layers characterize this system. Other species in the canopy include *Quercus stellata, Quercus marilandica, Nyssa sylvatica, Quercus laurifolia, Quercus falcata*, and *Liquidambar styraciflua*. Shrubs are typically limited in distribution within the system to local topographic highs and include species such as *Morella cerifera, Ilex vomitoria, Symplocos tinctoria, Cyrilla racemiflora*, and others. Widespread alterations following European settlement, including changes to natural fire regimes, have produced drastic changes to this system, and few large examples are extant. Examples appear to be somewhat more common in western Louisiana than in eastern Texas.

Distribution: This system is endemic to western Louisiana and eastern Texas, and examples appear to be somewhat more common in western Louisiana.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne, L. Elliott and J. Teague

CES203.191 CONCEPTUAL MODEL

Environment: This system represents the presumed matrix vegetation on relatively recent (Pleistocene) geologic formations within the range of longleaf pine in the outer (seaward) portions of the West Gulf Coastal Plain between the coastal prairies and the inner coastal plain in Louisiana and eastern Texas. In Louisiana, these are mapped as the Intermediate Terrace and the upper Prairie Terrace (Snead and McCulloh 1984), and in Texas as the Lissie Formation and the upper Beaumont Formation (Sellards et al. 1932). The Intermediate Terrace of Snead and McCulloh (1984) includes terraces formerly designated as the Montgomery, Irene, and most of the Bentley. These areas are characterized by poorly drained upland soils with high water tables (Bridges and Orzell 1989a). Landforms include mesic to seasonally saturated low areas and flats, on level to gently rolling uplands. Microtopographic variation is provided by the presence of swales and pimple mounds. Soils are sandy to silty loams that are strongly acidic, nutrient poor, and low in organic constituents. Typically these soils are hydric, with seasonal fluctuations between saturation and droughtiness (Elliott 2011). Within the range of longleaf pine, this system is bounded on the landward side by ~West Gulf Coastal Plain Upland Longleaf Pine Forest and Woodland (CES203.293)$$.

Key Processes and Interactions: Frequent fires (every 1-4 years), seasonal wetness and low nutrient availability of this ecological system inhibit the establishment of woody understory species and maintain a sparse canopy of longleaf pine (Stambaugh et al. 2011a and others). This frequent fire regime is necessary to maintain the open savanna condition and provides bare ground for *Pinus palustris* regeneration. Current examples must be managed with prescribed fire. Fires are usually low in intensity overall, consuming only shrubs and herbs, but will occasionally kill patches of young pine regeneration and rarely kill individual older trees. Historically, individual fires covered extensive areas. This high fire frequency is dependent on the presence of fine fuels in the form of grasses and other graminoids. Prescribed fire has been used as an attempt to reverse the effects of decades of fire suppression. However, the results of these attempts have been mixed. Uncertainty remains over the frequency of burning necessary to restore fire-dependent ecosystems; however, a return frequency of every 2-5 years appears best. Application of burns is often too infrequent, allowing woody understory species to crowd out longleaf or, in hardwood forests, oaks, beeches and other dominant

trees. Similarly, burns are ineffective if applied at the wrong life stage of plants or at the wrong point in the growing season. An example: late-spring to early-summer burns favor longleaf and associated herbaceous plants, whereas late-season or winter burns favor woody shrubs. However, prescribed burns, properly applied, are a crucial restoration and management tool in the pyrogenic longleaf pine ecosystems. Canopy gaps are created by fire mortality, lightning, and windthrow from hurricanes and tornados.
Threats/Stressors: This ecological system is much reduced form its original extent. Today, only 1 to 5% of this system remains in Louisiana (Smith 1993). Current examples of this ecological system are primarily threatened by drainage, other forms of physical damage form logging, and conversion to residential and commercial development and pine plantations (LDWF 2005). Longleaf pine forests were among the most valuable economic resources in the region at the turn of the twentieth century (Bray 1906). Overall losses of longleaf pine in Texas have exceeded those of all other southern states (Outcalt 1997); less than 16,200 hectares of mostly second-growth stands remain (McWilliams and Lord 1988). Land use practices continue to degrade remaining examples of longleaf pine communities (Bridges and Orzell 1989a).

Another primary threat is alteration of the natural fire regime. Longer fire-return intervals (10 years) will lead to significant woody encroachment of shrubs and fire-sensitive trees. This condition can also lead to increased fuel loading that will put the larger, more established trees at risk due to hotter, less frequent fires. An increase in cover of off-site woody species can suppress the regeneration and growth of species typical of this system in its natural state. Threats also include the limiting of prescribed burning due to urban interface, safety and smoke management concerns.

The proliferation of both invasive native and exotic vegetation is a negative impact on this ecosystem. Some native plants can be problematic in the absence of natural processes like fire. For example, *Ilex vomitoria* can crowd out other natives and become a dominant understory plant in some fire-suppressed areas. Most invasives are extremely difficult and costly to control once established. Other invasives already well-established include *Triadica sebifera, Sus scrofa* and non-native fire ants *Solenopsis invicta*.

If changes in regional climate bring about a decrease in precipitation, this could lead to drying and loss of this system.
Ecosystem Collapse Thresholds: Ecological collapse tends to result from habitat loss and fragmentation and conversion of the ecological system to other land uses such as forest plantations and residential and commercial development. In addition long-term alteration of the natural fire regime results in a shift in species composition and vegetation structure. These include even-aged canopy stands in which age structure has been homogenized by logging or clearing, stands where *Pinus taeda* or *Pinus elliottii* have replaced some or all of the *Pinus palustris*, where midstory oaks and/or low shrubs have become dense due to fire suppression, and where the graminoid-dominated ground cover has been lost due to soil disturbance or canopy closure. Collapse is also characterized by the absence of the many animal and plant species of conservation concern that inhabit this system (Van Lear et al. 2005).

M885. Southeastern Coastal Plain Evergreen Oak - Mixed Hardwood Forest

CES203.464 Central and South Texas Coastal Fringe Forest and Woodland

CES203.464 CLASSIFICATION

Concept Summary: This ecological system includes oak-dominated forests woodlands, shrublands and savannas occurring on deep sands of the Pleistocene-aged Ingleside barrier-strandplain of the central Texas coast and the Holocene-aged eolian sand deposits of the South Texas Sand Sheet. Topography varies from larger dunes to smaller ridges and swales. Vegetation of this physiognomically variable and dynamic system primarily includes patches (mottes) of forests, woodlands and shrublands dominated by *Quercus fusiformis*. Associated species vary in a north/south manner across the range of this system. Some examples contain dense shrublands dominated (almost to the exclusion of other species) by running clones of *Quercus fusiformis*. Other canopy species in the vicinity of Aransas National Wildlife Refuge, at the northern end of the range, include *Quercus marilandica, Quercus hemisphaerica, Persea borbonia*, and *Celtis laevigata*. In this area, understory species include *Ilex vomitoria, Smilax bona-nox, Vitis mustangensis*, and/or *Morella cerifera*. Other canopy species on the South Texas Sand Sheet, at the southern end of the range, include *Prosopis glandulosa var. glandulosa, Zanthoxylum hirsutum, Condalia hookeri, Lantana urticoides, Ziziphus obtusifolia var. obtusifolia*, and a very few other species. Many of the species found in the northern parts of the range of this system are absent in the southern occurrences. ~*Quercus fusiformis - Prosopis glandulosa var. glandulosa / Malvaviscus arboreus var. drummondii* Forest (CEGL007785)$$ can be referred to the southern expression, while ~*Quercus fusiformis - Persea borbonia* Forest (CEGL002117)$$ represents the northern expression. A characteristic component of the sparse ground cover within the mottes and forests across the entire range is *Malvaviscus arboreus var. drummondii*. Canopy openings are similar in composition to surrounding grasslands. In addition to *Schizachyrium littorale*, other herbaceous species common in canopy openings across the range of this system include *Paspalum plicatulum, Paspalum monostachyum, Andropogon gerardii, Sorghastrum nutans, Muhlenbergia capillaris, Helianthemum georgianum, Croton argyranthemus*, and *Froelichia floridana*. Minor changes in drainage can cause major differences in species composition. On the Ingleside barrier-strandplain, while *Paspalum monostachyum* may dominate slightly lower areas, deeper swales are typically dominated by *Panicum virgatum, Spartina patens, Fimbristylis* spp., *Hydrocotyle bonariensis, Rhynchospora* spp., *Fuirena* spp., *Eleocharis* spp., and *Cyperus* spp.

Distribution: This system is endemic to Texas. It is found within 10 km of the coast on deep sands of ancient Pleistocene strandplains (the Ingleside barrier-strandplain) at its northern extent and within a much greater distance from the coast (100 km) on the Holocene-aged eolian sand deposits of the South Texas Sand Sheet (primarily Kenedy and Brooks counties but extending into adjacent Jim Hogg, Hidalgo, and Willacy counties) at its southern extent.

Nations: US

Description Author: J. Teague and M. Pyne

CES203.464 CONCEPTUAL MODEL

Environment: This system occurs on deep sands of the Pleistocene-aged Ingleside barrier-strandplain and the Holocene- and Pleistocene-aged eolian sand deposits of the South Texas Sand Sheet. Ridge and swale topography characterizes these sites, with some large (up to 15 m tall) vegetated dunes present. Topography varies from larger dunes to smaller ridges and swales.

Key Processes and Interactions: Fire, climate, and edaphic factors all likely played a role historically in maintaining a more open structure in this vegetation. Historically, fire likely limited the development of woody cover. Likewise, edaphic conditions limited this system to deep sandy soils. Loss of these natural processes often results in a shift toward a more closed canopy and decrease in native grass cover. Threats to this system include fire suppression, coastal development, invasive exotics, and damage by vehicles.

CES203.261 Central Atlantic Coastal Plain Maritime Forest

CES203.261 CLASSIFICATION

Concept Summary: This system encompasses most woody vegetation of Atlantic Coast barrier islands and similar coastal strands, from Virginia Beach to central South Carolina (south approximately to the Cooper River where the true Sea Islands begin). It includes forests and shrublands whose structure and composition are influenced by salt spray, extreme disturbance events, and the distinctive climate of the immediate coast. Many examples of this system will include a component of *Quercus virginiana* or *Morella cerifera*. Also included are embedded freshwater depressional wetlands dominated by shrubs or small trees, such as *Cornus foemina, Persea palustris*, or *Salix caroliniana*. This system may experience less effects from fire than the equivalent ~Southern Atlantic Coastal Plain Maritime Forest (CES203.537)$$.

Description Author: R. Evans and M. Pyne

CES203.261 CONCEPTUAL MODEL

Environment: This system occurs on barrier islands and on coastal strands where barrier islands are lacking, and is seldom or never found more than 2 or 3 miles from the ocean. Chronic salt spray is an important influence on vegetation structure and composition; however, the extent to which plant communities found in this system are shaped by salt spray varies. Examples closest to the coast are most likely to exhibit classic streamlined canopy shape due to spray sculpting and are less likely to support salt-intolerant plant species. Heavier salt spray often determines the boundary of this system with ~Southern Atlantic Coastal Plain Dune and Maritime Grassland (CES203.273)$$. Maritime forest requires some shelter from the ocean, in the form of high dunes or extensive sand flats, in order to develop. This system may occur from the top of interior dunes to wet swales. Soils are sandy, except for mucks in the wettest swamps. Soils range from excessively drained to permanently saturated. They are presumably low in nutrient-holding capacity, but input of nutrients in salt spray probably makes this system fairly fertile. Topography and apparent moisture may vary widely with little change in vegetation. The ocean's moderation of climate may be a significant factor in the character of this system. A number of plant species extend much farther north in the maritime forests than they do even a few miles inland.

Key Processes and Interactions: Maritime forests occur in the most stable portions of barrier islands, but the maritime environment is still extremely dynamic. Wind events and hurricanes will have significant impacts on this system. The environment for these forests may be severely altered or destroyed by geologic processes, such as the slow movement of dunes or their catastrophic destruction by storms. Sand movement may also create new sites for this system to occupy. Chronic salt spray and intense salt spray during storms are important influences on vegetation structure and composition; however, the extent to which plant communities found in this system are shaped by salt spray varies. Extreme salt spray or saltwater flooding in storms can severely disturb vegetation, though it recovers if the landforms have not been altered. Mature *Quercus virginiana* trees are fire-resistant when mature, and their litter also does not easily burn (Stalter and Odum 1993). Fire may have naturally occurred infrequently in this system, but probably was not an important factor. Extreme salt spray or saltwater flooding in storms can severely disturb vegetation, although the vegetation recovers if the landforms have not been altered.

Threats/Stressors: Conversion of this type has primarily resulted from clearing and development. Maritime forests occur on the most stable portions of barrier islands and are very attractive building sites. Clearing lots for houses involves disturbing or destroying most, if not all, of the natural vegetative cover to make space for homes, parking areas, drainage fields, and septic systems. Following construction, native vegetation is often replaced by lawns and ornamental shrubs, many of which are exotic and/or invasive (Bellis 1995).

Remnants of maritime forest systems are also threated by edge effects and fragmentation. Breaks in the canopy create eddies in the wind and increase deposition of salt spray. Removal of vegetation on the seaward side increases salt spray deposition on interior portions and can lead to the death of canopy trees and other vegetation. Adjacent clearing, small openings for houses, and roads all contribute to these problems. In addition, several studies have confirmed that road building on barrier islands affects salt transport patterns into the interior of maritime forests (Eaton 1979, Seneca and Broome 1981).

Roads threaten the growth patterns and species composition because opening the forest canopy allows increased salt penetration to the forest interior. Areas without extensive fragmentation into small lots will still suffer degradation from construction of roads, even those that parallel the axis of the barrier island (Bellis 1995). Any kind of canopy opening exposes the uncleared areas of forest vegetation to increases in salt aerosol impact, wind shear, and altered drainage (Gaddy and Kohlsaat 1987). Generally, at least one main road is constructed along the entire length of a barrier island, above the dune ridge at the perimeter of maritime forests, to permit easy access to beaches. Other roads are built laterally to the trunk road for access to developments and private residences. These feeder roads, such as those constructed to provide beach access, are typically parallel to the direction of onshore winds, and serve to intensify the effects of salt spray and wind shear, further degrading the canopy. These would be regarded as having moderately severe degradation. The presence of only roads parallel to the axis of the barrier island represent low severity of degradation, although these are cumulative processes and the degradation will continue to increase with time.

An additional stressor to wetland communities in this system is the removal of groundwater from barrier island aquifers. Rainfall is generally the only source of freshwater on barrier islands, and the maritime forest community acts as the primary watershed. Precipitation entering the watershed is rapidly drawn deep into a freshwater lens, which floats above the denser saltwater in the permeable sediments beneath barrier islands. Pumping of groundwater can dry out wetlands in dune swales. Excessive pumping of freshwater from the lens for residential and commercial purposes can lead to loss of the hydrostatic head in the freshwater lens, which could, in turn, increase the rate of saltwater intrusion into surface waters on the island (Ward 1975, Winner 1975, 1979, Bellis 1995).

The most significant potential climate change effects over the next 50 years (until the early 2060s) include rising sea level and an increase in storms. The climate is expected to be warmer, and estimates of changes in rainfall amounts vary widely. Most maritime upland forest sites are more than 1 m above sea level and are unlikely to be directly inundated. Even if the Outer Banks of North Carolina collapses and most of it is lost, the wide areas that support most of the maritime forests will remain as islands. However, erosion of foredunes and the resulting increased salt spray may be significant impacts. Coastal erosion will likely reduce their extent. Increased hurricane activity, with associated storm surge into the lower portions, heavy salt spray and windthrow will increase mortality of trees and other vegetation (NCDENR 2010). Under possible conditions of climate change, increased natural disturbance by wind, salt spray, and storm surge intrusion will be significant, but the magnitude is quite uncertain. Examples of this system contain species that can recover from these disturbances, but increased frequency will result in younger canopies, more time spent in recovery stages, and shifts toward the most tolerant species. Some maritime forests will likely become maritime shrub and some maritime shrub will become grassland (NCDENR 2010).

Invasive exotic species are also threats, including *Vitex rotundifolia, Ligustrum sinense* (C. Jolls pers. comm.) and introduced exotic *Phragmites australis* (Saltonstall 2002).

Ecosystem Collapse Thresholds: Ecological collapse results from loss of the canopy, either from anthropogenic mechanical disturbance (land clearing for development) or from severe alteration of the substrate from migration of moving dunes (sandhills), or from erosion. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate. Occurrences where vegetation is killed by transient saltwater penetration during storms appear to recover naturally, but repeated saltwater penetration or trapping of saltwater leads to wholesale plant mortality and development of a different ecosystem.

Ecological collapse can also result from severe edge effects in small fragments. Small patches with natural edges are probably fairly functional, but sharp artificial edges lead to penetration of salt spray, eventual mortality of the trees, and disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and damage from salt spray and overwash (Bellis 1995).

Environmental degradation is a continuous process largely driven by anthropogenic destruction and fragmentation, and the disruption of biotic processes tracks this. On unprotected barrier islands (areas that do not have some protected conservation status), site preparation and ground disturbance for housing construction or infrastructure typically destroys most of the native vegetation on a small lot. This process means that the forest canopy is reduced as lots are cleared for construction, parking and septic systems, as well as to provide space for managed vegetation such as lawns. This habitat alteration not only removes the canopy, but disrupts natural processes, including plant succession, nutrient cycling, litter accumulation, and groundwater recharge, and promotes invasion by weeds and exotic species (Bellis 1995). Even if some small lots are at least temporarily left undisturbed, these lots are near the presumed minimum area for a stand of maritime forest, so wildlife is driven out and they function very poorly as refugia for native plant and animal species (Bellis 1995).

CES203.503 East Gulf Coastal Plain Maritime Forest

CES203.503 CLASSIFICATION

Concept Summary: This system encompasses a mosaic of woody vegetation present on barrier islands and near-coastal strands along the northern Gulf of Mexico, from the Florida panhandle to southern Mississippi. Examples may include forests and/or shrublands that are found in somewhat more protected environments than ~East Gulf Coastal Plain Dune and Coastal Grassland (CES203.500)$$. Such areas include relatively stabilized coastal dunes, sometimes with a substantial shell component. Vegetation structure and composition are influenced by salt spray, extreme disturbance events, and the distinctive climate of the immediate coast. Stands may be dominated by a variety of needle-leaved and broad-leaved evergreen trees, including *Pinus clausa, Pinus elliottii var. elliottii, Pinus palustris, Quercus virginiana, Sabal palmetto, Carya glabra*, and *Carya pallida*. Wetland inclusions may be dominated by *Taxodium ascendens* and *Magnolia virginiana*. The most heavily salt-influenced examples may appear pruned or sculpted.

- Slash Pine: 84 (Eyre 1980) **<**

Distribution: This system is found along the northern Gulf of Mexico, from the Florida panhandle to southern Mississippi, restricted to the most coastward part of the "Gulf Coast Flatwoods" (Ecoregion 75a of EPA (2004)).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans and M. Pyne

CES203.503 CONCEPTUAL MODEL

Environment: This system is found on barrier islands and near-coastal strands, on stable dune-and-swale topography in somewhat more protected environments along the northern Gulf of Mexico. More specifically, these areas are generally landward of the foredune and transitional backdune zones. Examples may include forests and/or shrublands that are found in somewhat more protected environments than adjacent dune and coastal grassland vegetation. The system typically includes a series of stabilized dunes and interdune swales oriented parallel to the coastline. Soils are primarily wind- and wave-deposited, well-drained quartz sands of Appalachian origin (Drehle 1973, Johnson and Barbour 1990), sometimes with a substantial shell component, that have been stabilized long enough to support trees and shrubs. As the forest establishes, soil temperature fluctuations moderate and humus begins to build up over the well-drained sands, contributing to moisture retention and leading to more mesic conditions, especially in swales where soil moisture is typically higher (FNAI 1990).

Key Processes and Interactions: The maritime environment for these forests is extremely dynamic, even though they occur on the most stable portions of barrier islands. Maritime forest systems remain subject to periodic severe physical stresses. The environment for these forests may be severely altered or destroyed by geologic processes such as the slow movement of dunes or their destruction by storms and hurricanes. Sand movement may also create new sites for this system to occupy or degrade them through erosion or sand burial. Chronic salt spray (sea salt aerosol), as well as intense salt spray during storms are important influences on vegetation structure and composition; however, the extent to which plant communities found in this system are shaped by salt spray varies. The most heavily salt-influenced examples of these systems may appear pruned or sculpted. Extreme salt spray or saltwater flooding in storms can severely disturb vegetation, though it recovers if the landforms have not been altered. Fire may have naturally occurred infrequently in this system, but probably was not an important factor. Mature *Quercus virginiana* trees are fire-resistant when mature, and their litter also does not easily burn (Stalter and Odum 1993).

Hurricanes frequently make landfall in the northern Gulf of Mexico and have a significant impact on coastal systems. Even when they do not make landfall in the region, the storm surge and wave action generated by an off-shore storm can have a significant impact. For example, a total of 112 hurricanes made landfall from Wakulla County, Florida, to Hancock County, Mississippi, during the period 1926 to 2005 (Jarrell et al. 1992 with updates); 36 major hurricanes (Category 3 or higher) made landfall along the Gulf Coast from Louisiana to the Florida Panhandle between 1851 and 2004 (Blake et al. 2005). Hurricane-associated storm surges can overwash the dune system and cause significant erosion and/or sand burial of maritime forests (Landfire 2007a).

The role of fire in this system is poorly documented. The majority of this system occurs on narrow barrier islands along the northern Gulf of Mexico. FNAI (1990) indicates that the mesic conditions and insular locations of well-developed maritime hammock communities inhibit natural fires, which occur no more frequently than once every 26 to 100 years. Mature *Quercus virginiana* trees are fire-resistant when mature, and their litter also does not easily burn (Stalter and Odum 1993). Liu et al. (2003), in their study of sediment cores from Little Lake, Alabama, suggested that wildfires have been common in the coastal ecosystems in Alabama; however, they offered no frequency estimates. They did suggest a correlation between hurricanes and fire. This correlation was also supported by Meyers and van Lear (1998) who suggest that interactions between hurricanes and fires once played a major role in the development of ecosystems in the southern U.S., influencing their composition, structure, and pattern on the landscape (Landfire 2007a).

The following fire-return interval estimates were based on Huffman and Platt (2004) and the return interval in similar ecological systems on the mainland. Fire interval and intensity depend on the patch vegetation type. In *Quercus/Ceratiola ericoides*-dominated ridges, there is little fuel to sustain surface fires; in this vegetation type, fires are typically replacement fires that burn through the shrub crowns. This return interval was estimated to be 25 to 100 years. These fires were more likely to have occurred following a hurricane or other intense storm-related event when more fuel became available and fire intensity presumably would have been higher. Pine-dominated swales and flats most likely burned more frequently than the *Quercus/Ceratiola ericoides*-dominated ridges. Fires in these swales were primarily light surface fires occurring every four years during the growing season. More intense replacement fires may have occurred following hurricanes, when more fuel was available as a result of storm damage (Landfire 2007a).

Threats/Stressors: Conversion of this type has primarily resulted from clearing and development. Maritime forests occur on the most stable portions of barrier islands and are very attractive building sites. Clearing lots for houses involves disturbing or destroying most, if not all, of the natural vegetative cover to make space for homes, parking areas, drainage fields, and septic systems. Following construction, native vegetation is often replaced by lawns and ornamental shrubs, many of which are exotic (Bellis 1995).

Remnants of maritime forest systems are also threated by edge effects and fragmentation. Breaks in the canopy create eddies in the wind and increase deposition of salt spray. Removal of vegetation on the seaward side increases salt spray deposition on interior portions and can lead to their death. Adjacent clearing, small openings for houses, and roads all contribute to these problems. In addition, several studies have confirmed that road building on barrier islands affects salt transport patterns into the interior of maritime forests (Eaton 1979, Seneca and Broome 1981).

Roads threaten the growth patterns and species composition because opening the forest canopy allows increased salt penetration to the forest interior. Areas without extensive fragmentation into small lots will still suffer degradation from construction of roads, even those that parallel the axis of the barrier island (Bellis 1995). Any kind of canopy opening exposes the uncleared areas of forest vegetation to increases in salt aerosol impact, wind shear, and altered drainage (Gaddy and Kohlsaat 1987). Generally, at least one main road is constructed along the entire length of a barrier island, above the dune ridge at the perimeter of maritime forests, to permit easy access to beaches. Other roads are built laterally to the trunk road for access to developments and private residences. These feeder roads, such as those constructed to provide beach access, are typically parallel to the direction of onshore winds, and serve to intensify the effects of salt spray and wind shear, further degrading the canopy. These would be regarded as having moderately severe degradation. The presence of only roads parallel to the axis of the barrier island represent low severity of degradation, although these are cumulative processes and the degradation will continue to increase with time.

An additional stressor to wetland communities in this system is the removal of groundwater from barrier island aquifers. Rainfall is generally the only source of freshwater on barrier islands, and the maritime forest community acts as the primary watershed. Precipitation entering the watershed is rapidly drawn deep into a freshwater lens, which floats above the denser saltwater in the permeable sediments beneath barrier islands. Pumping of groundwater can dry out wetlands in dune swales. Excessive pumping of freshwater from the lens for residential and commercial purposes can lead to loss of the hydrostatic head in the freshwater lens, which could, in turn, increase the rate of saltwater intrusion into surface waters on the island (Ward 1975, Winner 1975, 1979, Bellis 1995).

The most significant potential climate change effects over the next 50 years include rising sea level and an increase in storms. The climate is expected to be warmer, and estimates of changes in rainfall amounts vary widely. Most maritime upland forest sites are more than 1 m above sea level, and are unlikely to be directly inundated. Erosion of foredunes and the resulting increased salt spray may be significant impacts. Coastal erosion will likely reduce their extent. Increased hurricane activity, with associated storm surge into the lower portions. heavy salt spray and windthrow will increase mortality of trees and other vegetation (NCDENR 2010). Under possible conditions of climate change, increased natural disturbance by wind, salt spray, and storm surge intrusion will be significant, but the magnitude is quite uncertain. Examples of this system contain species that can recover from these disturbances, but increased frequency will result in younger canopies, more time spent in recovery stages, and shifts toward the most tolerant species. Some maritime forests will likely become maritime shrub and some maritime shrub will become grassland (NCDENR 2010).

Ecosystem Collapse Thresholds: Ecological collapse results from loss of the canopy, either from anthropogenic mechanical disturbance (land clearing for development) or from severe alteration of the substrate from migration of moving dunes (sandhills), or from erosion. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate. Occurrences where vegetation is killed by transient saltwater penetration during storms appear to recover naturally, but repeated saltwater penetration or trapping of saltwater leads to wholesale plant mortality and development of a different ecosystem.

Ecological collapse can also result from severe edge effects in small fragments. Small patches with natural edges are probably fairly functional, but sharp artificial edges lead to penetration of salt spray, eventual mortality of the trees, and disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and damage from salt spray and overwash (Bellis 1995).

Environmental degradation is a continuous process largely driven by anthropogenic destruction and fragmentation. On unprotected barrier islands (areas that do not have some protected conservation status), site preparation and ground disturbance for housing construction typically destroys most of the native vegetation on a small lot. These examples would have a high severity of degradation.

The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance. Development for human settlement means that the forest canopy is reduced as lots are cleared for construction, parking and septic systems, as well as to provide space for managed vegetation such as lawns. This habitat alteration not only removes the canopy, but disrupts natural processes, including plant succession, nutrient cycling, litter accumulation, and groundwater recharge, as well as invasion by weeds and exotic species (Bellis 1995). Even if some small lots are at least temporarily left undisturbed, these lots are near in size to the presumed minimum area for a stand of maritime forest, so wildlife is driven out, and they function very poorly as refugia for native plant and animal species (Bellis 1995).

CES203.513 Mississippi Delta Maritime Forest

CES203.513 CLASSIFICATION

Concept Summary: This system includes forests on barrier islands and spits formed during the deltaic shifts of the Mississippi River. It also includes the woody vegetation of salt domes in the Mississippi River deltaic plain. Since natural deltaic processes have been altered, barrier islands are no longer being formed in the Mississippi Delta region and existing barrier islands are undergoing subsidence and beach erosion. Some documented stands that apparently pertain to this system are found on Native American middens (shell mounds) located in the salt marshes of Hancock County, Mississippi. This system currently includes one forested beach ridge located at Grande Isle in Louisiana.

Related Concepts:

- Live Oak: 89 (Eyre 1980) **<**

Distribution: This system is apparently restricted to Louisiana. It is found on barrier islands and spits formed during the deltaic shifts of the Mississippi River.

Nations: US

Description Author: J. Teague and M. Pyne

CES203.513 CONCEPTUAL MODEL

Environment: This system includes forests on barrier islands and spits formed during the deltaic shifts of the Mississippi River. It also includes the woody vegetation of salt domes in the Mississippi River deltaic plain. Some documented stands that apparently pertain to this system are found on Native American middens (shell mounds) located in the salt marshes of Hancock County, Mississippi (Eleuterius and Otvos 1979). This system also includes one forested beach ridge located at Grande Isle in Louisiana.

Key Processes and Interactions: The maritime environment for these forests is extremely dynamic and may be severely altered or destroyed by geologic processes, including catastrophic destruction by storms. Fire may have naturally occurred infrequently in this system, but probably was not an important factor. Mature *Quercus virginiana* trees are fire-resistant when mature, and their litter also does not easily burn (Stalter and Odum 1993). Maritime forest systems remain subject to periodic severe physical stresses, although less than coastal dune and grassland systems. Vegetation structure and composition are influenced by salt spray (sea salt aerosol) and extreme disturbance events such as hurricanes, erosion, accretion and sand burial. Chronic salt spray, as well as intense salt spray during storms are important influences on vegetation structure and composition; however, the extent to which plant communities found in this system are shaped by salt spray varies. The most heavily salt-influenced examples of these systems may appear pruned or sculpted. Extreme salt spray or saltwater flooding in storms can severely disturb vegetation, though it recovers if the landforms have not been altered.

Hurricanes frequently make landfall in the northern Gulf of Mexico region, and have a significant impact on coastal systems. Even when they do not make landfall, the storm surge and wave action generated by an off-shore storm can have a significant impact. A total of 112 hurricanes made landfall from Wakulla County, Florida, to Hancock County, Mississippi, during the period 1926 to 2005 (Jarrell et al. 1992 with updates). From the period 1851 to 2004, 36 major hurricanes (Category 3 or higher) made landfall along the Gulf Coast from Louisiana to the Florida Panhandle (Blake et al. 2005). Hurricane-associated storm surges can overwash the dune system and cause significant erosion and/or sand burial of maritime forests. Personal observations along coastal areas of the Florida panhandle region in 2005 revealed large areas of vegetation extending several hundred yards inland that were killed or significantly impacted by saltwater inundation (Landfire 2007a).

The role of fire in this system is poorly documented. The majority of this system occurs on narrow barrier islands along the northern Gulf of Mexico. FNAI (1990) indicates that the mesic conditions and insular locations of well-developed maritime hammock communities inhibit natural fires, which occur no more frequently than once every 26 to 100 years. Liu et. al. (2003), in their study of sediment cores from Little Lake, Alabama, suggested that wildfires have been common in the coastal ecosystems in Alabama; however, they offered no frequency estimates. They did suggest a correlation between hurricanes and fire. This correlation was also supported by Meyers and van Lear (1998) who suggest that hurricane-fire interactions once played a major role in the development of ecosystems in the southern U.S., influencing their composition, structure, and pattern on the landscape (Landfire 2007a).

The following fire-return interval estimates were based on the Huffman and Platt (2004) study of fire scars on slash pines on Little St. George Island (Florida) and the return interval in similar ecological systems on the mainland. Fires were primarily light surface fires occurring every four years during the growing season. More intense replacement fires may have occurred following hurricanes, when more fuel was available as a result of storm damage. There is little fuel to sustain surface fires in the *Quercus/Ceratiola ericoides*-dominated ridges. Fires in this vegetation type are typically replacement fires that burn through the shrub crowns. The return interval here was estimated at 25 to 100 years, and may have occurred following a hurricane or other intense storm-related event when more fuel was available and fire intensity was higher (Landfire 2007a).

Threats/Stressors: The most critical anthropogenic threat is that, due to the alteration of the natural deltaic processes, barrier islands are no longer being formed in the Mississippi Delta region and existing barrier islands are undergoing subsidence and beach erosion. Conversion of this type has primarily resulted from habitat fragmentation. Maritime forests occur on the most stable portions of barrier islands and are very attractive building sites. Clearing lots for houses involves disturbing or destroying most, if not all, the natural vegetative cover to make space for homes, parking areas, drainage fields, and septic systems. Following construction, native vegetation is often replaced by lawns and ornamental shrubs, many of which are exotic and possibly invasive (Bellis 1995).

Roads threaten the growth patterns and species composition because opening the forest canopy allows increased salt penetration to the forest interior. Areas without extensive fragmentation into small lots will still suffer degradation from construction of roads, even those that parallel the axis of the barrier island (Bellis 1995). Any kind of canopy opening exposes the uncleared areas of forest vegetation to increases in salt aerosol impact, wind shear, and altered drainage (Gaddy and Kohlsaat 1987). Generally, at least one main road is constructed along the entire length of a barrier island, above the dune ridge at the perimeter of maritime forests, to permit easy access to beaches. Other roads are built laterally to the trunk road for access to developments and private residences. These feeder roads, such as those constructed to provide beach access, are typically parallel to the direction of on shore winds, and serve to intensify the effects of salt spray and wind shear, further degrading the canopy. These would be regarded as having moderately severe degradation. The presence of only roads parallel to the axis of the barrier island represent low severity of degradation, although these are cumulative processes and the degradation will continue to increase with time.

An additional stressor to wetland communities within maritime forests is the removal of groundwater from barrier island aquifers. Rainfall is generally the only source of freshwater on barrier islands, and the maritime forest community acts as the primary watershed. Precipitation entering the watershed is rapidly drawn deep into a freshwater lens, which floats above the denser saltwater in the permeable sediments beneath barrier islands. Excessive pumping of freshwater from the lens for residential and commercial purposes can lead to loss of the hydrostatic head in the freshwater lens, which could, in turn, increase the rate of saltwater intrusion into surface waters on the island (Ward 1975, Winner 1975, 1979, Bellis 1995).

The most significant potential climate change effects over the next 50 years include rising sea level and an increase in storms. The climate is expected to be warmer, and estimates of changes in rainfall amounts vary widely. Under possible conditions of climate change, increased natural disturbance by wind, salt spray, and storm surge intrusion will be significant, but the magnitude is quite uncertain. Examples of this system contain species that can recover from these disturbances, but increased frequency will result in younger canopies, more time spent in recovery stages, and shifts toward the most tolerant species. Some maritime forests will likely become maritime shrub and some maritime shrub will become grassland (NCDENR 2010).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from loss of the characteristic canopy in the short term (either from anthropogenic mechanical disturbance such as land clearing for development or from alteration of the substrate from erosion and overwash due to storms or storm tides), but in the long term, the collapse of the system will result from subsidence and beach erosion of the barrier islands themselves, following the alteration of the natural deltaic processes (Morton 2008). Due to this alteration, barrier islands are no longer being formed in the Mississippi Delta region and the existing barrier islands are undergoing subsidence and beach erosion. In addition, rising sea level is compounding this problem and causing transgressive inland migration of the shoreline, which will ultimately lead to the loss of the barrier islands themselves.

Areas that have been cleared and abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate. Occurrences where vegetation is killed by transient saltwater penetration during storms appear to recover naturally, but repeated saltwater penetration or trapping of saltwater leads to wholesale plant mortality and development of a different ecosystem.

Ecological collapse can also result from severe edge effects in small fragments. Small patches with natural edges are probably fairly functional, but sharp artificial edges lead to penetration of salt spray, eventual mortality of the trees, and disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and damage from salt spray and overwash (Bellis 1995).

Environmental degradation is a continuous process largely driven by anthropogenic destruction and fragmentation, and the disruption of biotic processes tracks this. On unprotected barrier islands (areas that do not have some protected conservation status), site preparation and ground disturbance for housing construction or infrastructure typically destroy most of the native vegetation on a small lot. This process means that the forest canopy is reduced as lots are cleared for construction, parking and septic systems, as well as to provide space for managed vegetation such as lawns. This habitat alteration not only removes the canopy, but disrupts natural processes, including plant succession, nutrient cycling, litter accumulation, and groundwater recharge, as well as invasion by weeds and exotic species (Bellis 1995). Even if some small lots are at least temporarily left undisturbed, these lots are near the size of the presumed minimum area for a stand of maritime forest, so wildlife is driven out and they function very poorly as refugia for native plant and animal species (Bellis 1995).

CES203.537 Southern Atlantic Coastal Plain Maritime Forest

CES203.537 CLASSIFICATION

Concept Summary: This system encompasses a range of woody vegetation present on stabilized upland dunes of barrier islands and near-coastal strands, from central South Carolina (from approximately the Cooper River) southward to Volusia County, Florida. It includes vegetation whose structure and composition are influenced by salt spray, extreme disturbance events, and the distinctive climate of the immediate coast. Examples are known from the barrier islands of Georgia and Florida, such as Big Talbot Island, Florida, and probably Sapelo Island, Georgia. Most typical stands are dominated by oaks, primarily *Quercus virginiana* and/or *Quercus geminata*. Vegetation may also include different woodland communities often dominated by southern pine species. *Pinus palustris, Pinus serotina*, and *Pinus elliottii var. elliottii* are all important in documented examples. These examples tend to have densely shrubby subcanopies and understories with species such as *Quercus virginiana, Quercus geminata, Quercus hemisphaerica, Quercus chapmanii, Quercus myrtifolia*, and *Magnolia grandiflora*. Unlike maritime vegetation to the north, this system may be more heavily influenced by natural fire regimes that may help to explain the predominance of the fire-tolerant pine species. It has been postulated that the natural fire-return interval is from 20 to 30 years.

CES203.537 CONCEPTUAL MODEL

Environment: The primary range of this system coincides with the Sea Islands, a chain of more than 100 low islands off the Atlantic coast of South Carolina, Georgia, and northern Florida, extending from the Cooper River to the St. Johns River. Many of these islands have a long history of human use and occupation, including Spanish missions and garrisons in the 16th century. In addition, the Sea Islands were the first important cotton-growing area in North America. The degree to which this system has been altered by these events is unknown.

This system is found on these islands and associated near-coastal strands, on stable dune and swale topography in somewhat more protected environments. These areas are generally landward of the foredune and transitional backdune zones. Examples typically include forests and/or shrublands that are found in somewhat more protected environments than adjacent dune and coastal grassland vegetation. The system typically includes a series of stabilized dunes and interdune swales oriented parallel to the coastline. Soils are primarily wind- and wave-deposited, well-drained quartz sands of Appalachian origin (Drehle 1973, Johnson and Barbour 1990), sometimes with a substantial shell component, that have been stabilized long enough to support trees and shrubs. As the forest establishes, soil temperature fluctuations moderate and humus begins to build up over the well-drained sands, contributing to moisture retention and leading to more mesic conditions, especially in swales where soil moisture is typically higher (FNAI 1990).

Key Processes and Interactions: Maritime forests occur in the most stable portions of barrier islands, but the maritime environment is still extremely dynamic. Wind events and hurricanes will have significant impacts on this system. The environment for these forests may be severely altered or destroyed by geologic processes, such as the slow movement of dunes or their catastrophic destruction by storms. Sand movement may also create new sites for this system to occupy. Extreme salt spray or saltwater flooding in storms can severely disturb vegetation, though it recovers if the landforms have not been altered. Mature *Quercus virginiana* trees are fire-resistant when mature, and their litter also does not easily burn (Stalter and Odum 1993). Fire may have occurred naturally yet infrequently in this system, but probably was not an important factor.

The vegetation of this system has a structure and composition that is influenced by salt spray (sea salt aerosol), extreme disturbance events, and the distinctive climate of the immediate coast. Extreme salt spray or saltwater flooding in storms can severely disturb vegetation, although the vegetation recovers if the landforms have not been altered. Unlike maritime vegetation to the north, this system may be more heavily influenced by natural fire regimes that may help to explain the predominance of the fire-tolerant pine species. It has been postulated that the natural fire frequency is from 20 to 30 years.

Threats/Stressors: Conversion of this type has primarily resulted from clearing and development. Maritime forests occur on the most stable portions of barrier islands and are very attractive building sites. Clearing lots for houses involves disturbing or destroying most, if not all, the natural vegetative cover to make space for homes, parking areas, drainage fields, and septic systems. Following construction, native vegetation is often replaced by lawns and ornamental shrubs, many of which are exotic (Bellis 1995).

Remnants of maritime forest systems are also threated by edge effects and fragmentation. Breaks in the canopy create eddies in the wind and increase deposition of salt spray. Removal of vegetation on the seaward side increases salt spray deposition on interior portions and can lead to their death. Adjacent clearing, small openings for houses, and roads all contribute to these problems. In addition, several studies have confirmed that road building on barrier islands affects salt transport patterns into the interior of maritime forests (Eaton 1979, Seneca and Broome 1981).

Common threats and stressors include road construction, which is a direct cause of habitat fragmentation. Roads threaten the growth patterns and species composition because opening the forest canopy allows increased salt penetration to the forest interior. Generally, at least one main road is constructed along the entire length of a barrier island, above the dune ridge at the perimeter of maritime forests, to permit easy access to beaches. Other roads are built laterally to the trunk road for access to developments and private residences. Roads threaten the growth patterns and species composition because opening the forest canopy allows increased salt penetration to the forest interior. Several studies have confirmed that road building on barrier islands affects salt transport patterns into the interior of maritime forests (Eaton 1979, Seneca and Broome 1981).

An additional stressor to wetland communities in this system is the removal of groundwater from barrier island aquifers. Rainfall is generally the only source of freshwater on barrier islands, and the maritime forest community acts as the primary watershed. Precipitation entering the watershed is rapidly drawn deep into a freshwater lens, which floats above the denser saltwater in the permeable sediments beneath barrier islands. Pumping of groundwater can dry out wetlands in dune swales. Excessive pumping of freshwater from the lens for residential and commercial purposes can lead to loss of the hydrostatic head in the freshwater lens, which could, in turn, increase the rate of saltwater intrusion into surface waters on the island (Ward 1975, Winner 1975, 1979, Bellis 1995).

The most significant potential climate change effects over the next 50 years include rising sea level and an increase in storms. The climate is expected to be warmer, and estimates of changes in rainfall amounts vary widely. Most maritime upland forest sites are more than 1 m above sea level, and are unlikely to be directly inundated. Even if the Outer Banks of North Carolina collapses and most of it is lost, the wide areas that support most of the maritime forests will remain as islands. However, erosion of foredunes and the resulting increased salt spray may be a significant impact. Coastal erosion will likely reduce their extent. Increased hurricane activity, with associated storm surge into the lower portions, heavy salt spray and windthrow will increase mortality of trees and other vegetation (NCDENR 2010). Under possible conditions of climate change, increased natural disturbance by wind, salt spray, and storm surge intrusion will be significant, but the magnitude is quite uncertain. Examples of this system contain species that can recover from these disturbances, but increased frequency will result in younger canopies, more time spent in recovery stages, and shifts toward the most tolerant species. Some maritime forests will likely become maritime shrub and some maritime shrub will become grassland (NCDENR 2010).

Ecosystem Collapse Thresholds: Ecological collapse results from loss of the canopy, either from anthropogenic mechanical disturbance (land clearing for development) or from severe alteration of the substrate from migration of moving dunes (sandhills), or from erosion. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate. Occurrences where vegetation is killed by transient saltwater penetration during storms appear to recover naturally, but repeated saltwater penetration or trapping of saltwater leads to wholesale plant mortality and development of a different ecosystem.

Ecological collapse can also result from severe edge effects in small fragments. Small patches with natural edges are probably fairly functional, but sharp artificial edges lead to penetration of salt spray, eventual mortality of the trees, and disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and damage from salt spray and overwash (Bellis 1995).

Environmental degradation is a continuous process largely driven by anthropogenic destruction and fragmentation, and the disruption of biotic processes tracks this. On unprotected barrier islands (areas that do not have some protected conservation status), site preparation and ground disturbance for housing construction or infrastructure typically destroy most of the native vegetation on a small lot. This process means that the forest canopy is reduced as lots are cleared for construction, parking and septic systems, as well as to provide space for managed vegetation such as lawns. This habitat alteration not only removes the canopy, but disrupts natural processes, including plant succession, nutrient cycling, litter accumulation, and groundwater recharge, as well as invasion by weeds and exotic and/or invasive species (Bellis 1995). Even if some small lots are at least temporarily left undisturbed, these lots are near the size of the presumed minimum area for a stand of maritime forest, so wildlife is driven out and they function very poorly as refugia for native plant and animal species (Bellis 1995).

Areas without extensive fragmentation into small lots will still suffer degradation from construction of roads (Bellis 1995). Any kind of canopy opening exposes the uncleared areas of forest vegetation to increases in salt aerosol impact, wind shear, and altered drainage.

CES203.560 Southern Coastal Plain Dry Upland Hardwood Forest

CES203.560 CLASSIFICATION

Concept Summary: This is one of three hardwood-dominated systems found in the East Gulf Coastal Plain and adjacent areas of central Florida. This type is found in the Southern Coastal Plain and Southeastern Plains (EPA Level III Ecoregion 75 and parts of 65).

Examples attributable to this type are typically deciduous or mixed evergreen oak-dominated forests, often with a pine component present. Although the southern portion of the range of this system overlaps ~Southern Coastal Plain Oak Dome and Hammock (CES203.494)$$, the latter is dominated by evergreen oak species, and the two should not be confused. The core range of this type extends northward to the approximate historical range of *Pinus palustris*; although most deciduous species do not mimic this range, this boundary does appear to be a reasonable demarcation boundary north of which *Quercus alba* becomes more abundant and south of which *Quercus hemisphaerica* is more diagnostic. Like all hardwood systems of this region, examples occur within a landscape matrix historically occupied by pine-dominated uplands and consequently this system only occurred in fire-sheltered locations in naturally small to large patches. Examples of this system tend to occur on sites intermediate in moisture status (mostly dry to dry-mesic), although occasionally very dry (xeric) stands may also be included. Toward the northern range limits of this system, it may have been less restricted to small patches in fire-protected locations, and may have been formerly more prevalent on the landscape even in areas heavily influenced by fire.

Important tree species vary geographically and according to previous disturbance. *Quercus hemisphaerica* is a typical species in many examples, with *Quercus stellata, Quercus falcata*, and *Quercus alba* less frequently encountered, but dominant in some stands. The overstory of some examples may be quite diverse, with hickories and other hardwood species often present. Typically mesic sites, as indicated by species indicative of these conditions (e.g., *Fagus grandifolia*), are covered under other systems. *Pinus taeda* is sometimes present, but it is unclear if it is a natural component or has entered only as a result of past cutting. *Pinus glabra* or *Pinus echinata* may also be present in some examples. Stands may be found on slopes above rivers and adjacent to sinkholes, as well as other fire-infrequent habitats including narrow bands between mesic slopes below and pine-dominated flats above.

Distribution: This system is found in the East Gulf Coastal Plain and adjacent areas of central Florida ranging northward into central Mississippi and Alabama.

Nations: US

Concept Source: M. Pyne and R. Evans

Description Author: M. Pyne and R. Evans

CES203.560 CONCEPTUAL MODEL

Environment: Topographically, these sites tend to occur on upper to mid slopes, but occasionally on broader uplands with reduced fire frequencies. A range of soils may be present from loamy and clayey to coarse sands, but are generally well-drained but not excessively drained. Soils are generally acidic, though calcareous soils occur occasionally. Sites are somewhat protected from most natural fires by steep topography and by limited flammability of the vegetation.

Key Processes and Interactions: Sites where this system occurs almost invariably grade upslope into pine-dominated systems, especially stands containing *Pinus palustris* and, to a lesser extent, *Pinus echinata*. If these sites were burned more frequently, the vegetation would likely be replaced by more fire-tolerant southern pines. Fires that penetrate stands of this type are generally low in intensity and have fairly limited ecological effect. In general, more frequent or intense fire would move the vegetation on the site toward more fire-tolerant components. Conversely, with the prolonged complete absence of fire, less fire-tolerant species could invade, causing the vegetation to resemble the more mesic slope forests below.

Frequent surface fires occurred on a 4- to 8-year return interval from both lightning and Native American ignitions. These frequent light surface fires maintained the grassy understory and kept more fire-tolerant hardwoods and shrubs from capturing the understory and forming a midstory layer. Lightning fires occurred primarily during the spring dry season (April and May) with a secondary peak of Native American and settler burning during the fall (October and November) (Landfire 2007a). Occasionally, during extensive droughts, mixed-severity or stand-replacement fires did occur, especially in drier *Pinus echinata*-dominated stands. Local thunderstorms created gaps on a small but continual basis. More extensive regional disturbances included tropical storms during the growing season and ice storms during winter (in the northern part of the range). Dense stands of middle to older aged *Pinus* species (where present) were susceptible to periodic mortality from bark beetle epidemics (Landfire 2007a).

Threats/Stressors: The most critical anthropogenic threats include removal of the characteristic dominant hardwoods and a lack of fire. Removal of the characteristic dominant hardwoods (primarily *Quercus* species and *Carya* species) through logging may result in a stand dominated by wind-blown or bird-dispersed tree species, including Acer rubrum, Celtis spp., *Fraxinus americana, Juglans nigra, Juniperus virginiana, Liquidambar styraciflua, Liriodendron tulipifera, Prunus serotina, Robinia pseudoacacia, Sassafras albidum, Ulmus americana*, and the exotics *Albizia julibrissin, Vernicia fordii (= Aleurites fordii)*, and *Melia azedarach*. Sites may also be converted to *Pinus* species plantations. Lack of fire in the system leads to a closing of the subcanopy and consequent loss of ground layer diversity. Feral hog (*Sus scrofa*) activity, combined with invasion of exotic species, are also major threats. Another major threat is conversion to human-created land uses, including residential development, quarries, industrial development, and infrastructure development. The most significant potential climate change effects over the next 50 years include periods of drought, interspersed with more intense storms, which will affect the health and survival of the trees.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (particularly *Quercus* and *Carya*) to regenerate. Periods of drought will also affect the health and survival of the canopy trees. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Feral hog (*Sus scrofa*) activity, combined with invasion of exotic species, can eradicate the native ground and shrub flora (Engeman et al. 2007, Edwards et al. 2013).

CES203.494 Southern Coastal Plain Oak Dome and Hammock

CES203.494 CLASSIFICATION

Concept Summary: This small-patch system occurs in the Southern Coastal Plain (EPA ecoregion 75). Examples are known from some more inland portions of this region as well as the Southeastern Plain (EPA ecoregion 65) in Georgia and Alabama. Relatively dense stands of *Quercus virginiana* and/or *Quercus geminata* are diagnostic of this system. Examples often occupy locally distinct microhabitats that differ from the surrounding landscape, such as shallow depressions or slight topographic highs in a predominantly *Pinus palustris* -dominated landscape. Although embedded in a matrix of vegetation with extremely frequent fire regimes, patches of this system are subject to only infrequent or rare fire events. Under more frequent fire regimes, these sites would likely be occupied by *Pinus palustris*. It has been postulated that winter burning regimes have allowed this type to expand. A range of soil and moisture conditions may be present. More mesic examples have relatively thin soils (to 50 cm) above clay, while xeric examples occupy deep (>130 cm) well-drained sands. Dominant plants of mesic examples include *Quercus virginiana* and *Quercus hemisphaerica*, along with *Diospyros virginiana*. Vines including *Campsis radicans* and *Smilax* spp. dominate the sparse ground cover. In xeric examples, dominants include *Quercus geminata, Pinus palustris, Quercus virginiana, Aristida beyrichiana*, and *Stylisma humistrata*. This system is low in plant species diversity compared to most other habitats in the region.

CES203.494 CONCEPTUAL MODEL

Environment: Examples are thickets or groves of *Quercus* species in a *Pinus* spp.-dominated landscape (Myers 1990). These typically occupy locally distinct microhabitats that differ from the surrounding landscape, such as shallow depressions or slight topographic highs in a predominantly *Pinus palustris*-dominated landscape. A range of soil and moisture conditions may be present. As currently defined, this system includes examples across a moisture gradient from mesic to xeric, ranging across parts of the southeastern coastal plains from Georgia to Mississippi. In Georgia, more mesic examples of this system have relatively thin soils (to 50 cm) above clay, while xeric examples occupy deep (>130 cm) well-drained sands (Drew et al. 1998). In Florida, the xeric hammock typically develops on excessively drained sands where fire exclusion has allowed for the establishment of an oak canopy (FNAI 2010a). This may occur naturally, when the area has isolation from, or significant barriers to, fire. This can also occur as the result of human intervention, as at old homesites where fire was excluded for many years. In these areas, xeric hammock is found as small patches within or near sandhill or scrub. Xeric hammock can also occur on high islands within flatwoods or even on a high, well-drained ridge within a floodplain. Xeric hammock can occur on barrier islands and in other coastal situations, as an advanced successional stage of coastal scrub.

Along and near the east coast of Florida, from Cape Canaveral and northward, there is more shell or humus in the sand, and a tendency to have hammocks containing *Quercus virginiana* with coastal strand rather than scrub; on the other hand, where there is more dry acidic sand, scrub occurs nearer the coast and *Quercus geminata* hammocks are found further back from the coast (A. Johnson pers. comm.).

Key Processes and Interactions: Although embedded in a matrix of vegetation with extremely frequent fire regimes, patches of this system are subject to only infrequent or rare fire events. Under more frequent fire regimes, these sites would likely be occupied by *Pinus palustris*. Myers (1990) postulated that winter -burning regimes have allowed for the expansion of this type. *Quercus geminata* and *Quercus myrtifolia* are both clonal species which establish large rhizome systems capable of quickly resprouting following injury. Xeric hammocks, whether natural or anthropogenic, result from years of fire exclusion, maintained and further enhanced by incombustible oak litter and a sparsity of herbs. The thick bark of *Quercus geminata* makes these trees somewhat resistant to fire. Once they form a canopy that shades the understory, the trees generate a layer of leaf litter that covers open patches of sand and leads to more shaded, mesic ground conditions. The resulting shaded habitat can allow more fire-intolerant species such as *Magnolia grandiflora* to establish (Daubenmire 1990). Once the canopy is greater than 2 m high, even hot summer burns may not be sufficient to kill the dome, which can become established after only 7 to 16 years of fire exclusion (Guerin 1993). At that stage, oaks would only be killed through a catastrophic burn during dry conditions. Otherwise, the spread of oaks could be halted through mechanical removal or the use of herbicides if the management intent is the re-establishment of the fire-maintained community that was replaced by the xeric hammock. Xeric hammocks also form from long unburned oak scrub (Laessle 1958). There is a dynamic tension between the *Quercus*-dominated patches and the *Pinus*-dominated matrix. Oak domes are a natural part of the landscape, but can also result from human-caused fire exclusion. Near the coast, these communities are affected by salt spray (sea salt aerosol). At and near the coast, salt spray maintains the *Quercus geminata* at shrub height as much as does fire; one may observe a gradient of increasingly taller *Quercus geminata* as you move inland and the effect of salt spray becomes diminished (A. Johnson pers. comm.).

Threats/Stressors: Conversion of this type has commonly come from removal of the hardwood vegetation and its replacement by residential or commercial development, or by plantations composed of *Pinus* species. In areas of increasing suburbanization, these plantations may subsequently be replaced by residential or commercial developments. Common stressors and threats include feral hog (*Sus scrofa*) rooting and livestock grazing, which are sources of soil disturbance. The spreading *Quercus* canopy of the xeric hammocks provides a shady refuge in otherwise open, sunny areas. As a result, hammocks have long been utilized (and disturbed) by humans seeking comfortable homesites or camping and recreation areas (FNAI 2010a). Invasive exotic plants are also a threat. Some problematic plants for this system include *Dioscorea bulbifera, Eremochloa ophiuroides, Imperata cylindrica, Lespedeza bicolor, Lespedeza cuneata, Lonicera japonica*, and *Melinis repens (= Rhynchelytrum repens)* (Brewer 2008).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (e.g., *Quercus*) to regenerate. Feral hog (*Sus scrofa*) activity, combined with invasion of exotic plant species, can eradicate the native ground and shrub flora (Engeman et al. 2007, Edwards et al. 2013). Oak domes seen to be persistent features in the *Pinus palustris*-dominated landscape. If the site is converted to some other land use, ecological collapse would tend to result from the removal of the entire natural forest and the loss of all ecosystem function as a forest or woodland.

CES203.466 West Gulf Coastal Plain Chenier and Upper Texas Coastal Fringe Forest and Woodland

CES203.466 CLASSIFICATION

Concept Summary: This system includes a range of woody vegetation typically dominated by *Quercus virginiana* present along the northern Gulf of Mexico, from Vermillion Bay in Louisiana to the upper Texas coast. Landscape position includes shell ridges along the coast and bay margins, coastal salt domes, stranded ancient barrier ridges (Ingleside barrier strandplain), and chenier ridges of the Chenier Plain. In addition to *Quercus virginiana*, other species such as *Celtis laevigata* and *Quercus nigra* may be present to codominant in the canopy which may also include *Carya illinoinensis, Diospyros virginiana, Fraxinus pennsylvanica, Liquidambar styraciflua*, and *Magnolia grandiflora*.

- Live Oak: 89 (Eyre 1980) **<**

Distribution: This ecological system is found in small patches along the northern Gulf of Mexico, from Vermillion Bay in Louisiana to the upper Texas coast.
Nations: US
Concept Source: J. Teague and R. Evans
Description Author: J. Teague, R. Evans, M. Pyne and L. Elliott

CES203.466 CONCEPTUAL MODEL

Environment: This system occupies sand and shell ridges (Quaternary deposits) which resulted from ancient abandoned beach ridges associated with migrating shorelines, shell ridges, as well as salt domes near the coast. The Ingleside barrier strandplain, an ancient barrier ridge composed of deep sands and occurring well inland of the current Gulf shoreline, may support occurrences of this system. Most occurrences occupy ridges formed from sediments deposited along ancient shorelines. These ridges (cheniers), which often parallel the coast and are composed of coarse material such as sand or shell, may be up to 3 m above mean sea level. Some occurrences occupy coastal salt domes, which may rise 30 m above the surrounding landscape. The soils are typically Entisols of coarse-textured material, either sand or shell. The Ecological Site Description, which may be related to this system, is the Coastal Sand ecoclass (Elliott 2011).
Key Processes and Interactions: This ecological system is heterogeneous in physiognomy, including forests, woodlands and shrublands. The Chenier Plain was historically characterized by a prograding coastline replenished by sediments carried to the Gulf of Mexico initially by the Mississippi and subsequently the Atchafalaya and other rivers. It is void of barrier islands and sediments are reworked by waves into beach ridges, sometimes with a substantial shell component. This process has been continuing since the last glacial retreat, and as the coastline prograded, older beach ridges were left as interior ridges surrounded by marsh. These interior beach ridges are referred to as cheniers (from the French word for oak) because they were historically dominated by *Quercus virginiana*. Ridges parallel the coast and are usually 3-5 m above mean sea level. Though not confined to coastal areas, salt domes are a distinctive feature along the Gulf Coast of upper Texas and Louisiana where they often form a drastic contrast to the low-lying Coastal Plain sediments surrounding them. Formed by the rise of salt masses which push up overlying strata, salt domes may rise 30 m above the surrounding landscape. The natural vegetation of cheniers and coastal salt domes are quite similar. The Ingleside barrier strandplain is a Pleistocene barrier ridge that is exposed discontinuously along the Texas coast. One of these areas is located northeast of Galveston Bay and supports *Quercus virginiana*-dominated woodlands included within this ecological system. Shell ridges located along coast and bay margins are typically dominated by halophytic shrubs. Similar vegetation may also be found on coastal dredge spoil. Vegetation structure and composition of occurrences of this system may be influenced by salt spray (on those

shell ridges, salt domes and cheniers closest to the gulf), tropical storms and hurricanes, and the distinctive climate of the immediate coast. Studies have shown that chenier forests and woodlands are very important stop-over sites for neotropical migrants during both spring and fall migration.
Threats/Stressors: The primary threats to this ecological system are clearing and conversion to other land uses such as pasture, residential development, and infrastructure, sand mining, invasive species such as *Triadica sebifera*, and the reduced formation of new beach ridges (Neyland and Meyer 1997). Only 2 to 10% of the presettlement occurrences of this system remain in Louisiana (LDWF 2005) and these fragmented remnants are further impacted by overgrazing and invasive species. Very little of this system is under conservation ownership (LDWF 2005).
Ecosystem Collapse Thresholds: Ecological collapse tends to result from habitat loss and fragmentation and conversion of the ecological system to other land uses such as pasture and residential and commercial development. Collapse is also characterized by the absence of the many animal and plant species of conservation concern that inhabit this system.

M008. Southern Mesic Mixed Broadleaf Forest

CES203.079 Crowley's Ridge Mesic Loess Slope Forest

CES203.079 CLASSIFICATION

Concept Summary: This ecological system of mesic upland forests is confined to Crowley's Ridge, which extends from Missouri south into Arkansas along the western side of the lower Mississippi River. This vegetation and the ridge itself are very distinctive from that of the adjacent alluvial plain. The ridge is a remnant loess-capped feature rising from 30 m to over 60 m (100-200 feet) above the alluvial plain surface, to about 150 m (450 feet) above sea level. The base of the ridge is composed of Tertiary substrates overlain by Quaternary alluvial deposits and capped with up to 15 m (50 feet) of Pleistocene loess. The system is generally composed of mesic forests that occupy ravines between narrow, "finger" ridges and slopes in a highly dissected landscape. The sites tend to be more mesic than sites elsewhere in the southeastern United States. In many cases, these slopes and ravines provide habitat for plant species that are rare or absent from other parts of the alluvial plain (e.g., *Liriodendron tulipifera, Tilia americana*). Canopies are dominated by *Fagus grandifolia, Quercus alba*, and *Liriodendron tulipifera*, with many associates.

Distribution: This system is endemic to Crowley's Ridge (Arkansas, Missouri), which is a distinctive landscape feature in the Mississippi River Alluvial Plain.
Nations: US
Concept Source: T. Foti, D. Zollner, and M. Pyne
Description Author: T. Foti, D. Zollner, M. Pyne

CES203.079 CONCEPTUAL MODEL

Environment: These diverse-canopy forests occur in ravines in a highly dissected environment. The system is best expressed on southern Crowley's Ridge, Arkansas (Cross County south through Phillips County), with additional limited occurrences to the north, in undisturbed valleys and coves. Deep loessal soil is the most characteristic and diagnostic component of the environment of this system.

Key Processes and Interactions: These are stable, generally fire-sheltered forests, with relatively low fire frequency and intensity. There is some natural disturbance from the effects of windstorms and collapse of the fragile loess. This mesic loess forest type typically experiences surface fires with return intervals of from 30 to greater than 100 years. Mixed-severity fires will occur approximately every 100 years, opening the canopy with increased mortality. This effect may also be achieved by recurrent, severe insect defoliations or droughts. Straight-line winds or microbursts may cause blowdowns on a scale of 1 to 100 acres. Stand-replacement fires happen very infrequently (Landfire 2007a).

Threats/Stressors: Conversion of this type has primarily resulted from canopy removal and habitat fragmentation. The most critical anthropogenic threat is mining of gravel from the Quaternary alluvial and Tertiary marine deposits at the base of the ridge since these represent virtually the only extensive gravel deposits in northeastern Arkansas and southeastern Missouri (the Mississippi Alluvial Plain does not typically have gravel deposits). Considerable suburban and exurban residential and small-farm development is causing extensive conversion and fragmentation of forested sites - almost no extensive forested areas occur outside of federal and state properties. Existing forested areas are affected by removal of the characteristic canopy species due to logging and timber extraction. High-grading is a frequent practice, with more desirable species being removed in preference to *Fagus grandifolia*, which is less desirable in the lumber trade.

Aside from actual site conversion, feral hogs (*Sus scrofa*) represent one of the greatest threats to biodiversity in these forests (Engeman et al. 2007). They can be especially difficult to control in sensitive slope forests. In addition, invasive exotic species, including *Ailanthus altissima, Macrothelypteris torresiana, Microstegium vimineum, Paulownia tomentosa, Phyllostachys aurea*, and *Pueraria montana var. lobata*, can become dominant in the ground and shrub layers following canopy disturbance. For mesic hardwood forests containing *Fraxinus* species, emerald ash borer (which as of October 2013 has been reported from southeastern Missouri) may also be (or become) a significant stressor.

The most significant potential climate change effects over the next 50 years include an increase in storms, which would contribute to severe erosion of the substrate. Climate change may also bring increased periods of drought, which will affect the health and survival of the moisture requiring trees, as well as increase the probability of damaging wildfire.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from loss of the canopy, either from anthropogenic mechanical disturbance (land clearing for mining, development, forestry, or agriculture) or from severe alteration of the substrate from erosion and collapse of the fragile loess. Ecological collapse can also result from such severe fragmentation (as in remnant patches left scattered among developments and roads) that wildlife is driven out and natural processes are lacking. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and damage from erosion of the substrate. Effects of forest fragmentation include the introduction of barriers to the movement of native animal and plant species, degradation of native habitats, degradation of water quality, and the introduction of non-native plant and animal species (Arkansas Forestry Commission 2010). In particular, feral hogs can significantly impact forest composition and structure (Engeman et al. 2007).

CES203.481 East Gulf Coastal Plain Northern Loess Bluff Forest

CES203.481 CLASSIFICATION

Concept Summary: This system is largely confined to steep bluffs bordering the northern portion of the eastern edge of the Mississippi River Alluvial Plain. The geology is typically mapped as the Jackson Formation. These bluffs extend up to 150 m (500 feet) in elevation and from 30 to 60 m (100-200 feet) above the adjacent plain. They consist of a belt of Pleistocene and Tertiary eolian deposits that are often deeply eroded and very steep, with fertile topsoil and abundant moisture. The vegetation is often richer than surrounding non-loessal areas, or those with only thin loess deposits. The forests found on these bluffs are intermediate in soil moisture for the region and may best be thought of as mesic. The vegetation may sometimes be referred to as western mesophytic forest and may share some superficial similarities with cove forests of the Interior Highlands. In many cases, these bluffs provide habitat for plant species that are rare or absent from other parts of the Coastal Plain. The composition of these forests changes from north to south along the bluffs; more southerly examples are represented by the ~East Gulf Coastal Plain Southern Loess Bluff Forest (CES203.556)$$, and these would contain *Magnolia grandiflora* as an important component. As currently defined this system ranges northward from about 32°N latitude (where the Big Black River cuts through the bluffs), and occurs only in the westernmost portions of the Upper East Gulf Coastal Plain, including northern and central Mississippi, western Tennessee, and western Kentucky, being restricted to the northern part of the Loess Bluff Hills (EPA Ecoregion 74a).

Related Concepts:

- Beech - Sugar Maple: 60 (Eyre 1980) **<**
- Northern Red Oak: 55 (Eyre 1980) **<**

Distribution: This system is endemic to the loess bluffs ("Bluff Hills" [Ecoregion 74a] of EPA (2004)) along the eastern edge of the Mississippi River Alluvial Plain in Mississippi, Tennessee, and Kentucky.

Nations: US

Concept Source: R. Evans and M. Pyne

Description Author: R. Evans and M. Pyne

CES203.481 CONCEPTUAL MODEL

Environment: This system is largely confined to the lower portions of steep bluffs east of the Mississippi River. These bluffs consist of a belt of Pleistocene and Tertiary eolian deposits (Braun 1950) that are often deeply eroded and very steep, with fertile topsoil and abundant moisture (Miller and Neiswender 1987). The core of this is mapped as the Jackson Formation (Hardeman 1966) and corresponds more broadly with Ecoregion 74a (Bluff Hills) (EPA 2004). These bluffs border the eastern edge of the Mississippi River Alluvial Plain from about 32°N latitude (where the Big Black River cuts through the bluffs) northward to western Tennessee and Kentucky. Examples may extend up to 150 m (500 feet) in elevation and from 30 to 60 m (100-200 feet) above the adjacent Mississippi Alluvial Plain. In Tennessee the loess soils may be 9-27.5 m (30-90 feet deep) (Springer and Elder 1980).

Key Processes and Interactions: These are stable, generally fire-sheltered forests. These forests probably generally exist naturally as old-growth forests, with canopy dynamics dominated by gap-phase regeneration. As modeled here, replacement disturbance is over 60% and more likely due to weather-related events than fire. Included among these are windthrow, lightning, and ice damage, as well as the inclusion of the erosion and mass wastage (Bryant et al. 1993) that give the bluffs their characteristic steepness. Widespread insect or disease mortality has not been reported. Wind/weather/stress replacement frequency is modeled near 240 years, replacement fire return at approximately 385 years, and all fire return frequency at about 85 years. "Open" structure is uncommon, even when defined as canopy closure less than 81%, and may be created by mixed-severity fire. Surface fire may maintain open conditions, but it does not transition closed classes. Disturbance is presumed to mirror mixed mesophytic forest, occurring primarily in small gaps (less than one-quarter acre), although the occurrence of aggregates of intolerant species suggests that larger scale disturbances occasionally play a role (Landfire 2007a). In addition, periodic droughts may cause death of or stress to moisture-requiring canopy trees. There is presumably some natural disturbance from the effects of windstorms, which are relatively frequent in the range of this system.

Threats/Stressors: Conversion of this type has primarily resulted from repeated canopy removal through logging, which is also the most critical anthropogenic threat. These sites were historically less frequently logged than the adjacent pine-dominated uplands, with more desirable species being removed in preference to *Fagus grandifolia*, which is less desirable in the lumber trade. In addition, some mesic hardwood forests in more moderately dissected terrain have been converted to pine plantations or impacted (destroyed or fragmented) by agriculture. Bluff habitats are often prime sites for development, especially along major rivers. Complete devastation by natural agents was probably very rare in this forest type (Batista and Platt 1997). These forests also suffer the effects of ozone and acidic atmospheric deposition.

Aside from actual site conversion, feral hogs (*Sus scrofa*) represent one of the greatest threats to biodiversity in these forests (Engeman et al. 2007). They can be especially difficult to control in sensitive slope forests (Edwards et al. 2013). Invasive exotic species, including *Lonicera japonica* and *Ligustrum sinense*, can become dominant in the ground and shrub layers following canopy disturbance. The most significant potential climate change effects over the next 50 years include periods of drought, which will affect the health and survival of the moisture-requiring trees, as well as increase the probability of damaging wildfire.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (including *Fagus grandifolia*) to regenerate. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Ecological collapse can also result from such severe fragmentation (as in remnant patches left scattered among developments and roads) that wildlife is driven out and natural processes are lacking. Feral hog activity, combined with invasion of exotic species, can eradicate the native ground and shrub flora (Engeman et al. 2007, Edwards et al. 2013).

CES203.477 East Gulf Coastal Plain Northern Mesic Hardwood Slope Forest

CES203.477 CLASSIFICATION

Concept Summary: This system includes mesic deciduous hardwood forests of inland portions of the East Gulf Coastal Plain, including Alabama, Mississippi, western Kentucky, and western Tennessee. This system covers parts of the more mesic forests in the coastal plain portion of the Western Mesophytic Forest Region referred to as mesophytic mixed hardwoods, as well as mesic forests in the adjacent "Oak-Pine-Hickory" region to the south. Examples of this system occur on slopes and ravines between dry uplands and stream bottoms. Mesic forests of the loess bluffs are treated in separate ecological systems, being confined to that landform of steep bluffs and ravines on deep loess. The most characteristic feature of the vegetation in some examples may be *Fagus grandifolia*, but a variety of other hardwood species may also be found in the overstory, and *Fagus grandifolia* may not always be present. Some stands may be dominated by *Fagus grandifolia* and *Quercus alba*, others by *Quercus alba* or *Quercus pagoda* with other mesic hardwoods. In addition, *Pinus taeda* may be common in some examples in the southern portion of the range and, depending on previous disturbance and site conditions, may be locally dominant [see CEGL004763]. To the south this system is replaced by ~Southern Coastal Plain Mesic Slope Forest (CES203.476)$$, which is within the range of *Pinus glabra* and *Magnolia grandiflora*.

- White Oak: 53 (Eyre 1980) **<**

Distribution: This system is found in northern and inland portions of the East Gulf Coastal Plain, including Alabama, Mississippi, western Kentucky, and western Tennessee. It does not occur in Arkansas. This area is equivalent to the coastal plain portion of the Western Mesophytic Forest Region of Braun (1950) and the "Oak-Pine-Hickory" region of Greller (1988).
Nations: US
Concept Source: R. Evans, M. Pyne, A. Schotz
Description Author: R. Evans, M. Pyne, A. Schotz

CES203.477 CONCEPTUAL MODEL

Environment: This system occurs along the eastern margin of the Upper Coastal Plain where elevation is greatest and influence of loess is minimal where stands occur as predominantly slope forests in relatively deep, dissected stream valleys. The vegetation in this region has been broadly considered distinct from other coastal plain forests (Bryant et al. 1993, Fralish and Franklin 2002) but has received almost no specific study (Franklin and Kupfer 2004). Although vastly forested when compared to the loess plains to the west (USGS 1992), most of the vegetation is recovering from one or more forms of severe disturbance (Franklin and Kupfer 2004). *Quercus alba* dominates the upland forests, examples of which have been studied in a limited portion of this area by Franklin and Kupfer (2004), but these communities have not been described to the same detail as other ecological systems.
Key Processes and Interactions: These are stable, generally fire-sheltered forests. There is presumably some natural disturbance from the effects of hurricanes (to the south), or from other windstorms, which are relatively frequent in the range of this system. Most of the vegetation is recovering from one or more forms of severe anthropogenic disturbance (Franklin and Kupfer 2004). Infrequent, low-intensity surface fires and rare mosaic or replacement fires are typical in this system (Fire Regime Group III) (Landfire 2007a). The mean fire-return interval (MFRI) is about 35 years with wide year-to-year and within-type variation related to moisture cycles, degree of sheltering, and proximity to more fire-prone vegetation types. Anthropogenic fire is also part of this variation. Exposure to occasional fires and severe storms may create some canopy disturbances, which can be followed by waves of tree recruitment, growth, and death resulting in changes in the density and structure of tree populations and in consequent fluctuations in forest species composition. Periodic droughts will cause death of or stress to moisture-requiring canopy trees.
Threats/Stressors: Conversion of this type has primarily resulted from repeated canopy removal through logging, which is also the most critical anthropogenic threat. These sites were historically less frequently logged than the adjacent pine-dominated uplands, with more desirable species being removed in preference to *Fagus grandifolia*, which is less desirable in the lumber trade. In addition, some mesic hardwood forests in more moderately dissected terrain have been converted to pine plantations or impacted (destroyed or fragmented) by agriculture. Bluff habitats are often prime sites for development, especially along major rivers. Complete devastation by natural agents was probably very rare in this forest type (Batista and Platt 1997). These forests also suffer the effects of ozone and acidic atmospheric deposition.

Aside from actual site conversion, feral hogs (*Sus scrofa*) represent one of the greatest threats to biodiversity in these forests (Engeman et al. 2007). They can be especially difficult to control in sensitive slope forests (Edwards et al. 2013). In addition, invasive exotic species including *Lygodium japonicum, Lonicera japonica*, and *Ligustrum sinense* can become dominant in the ground and shrub layers following canopy disturbance (Edwards et al. 2013).

The most significant potential climate change effects over the next 50 years include periods of drought, which will affect the health and survival of the moisture requiring trees, as well as increase the probability of damaging wildfire.
Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (including *Fagus grandifolia*) to regenerate. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Ecological collapse can also result from such severe fragmentation (as in remnant patches left scattered among developments and roads) that wildlife is driven out and natural processes are lacking. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and other disturbance. Feral hogs and other non-native species can significantly impact forest composition and structure (Engeman et al. 2007, Edwards et al. 2013).

CES203.556 East Gulf Coastal Plain Southern Loess Bluff Forest

CES203.556 CLASSIFICATION

Concept Summary: This system of upland hardwood-dominated forests is defined as including both the steep loess bluffs bordering the eastern edge of the Mississippi River Alluvial Plain, ranging from south-central Mississippi to southeastern Louisiana, as well as hardwood vegetation of the "Loess Plains" immediately to the east of these bluffs and ravines. The vegetation is often richer than surrounding non-loessal areas, or those with only thin loess deposits. At least in some examples of this system, tree species normally associated with bottomland habitats are found to be abundant or even dominant in non-flooded uplands. In many cases, the bluffs provide habitat "refugia" for plant species that are more common to the north. The general composition of these forests along the bluffs changes from north to south; the more northerly examples are represented in this classification by ~East Gulf Coastal Plain Northern Loess Bluff Forest (CES203.481)$$, north of the range of *Magnolia grandiflora* and *Pinus glabra*. As currently defined this system ranges from about 32°N latitude (where the Big Black River dissects the bluffs) southward and is restricted to the southern part of the Loess Bluff Hills (EPA Ecoregion 74a).

Related Concepts:
- White Oak: 53 (Eyre 1980) **<**

Distribution: This system is endemic to the loess bluffs ("Bluff Hills" [Ecoregion 74a] of EPA (2004)) and the immediately adjacent Southern Rolling Plains (western portion of EPA Ecoregion 74c) along the eastern edge of the Mississippi River Alluvial Plain in southwestern Mississippi and adjacent Louisiana.

Nations: US

Concept Source: R. Wieland and R. Evans

Description Author: R. Wieland, R. Evans, M. Pyne

CES203.556 CONCEPTUAL MODEL

Environment: This system occupies upland loess bluffs, ravines, and adjacent plains that are considerably higher in elevation than the adjacent Mississippi River Alluvial Plain. These bluffs consist of a belt of Pleistocene and Tertiary eolian deposits (Braun 1950) that are often deeply eroded and very steep, with fertile topsoil and abundant moisture. In many cases, the bluffs provide habitat "refugia" for plant species that are more common to the north (Delcourt and Delcourt 1975).

Key Processes and Interactions: Considering the southern bluffs in conjunction with a portion of the adjacent plains, along with proximity to the Gulf of Mexico, stands of this system tend to be somewhat less stable and more fire-prone than the bluffs alone to the north (Landfire 2007a). As modeled here, replacement disturbance has roughly equal probability of occurring by either fire or weather-related events. The latter include windthrow, lightning and ice damage, as well as the inclusion of the erosion and mass wastage that give the bluffs their characteristic steepness. Widespread insect or disease mortality has not been reported. Wind/weather/stress replacement frequency is modeled near 220 years, replacement fire return at approximately 215 years, and all fire return frequency at about 40 years. "Open" structure is uncommon, even when defined as canopy closure <81%, and may be created by mixed-severity fire. Surface fire may maintain open conditions, but it does not transition closed classes. Disturbance is presumed to occur primarily in small gaps (less than one-half acre). The presence of aggregates of intolerant species suggests that larger scale disturbances occasionally play a role, likely more so on the plains (Landfire 2007a). Periodic droughts will cause death of or stress to moisture-requiring canopy trees.

Threats/Stressors: Conversion of this type has primarily resulted from repeated canopy removal through logging, which is also the most critical anthropogenic threat. These sites were historically less frequently logged than the adjacent pine-dominated uplands, with more desirable species being removed in preference to *Fagus grandifolia*, which is less desirable in the lumber trade. In addition, some mesic hardwood forests in more moderately dissected terrain have been converted to pine plantations or impacted (destroyed or fragmented) by agriculture. Bluff habitats are often prime sites for development, especially along major rivers. Complete devastation by natural agents was probably very rare in this forest type (Batista and Platt 1997). These forests also suffer the effects of ozone and acidic atmospheric deposition.

Aside from actual site conversion, feral hogs (*Sus scrofa*) represent one of the greatest threats to biodiversity in these forests (Engeman et al. 2007). They can be especially difficult to control in sensitive slope forests (Edwards et al. 2013). In addition, invasive exotic species including *Lygodium japonicum, Lonicera japonica*, and *Ligustrum sinense* can become dominant in the ground and shrub layers following canopy disturbance (Edwards et al. 2013).

The most significant potential climate change effects over the next 50 years include periods of drought, which has affected parts of the coastal plain. Droughts will affect the health and survival of the moisture-requiring trees, as well as increase the probability of damaging wildfire.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (including *Fagus grandifolia*) to regenerate. Periods of drought will also affect the health and survival of the moisture requiring trees. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Ecological collapse can also result from such severe fragmentation (as in remnant patches left scattered among developments and roads) that wildlife is driven out and natural processes are lacking. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and other disturbance. Feral hogs and other non-native species can significantly impact forest composition and structure (Engeman et al. 2007, Edwards et al. 2013).

CES203.242 Southern Atlantic Coastal Plain Mesic Hardwood Forest

CES203.242 CLASSIFICATION

Concept Summary: This upland system of the Atlantic Coastal Plain ranges from Delaware south to interior Georgia in a variety of moist but non-wetland sites that are naturally sheltered from frequent fire. Such sites include lower slopes and bluffs along streams and rivers in dissected terrain, mesic flats between drier pine-dominated uplands and floodplains, and local topographic high areas within bottomland terraces or nonriverine wet flats. Soil textures are variable in both texture and pH. The vegetation consists of forests dominated by combinations of trees that include a significant component of mesophytic deciduous hardwood species, such as *Fagus grandifolia* or *Acer floridanum*. Its southern limit is generally exclusive of the natural range of *Pinus glabra* and *Magnolia grandiflora*. Upland and bottomland oaks at the mid range of moisture tolerance are usually also present, particularly *Quercus alba*, but sometimes also *Quercus pagoda, Quercus falcata, Quercus michauxii, Quercus shumardii*, or *Quercus nigra*. *Pinus taeda* is sometimes present, but it is unclear if it is a natural component or has entered only as a result of past cutting. Analogous systems on the Gulf Coastal Plain have pine as a natural component, and this may be true for some examples of this system. Understories are usually well-developed. Shrub and herb layers may be sparse or moderately dense. Within its range, *Sabal minor* may be a prominent shrub. Species richness may be fairly high in basic sites but is fairly low otherwise.

CES203.242 CONCEPTUAL MODEL

Environment: This system occurs in a variety of moist non-wetland sites that are naturally sheltered from frequent fire. The distribution of these forests is determined by the interaction of local topography and soil texture. Most common are lower slope and bluff examples along streams and rivers in dissected terrain, but some examples occur on mesic flats between drier pine-dominated uplands and floodplains or on local high areas within bottomland terraces or nonriverine wet flats. Soils cover the full range of mineral soil textures, except the coarsest sands. Richer and more mesic stands occur in more strongly concave and finer-textured areas. Soils are not saturated for any significant time during the growing season and seldom, if ever, are extremely dry. Soils developed from calcareous materials or rich alluvium may be basic; others are strongly acidic. Sites are protected from most natural fires by steep topography or by surrounding extensive areas of non-flammable vegetation (Batista and Platt 1997).

Key Processes and Interactions: Fire is naturally infrequent to absent in this system. Sites are protected from most natural fires by steep topography or by surrounding extensive areas of non-flammable vegetation (Landfire 2007a). If fire does penetrate, it is likely to be low in intensity but may have significant ecological effects. These forests probably generally exist naturally as old-growth forests, with canopy dynamics dominated by gap-phase regeneration. However, exposure to occasional fires and severe storms may create more frequent and larger canopy disturbances than analogous systems inland. Storm-related disturbance can be followed by waves of tree recruitment, growth, and death resulting in changes in the density and structure of tree populations and in consequent fluctuations in forest species composition. Disturbances in these forests appear to be critical for both regeneration and change in older stands (Batista and Platt 1997). Periodic droughts will cause death of or stress to moisture-requiring canopy trees.

Threats/Stressors: Conversion of this type has primarily resulted from repeated canopy removal through logging, which is also the most critical anthropogenic threat. These sites were historically less frequently logged than the adjacent pine-dominated uplands, with more desirable species being removed in preference to *Fagus grandifolia*, which is less desirable in the lumber trade. In addition, some mesic hardwood forests in more moderately dissected terrain have been converted to pine plantations or impacted (destroyed or fragmented) by agriculture. Bluff habitats are often prime sites for development, especially along major rivers. Complete devastation by natural agents was probably very rare in this forest type (Batista and Platt 1997). These forests also suffer the effects of ozone and acidic atmospheric deposition.

Aside from actual site conversion, feral hogs (*Sus scrofa*) represent one of the greatest threats to biodiversity in these forests (Engeman et al. 2007). They can be especially difficult to control in sensitive slope forests (Edwards et al. 2013). In addition, invasive exotic species including *Lygodium japonicum, Lonicera japonica*, and *Ligustrum sinense* can become dominant in the ground and shrub layers following canopy disturbance (Edwards et al. 2013). For mesic hardwood forests containing *Fraxinus* species or *Persea borbonia*, emerald ash borer (recently found in Georgia) and laurel wilt (spread by a non-native ambrosia beetle) may also be significant stressors, respectively.

The most significant potential climate change effects over the next 50 years include periods of drought, which has affected parts of the coastal plain. Droughts will affect the health and survival of the moisture-requiring trees, as well as increase the probability of damaging wildfire.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (including *Fagus grandifolia*) to regenerate. Periods of drought will also affect the health and survival of the moisture requiring trees. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Ecological collapse can also result from such severe fragmentation (as in remnant patches left scattered among developments and roads) that wildlife is driven out and natural processes are lacking. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and other disturbance. Feral hogs and other non-native species can significantly impact forest composition and structure (Engeman et al. 2007, Edwards et al. 2013).

CES203.502 Southern Coastal Plain Limestone Forest

CES203.502 CLASSIFICATION

Concept Summary: This system represents dry to dry-mesic deciduous forests of the East Gulf Coastal Plain where limestone, marl, or other calcareous substrates occur near enough to the surface to influence vegetation composition. Examples are most common in the Black Belt region of Alabama and Mississippi, but are also present in more isolated patches in other portions of the region, including western Alabama, eastern Georgia, and southwestern middle Tennessee. Generally, the vegetation consists of forests and woodlands on well-developed, deep soils. Related, but physiognomically distinct, vegetation surrounding rock outcrops and calcareous prairies is accommodated within other ecological systems.

Related Concepts:

- Eastern Redcedar: 46 (Eyre 1980) **<**
- Sugar Maple: 27 (Eyre 1980) **<**

Distribution: This system occurs in the East Gulf (and rarely the Atlantic) Coastal Plain, most commonly in the Black Belt region of Alabama and Mississippi. It is also present in more isolated patches in other portions of the region, including western Alabama, eastern Georgia, and marginally in southwestern middle Tennessee. It is also apparently found in the Tallahassee Hills/Valdosta Limesink Region EPA 65o (Florida, Georgia).

Nations: US

Concept Source: A. Schotz and R. Evans

Description Author: A. Schotz, R. Evans, M. Pyne

CES203.502 CONCEPTUAL MODEL

Environment: Stands typically occur on ridges and upper to middle slopes of the southern coastal plains where limestone, marl, or other calcareous substrates occur near enough to the surface to influence vegetation composition.

Key Processes and Interactions: Fire frequency and intensity are factors determining the relative mixture of deciduous hardwood versus evergreen trees in this system. Frequent surface fires occurred on a 5- to 10-year return interval from both lightning and Native American ignitions. These frequent light surface fires maintained the grassy understory and kept hardwoods and shrubs from dominating the understory and forming a midstory layer. Lightning fires occurred primarily during the spring dry season (April and May) with a secondary peak of Native American and settler burning during the fall (October and November) (Landfire 2007a). Occasionally, during extensive droughts, mixed-severity or stand-replacement fires did occur, especially in drier stands, or those containing *Juniperus virginiana* or rarely with *Pinus* species (e.g., *Pinus taeda* and/or *Pinus echinata*). In addition, local thunderstorm-caused blowdowns created gaps on a small but continual basis. More extensive regional disturbances included tropical storms during the growing season and ice storms during winter (in the northern part of the range). Dense stands of middle to older aged pines (where present) were susceptible to periodic mortality from bark beetle epidemics, and younger *Juniperus virginiana* trees were killed by periodic droughts.

Threats/Stressors: The most critical anthropogenic threats include removal of the characteristic dominant hardwoods and a lack of fire. Removal of the characteristic dominant hardwoods (primarily *Quercus* species and *Carya* species) through logging may result in a stand dominated by wind-blown or bird-dispersed tree species, including *Acer rubrum, Celtis* spp., *Fraxinus americana, Juglans nigra, Juniperus virginiana, Liquidambar styraciflua, Liriodendron tulipifera, Prunus serotina, Robinia pseudoacacia, Sassafras albidum, Ulmus americana*, and the exotic *Ailanthus altissima*. Lack of fire in the system leads to a closing of the subcanopy and consequent loss of ground layer diversity. Patches dominated by *Juniperus virginiana* (or rarely with *Pinus taeda* and/or *Pinus echinata*) are artifacts of past disturbance and succession in the absence of fire. These are likely to eventually succumb to drought, fire or insect damage (in the case of *Pinus* species, which are generally atypical due to the high base status in the soils). Another major threat is conversion to human-created land uses, including residential development, quarries, industrial development, and infrastructure development (TNC 1996c).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (*Quercus* species and *Carya* species) to regenerate. When this deterioration of the canopy is combined with the absence of fire, the floristic characters of the stand are lost entirely. Feral hog activity, combined with invasion of exotic species, can eradicate the native ground and shrub flora (Engeman et al. 2007, Edwards et al. 2013). Ecological collapse can result from conversion to human-created land uses, including residential development, quarries, industrial development, and infrastructure development (TNC 1996c).

CES203.476 Southern Coastal Plain Mesic Slope Forest

CES203.476 CLASSIFICATION

Concept Summary: This forested system of the southern East Gulf and Atlantic coastal plains occurs on steep slopes, bluffs, or sheltered ravines where fire is naturally rare, generally within the natural range of *Pinus glabra* and *Magnolia grandiflora*. Stands are mesic, and vegetation typically includes species such as *Fagus grandifolia, Magnolia grandiflora, Illicium floridanum*, and other species rarely encountered outside this system in the region. Related forests which occur on deep loess soils along the western margin of the region are classified as ~East Gulf Coastal Plain Southern Loess Bluff Forest (CES203.556)$$. Some component associations are also found in temporarily flooded floodplains adjacent to these slopes, but this is primarily an upland system. The system also includes essentially upland vegetation of Pleistocene terraces, although these are conceptually transitional to creek floodplain systems.

- Loblolly Pine - Hardwood: 82 (Eyre 1980) **<**
- Upland Mixed Hardwood Forest (Christensen 2000) **<**
- White Oak: 53 (Eyre 1980) **<**

Distribution: This mesic upland system of the southern (Atlantic and Gulf) coastal plains is found in suitable conditions from southern South Carolina south to northern Florida and west to (and including) the loessal plains of Mississippi and Louisiana. Its range is generally congruent with the natural range of *Pinus glabra* as mapped by Kossuth and Michael (1990) and *Magnolia grandiflora* as mapped by Outcalt (1990).

Nations: US

Concept Source: A. Schotz and R. Evans

Description Author: A. Schotz, R. Evans, M. Pyne and C. Nordman

CES203.476 CONCEPTUAL MODEL

Environment: This system is restricted to steep slopes, bluffs, or sheltered ravines where fire is naturally rare. This mesic habitat is confined to very limited, fire-sheltered areas within the natural ranges of *Pinus glabra* (Kossuth and Michael 1990) and *Magnolia grandiflora* (Outcalt 1990). This system occurs in a variety of moist, non-wetland sites that are naturally sheltered from frequent fire. These are typically narrow bands of vegetation between floodplain forests and upland communities dominated by *Pinus palustris* (Batista and Platt 1997). Most common are lower slope, bluff, and ravine examples along streams and rivers in dissected terrain, but some examples occur on mesic flats between drier pine-dominated uplands and floodplains or on local high areas within bottomland terraces or nonriverine wet flats. There may be larger patches where side -drains join larger streams. Under closed-canopy conditions, fire may only partially penetrate this system from adjacent uplands. Soils are typically deep, fine-textured, and moderately well-drained. Soils cover the full range of mineral soil textures, except for the coarsest sands. Soils are not saturated for any significant time during the growing season and seldom, if ever, are extremely dry. Soils developed from calcareous materials or rich alluvium may be basic; others are strongly acidic. Richer and more mesic stands occur in more strongly concave and finer-textured areas. Sites are normally protected from most natural fires by steep topography or by surrounding extensive areas of non-flammable vegetation. This system occurs in a region of mild winters, high annual rainfall and high evapotranspiration, as well as a high likelihood of hurricane landfall (Ware et al. 1993). These forests may represent relicts derived from the early Tertiary flora (Batista and Platt 1997).

Key Processes and Interactions: These are stable, fire-sheltered forests. Fire is naturally infrequent to absent in this system. Sites are protected from most natural fires by steep topography or by surrounding extensive areas of non-flammable vegetation (Landfire 2007a). If fire does penetrate, it is likely to be low in intensity but may have significant ecological effects. These forests probably generally exist naturally as old-growth forests, with canopy dynamics dominated by gap-phase regeneration. There is presumably some natural disturbance from the effects of hurricanes, which are relatively frequent in the range of this system, creating more frequent and larger canopy disturbances than analogous systems inland. Hurricanes can be followed by waves of tree recruitment, growth, and death resulting in changes in the density and structure of tree populations and in consequent fluctuations in forest species composition. Disturbances in these forests appear to be critical for both regeneration and change in older stands (Batista and Platt 1997). Periodic droughts will cause death of or stress to moisture-requiring canopy trees.

Threats/Stressors: Conversion of this type has primarily resulted from repeated canopy removal through logging, which is also the most critical anthropogenic threat. These sites were historically less frequently logged than the adjacent pine-dominated uplands, with more desirable species being removed in preference to *Fagus grandifolia*, which is less desirable in the lumber trade. In addition, some mesic hardwood forests in more moderately dissected terrain have been converted to pine plantations or impacted (destroyed or fragmented) by agriculture. Complete devastation by natural agents was probably very rare in this forest type (Batista and Platt 1997). These forests also suffer the effects of ozone and acidic atmospheric deposition.

Aside from actual site conversion, such as for residential development, feral hogs (*Sus scrofa*) represent one of the greatest threats to biodiversity in these forests (Engeman et al. 2007). They can be especially difficult to control in sensitive slope forests (Edwards et al. 2013). In addition, invasive exotic species including *Lygodium japonicum, Lonicera japonica*, and *Ligustrum sinense* can become dominant in the ground and shrub layers following canopy disturbance (Edwards et al. 2013).

The most significant potential climate change effects over the next 50 years (until the early 2060s) include periods of drought, which will affect the health and survival of the moisture requiring trees. Slope forests support many species at the southern edges of their ranges, which could be threatened by extreme warm temperatures. Plants which thrive in warmer temperatures and a longer growing season may increase while the plants typical of more northern areas could decline (Nordman 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (including *Fagus grandifolia*) to regenerate. Periods of drought will also affect the health and survival of the moisture-requiring trees. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Feral hog activity, combined with invasion of exotic species, can eradicate the native ground and shrub flora (Engeman et al. 2007, Edwards et al. 2013).

CES203.280 West Gulf Coastal Plain Mesic Hardwood Forest

CES203.280 CLASSIFICATION

Concept Summary: This ecological system is found in limited upland areas, including ravines and sideslopes, of the Gulf Coastal Plain west of the Mississippi River. These areas are topographically isolated from historically fire-prone, pine-dominated uplands in eastern Texas, western Louisiana, and southern Arkansas. Sites are often found along slopes above perennial streams in the region. These sites have moderate to high fertility and moisture retention. Soils can be quite variable, ranging from coarse to loamy in surface texture. Most are acidic in surface reactions and less commonly circumneutral. Vegetation indicators are mesic hardwoods such as *Fagus grandifolia, Quercus alba*, and *Ilex opaca*, although scattered, large-diameter pines (most often *Pinus taeda*) are also often present. Spring-blooming herbaceous species are typical in the understory of most examples.

- White Oak: 53 (Eyre 1980) **<**

Distribution: This system is limited to particular upland areas (especially ravines and sideslopes) of the Gulf Coastal Plain west of the Mississippi River, with some occurrences on Macon Ridge (a terrace ecoregion in the Mississippi River Alluvial Plain) in Louisiana.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, M. Pyne, E. Lunsford and L. Elliott

CES203.280 CONCEPTUAL MODEL

Environment: Sites are often found along slopes above perennial streams in the region. These sites have moderate to high fertility and moisture retention. Soils can be quite variable, ranging from coarse to loamy in surface texture. Most are acidic in surface reactions and less commonly circumneutral. It is found on Tertiary formations, from the Willis Formation in the south, northward through Eocene formations; it is primarily restricted to fairly rugged landscapes on ravines, steep slopes and low landscape positions, often near streams. It often occupies lower slope positions and adjacent steep slopes, where topographic position results in moisture accumulation and lower solar insolation. These sites may occur adjacent to bottomlands, but on more well-drained soils and/or slightly higher topographic positions (Elliott 2011).
Key Processes and Interactions: The mesic nature of sites occupied by this system, along with the topography of the sites and the limited fine fuel production in the system, results in reduced fire frequency.
Threats/Stressors:
Ecosystem Collapse Thresholds:

1.B.1.Nc. Californian Forest & Woodland

M009. Californian Forest & Woodland

CES206.935 California Central Valley Mixed Oak Savanna

CES206.935 CLASSIFICATION

Concept Summary: Historically, these savannas occurred on alluvial terraces and flat plains, often with deep, fertile soils, throughout the California Central Valley from Lake Shasta south to Los Angeles County. This system is found from 10-1200 m (30-3600 feet) elevation; receiving on average 50 cm (range 25-100 cm) of precipitation per year, mainly as winter rain. Variable canopy densities in existing occurrences are likely due to variation in soil moisture regime, natural patch dynamics of fire, and land use (fire suppression, livestock grazing, herbivory, etc.). *Quercus lobata* was the characteristic oak species of these savannas, though other species were present, including *Quercus wislizeni, Quercus agrifolia, Quercus douglasii, Aesculus californica, Cercis canadensis var. texensis, Juniperus californica*, and *Nassella pulchra*. There is some evidence that much of the understory prior to the invasion by non-native annual grasses and forbs was composed of native annual herbs such as *Hemizonia, Eriogonum, Trifolium, Gilia, Navarretia, Lupinus, Calycadenia, Lessingia, Lotus, Daucus*, and *Holocarpha* spp. There is considerable seasonal and annual variation in cover of understory species due to phenology and intra-annual precipitation and temperature variation.

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, M.S. Reid

CES206.935 CONCEPTUAL MODEL

Environment: These savannas historically occurred on alluvial terraces and flat plains, often with deep, well-drained fertile soils, throughout the California Central Valley from Lake Shasta south to Los Angeles County. This system is found from 10-1200 m (30-3600 feet) elevation; receiving on average 50 cm (range 25-100 cm) of precipitation per year, mainly as winter rain. Summers are generally hot and dry. Variable canopy densities in existing occurrences are likely due to variation in soil moisture regime and natural patch dynamics of fire, also intra-annual precipitation and temperature variability result in variability in cover of plants.

Key Processes and Interactions: Fire regime: frequent surface fires since good fuels of grasses, and carried from adjacent grasslands. Summer to early fall; FRI 5-100+ (Sawyer et al. 2009). Very productive and fire-prone landscape. From Sawyer et al. (2009): Literature describing post-fire natural regeneration and long-term fire recovery of *Quercus lobata* woodlands is minimal. Plants have the ability to survive fire, and stands probably burned frequently and hot with dry grasses and oak litter carrying surface fires. Larger mature trees are usually resistant to moderate-severity fire because of their thick bark. While seedlings and saplings are top-killed by such fire, juveniles sprout from root crowns. However, older mature trees that are top-killed do not have this same ability. Animals such as scrub jays also facilitate regeneration of *Quercus lobata*, because they prefer burned areas as acorn-caching sites, and buried acorns usually survive fire (Howard 1992, Wills 2006). Hot surface fires may kill large trees that have extensive internal rot, and usually kill small trees. Crown fires will kill a large number of valley oak of all size classes (Howard 1992). Herbivory from ungulates winter range; ground burrowers; oak regeneration is dependent upon bare soil and dispersal from birds/small mammals burial of seeds. Valley oak regeneration to replace mature trees is lower than in other deciduous oak species (Landfire 2007a). Some studies indicate that this is due to a rare occurrence of necessary climate conditions, such as a warm summer followed by several wet years.

Threats/Stressors: Conversion of this type has commonly come from intensive clearing for irrigated agricultural land, urbanization and other purposes (other development). From Sawyer et al. (2009): it's estimated that approximately 90% of *Quercus lobata* stands that existed prior to European contact have been destroyed by urbanization and intensive land conversion. What remains of these forests are only remnants of what once existed in the Central Valley, other valleys, and foothill locations in California (Allen-Diaz et al. 2007). The remaining patches occur in a matrix of agricultural, urban and suburban land, and annual grasslands.

Common stressors and threats include land use (fire suppression, livestock grazing, herbivory, etc.); recent oak fungal pathogens; some studies suggest that low levels of recruitment may be related to competition from exotic grasses and forbs (Wills 2006), drought, rodent and insect damage, grazing by cattle, seedling and acorn predation by wild and domestic animals (Landfire 2007a). *Quercus lobata* is dying in some areas due to lower water tables and the accumulation of saline irrigation runoff. Low rates of *Quercus lobata* regeneration result in low replacement of mature trees and habitat loss. Infrequent fires result in more significant understory of shrubs and non-native herbs (e.g., *Bromus* spp., *Avena* spp., *Frangula californica ssp. tomentella (= Rhamnus tomentella), Rhamnus ilicifolia*, and *Heteromeles arbutifolia*). Modified water patterns and non-native plants have affected most remaining stands. Problems facing managers include lack of sapling recruitment, loss of mature trees because of lowered water tables, and saline irrigation runoff. Mature trees are sensitive to overwatering, pruning, grade changes, and asphalt covering their root systems. Feral pigs cause considerable damage (Howard 1992). Sawyer et al. (2009) continued: Due to fire exclusion, valley oak woodlands frequently contain an understory of shrubs, evergreen oaks and conifer saplings and trees, and a deep litter of oak leaves, needles, and downed woody debris. Prescribed burning in non-drought years could increase oak abundance. More regular fires could reduce or eliminate invasion by evergreen oaks and conifers and open up sites for valley oak seedling establishment or oak sprouting. However, the threat of severe fire in oak stands has increased greatly where valley oak woodlands border conifer forests. Also, deeply fire-scarred trees are susceptible to various heart-rot fungi and to windthrow (Howard 1992).

In the Central Valley, regional climate models project mean annual temperature increases of 1.4-2.0°C (1.8-3.6°F) by 2070. The projected impacts will be warmer winter temperatures, earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 47-175 mm (1-7 inches) by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Potential climate change effects could include: deep-rooted or phreatophytic species under greater stress and death; drop in groundwater table; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favoring certain invasive species (Brooks and Minnich 2006); and increased competition for water from all users stresses the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from (adapted from WNHP 2011): cessation of regular fire resulting in dominance of conifers and loss of the *Quercus lobata* trees or shrubs from the occurrence; a lack of oak regeneration due to lack of fire or seed dispersal or feral pig damage; loss of mature oaks due to lowered water tables, fungal-induced heart rot; increased salinity from agricultural runoff, windthrow, or severe fires; heavy invasion of exotic plant species, displacing the native grasses and forbs; occurrences are small in size (less than 5 acres/2 ha) and surrounded by non-natural land uses; logging activity has removed mature oaks, and remaining trees are of a single age class and younger than 100 years.

Environmental Degradation (adapted from WNHP 2011): High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; fire is no longer occurring, there is severe departure from the historic regime (FRCC = 3); water tables have dropped and soils are polluted with irrigation runoff. Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2).

Disruption of Biotic Processes (adapted from WNHP 2011): High-severity disruption of biotic processes appears where greater than 30% absolute cover of exotic invasives; non-native species dominate understory with minor native component (native species cover in shrub and herb layers <50%); conifers have >50% relative cover of the trees; overall species richness has declined, with fewer than 4 of the expected native species occurring in the shrub or herb layers; mature oaks have been lost due to lowered water tables, fungal-induced heart rot, increased salinity from agricultural runoff, windthrow, or severe fires; feral pigs are destroying regeneration layers. Moderate-severity appears where exotic invasives prevalent with 5-30% absolute cover; native species have 50-90% of the cover, non-natives can be codominant; conifers present but have not overtopped the oaks; overall species richness has declined, but at least 4 to 9 of the expected native species occurring in the shrub or herb layers; some of the mature oaks have been removed by logging, most oaks are <100 years of age.

CES206.922 California Coastal Closed-Cone Conifer Forest and Woodland

CES206.922 CLASSIFICATION

Concept Summary: Small occurrences of this system may be found in scattered locations along California's entire coastline and onto the Channel Islands. They are found on marine sedimentary, non-metamorphosed features, often with podsols on sterile sandstone. These forests and woodlands are limited to coastal areas with moderate maritime climate and likely receive more annual precipitation than nearby coastal chaparral. Highly localized endemic tree species include *Hesperocyparis macrocarpa, Hesperocyparis goveniana*, and *Hesperocyparis abramsiana* in scattered groves along coastal Mendocino, San Mateo, Santa Cruz, and Monterey counties. *Pinus contorta var. contorta, Pinus contorta var. bolanderi, Pinus muricata, Pinus torreyana*, and *Pinus radiata* are dominant or codominant in these and other occurrences. These occurrences can also include pygmy woodland expressions where nearly lateritic subsoil underlies acidic sands (ancient marine terraces). Stunted and twisted *Pinus contorta var. contorta* stands along the Oregon coast (often called pygmy forests) are also part of this system. Other associated plant species include *Arctostaphylos nummularia, Ledum groenlandicum, Vaccinium ovatum, Gaultheria shallon, Rhododendron macrophyllum*, and *Morella californica*. The lichen and moss component of this system is very diverse, includes *Cladonia* spp., and can be abundant in these communities.

Related Concepts:
- Knobcone Pine: 248 (Eyre 1980) **>**
- Lodgepole Pine: 218 (Eyre 1980) **><**

Distribution: This system is found in scattered locations along California's entire coastline and onto the Channel Islands and possibly just into southern Oregon in southern Coos and Curry counties.

Nations: MX, US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, M.S. Reid and G. Kittel

CES206.922 CONCEPTUAL MODEL

Environment: These woodlands occur in fire-prone, seasonally dry and nutritionally poor locations, in areas with a Mediterranean climate (Barbour 2007). Found in scattered locations along California's entire coastline and onto the Channel Islands, as well as along the southern Oregon coast and on two small Islands off the coast of Baja California, Mexico. These forests and woodlands are limited to coastal areas with moderate maritime climate and likely receive more annual precipitation than nearby coastal chaparral; fog drip can be an important source of moisture in some stands. They are found on marine sedimentary, non-metamorphosed features, often with Podsols on sterile sandstone. These occurrences can also include pygmy woodland expressions where nearly lateritic subsoil underlies acidic sands (ancient marine terraces). The soils are excessively well-drained in most cases, but stands of *Pinus contorta var. bolanderi* occur on poorly drained Spodosols.

Key Processes and Interactions: These woodlands typically are found in sharply demarcated localized groves with a single-aged and monospecific overstory (Barbour 2007). The dominant trees are mostly serotinous in fire response (Davis and Borchert 2006), requiring heat to open the closed cones. Degree of serotiny varies widely across these species, along a continuum of conditions, but all are serotinous to some degree (Keeley and Zedler 1998, Barbour 2007). *Pinus torreyana* is reported to shed seeds from third-year cones and continuously from those cones for several years (Lanner 1999). The seeds are wingless and large, suggesting they are animal dispersed and cached in the ground which protects them from fires. Most of the closed-cone conifers are killed in crown fires because they grow in or near highly flammable chaparral (Barbour 2007). Moreover, they self-prune poorly, typically retaining lower limbs to within a meter of the ground surface (Barbour 2007) so fire easily carries into the canopy. Because they often grow in dense thickets of small-stemmed individuals, they may burn intensely even in the absence of chaparral. Basically, the fire regime of many closed-cone conifers is the same as that of the surrounding shrublands and particularly characterizes *Hesperocyparis sargentii, Hesperocyparis forbesii, Hesperocyparis stephensonii, Pinus coulteri*, and *Pinus attenuata* (Landfire 2007a). The typical fire regime for most adjacent communities is known to have a return interval of less than 50 years (Barbour 2007).

Postfire regeneration of these species is closely linked to the frequency of fire relative to cone bank accumulation. For example, *Hesperocyparis sargentii* needs at least 20 years between fires to accumulate a cone bank sufficient to regenerate the stand. *Pinus coulteri* likely needs at least 25 years and preferably 30 years to develop an adequate cone bank. Fires that kill a stand before an adequate cone bank is in place will disappear (immaturity risk) as has been observed in *Hesperocyparis forbesii* and *Hesperocyparis sargentii*. Fire opens closed cones but not all stands necessarily burn in crown fires. Some may burn in ground and surface fires (Landfire 2007a). Severe drought can cause mortality of the trees without triggering seed dispersal; some *Hesperocyparis* species are susceptible to cypress canker, a fungus (*Coryneum cardinale*) (Barbour 2007).

Threats/Stressors: Conversion of this type has commonly come from logging which has removed the trees entirely, development including urban and suburban expansion, road-building and mining, and stand-replacing fires with no seedling recruitment. Most of the dominant tree species in these woodlands are found in only a few localities each, making the occurrences particularly vulnerable to loss due to a variety of impacts (development, changes in fire regime, lack of cone bank before burning, drought, etc.). The two occurrences in Mexico are very small and one of them is being impacted by domestic goats which have removed all regeneration seedlings/saplings for decades. Fire suppression activities in adjacent fire-prone vegetation communities will continue to be a threat for the conifer stands. These already small and generally isolated stands are continuing to be fragmented and reduced in area by suburban development, mining (for clay, diatomaceous earth, and sand), and road-building (Barbour 2007), as well as development of oil fields and associated service roads. Fragmentation is significant in privately-owned areas with "ranchette" development and a dense road network. Firebreaks, disease and smog/air pollution are other threats that have recently increased due to proximity to large urban and suburban areas of California.

In the west central coast regions, regional climate models project mean annual temperature increases of 1.6-1.9°C by 2070. The projected impacts will be warmer winter temperatures, earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 61-188 mm by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011).

In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from cessation of regular fire resulting in senescence of the conifers without seed dispersal; a lack of conifer regeneration due to lack of fire or seed dispersal; loss of mature conifers due to clearing, cutting, disease, smog-induced weakness, windthrow; fragmentation due to roads, suburban expansion, mining; occurrences are small in size (less than 5 acres/2 ha) and surrounded by non-natural land uses.

Environmental Degradation: High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; fire is no longer occurring, there is severe departure from the historic regime (FRCC = 3). Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2).

Disruption of Biotic Processes: High-severity disruption of biotic processes appears where [I found little to nothing in the literature to suggest exotics are a problem; please confirm or tell me I've missed something!]; conifers are too old and are senescing; overall species richness has declined, with fewer than 4 of the expected native species occurring in the shrub or herb layers; mature conifers have been lost due to fungal diseases, smog-induced weakness, or lack of cone bank and hence no regeneration post-fire; feral goats (or pigs?) are destroying regeneration layers. Moderate-severity appears where [again, are exotics problematic in these woodlands?]; overall species richness has declined, but at least 4 to 9 of the expected native species occurring in the shrub or herb layers; some of the mature conifers have been lost due to fungal diseases, or smog-induced weakness; regeneration layers may have been reduced by feral goats (or pigs?).

CES206.937 California Coastal Live Oak Woodland and Savanna

CES206.937 CLASSIFICATION

Concept Summary: These *Quercus agrifolia*-dominated woodlands occur throughout the Pacific coastal areas from Sonoma County, California, south to Baja California. Occurrences vary in canopy cover from dense conditions that support sparse understory vegetation of *Rubus ursinus, Symphoricarpos mollis, Heteromeles arbutifolia*, and *Toxicodendron diversilobum*, to more open conditions with perennial bunchgrass understory. The latter typically occur on south-facing slopes with soils of variable depth. Variable canopy densities in existing occurrences are likely due to variation in soil moisture regime, natural patch dynamics of fire, and land use (fire suppression, livestock grazing, herbivory, etc.).

Related Concepts:

- California Coast Live Oak: 255 (Eyre 1980) **>**
- Coast Live Oak Woodland (202) (Shiflet 1994) **>**

Distribution: Pacific coastal areas from Sonoma County, California, south to Baja California.

Nations: MX, US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, M.S. Reid

CES206.937 CONCEPTUAL MODEL

Environment: This system is found mainly below 500 m elevation in foothill environments (but up to 1200 m) on alluvial terraces, canyon bottoms, streambanks, slopes, and flats. It is typically found within 100 km of the coast, largely within the coastal fog belt (Allen-Diaz et al. 2007). Soils are moderately to well-drained, deep, sandy or loamy with high organic matter. More open occurrences with perennial bunchgrass undergrowth are typically on south-facing slopes with soils of variable depth. Annual precipitation is 40-80 cm, with January mean minimum daily temperatures of 5-10°C and July mean maximum daily temperatures of 18-23°C.

Key Processes and Interactions: From Sawyer et al. (2009): Dominant tree root system contains both roots that tap groundwater and extensive surface-feeding ones (Callaway 1990, as cited in Sawyer et al. 2009). It is the most susceptible of the California oaks to soil drought.

Fire is the dominant disturbance mechanism. Fire severity can range from high in oak woodlands with a high shrub component to moderate or low in open woodlands and savannas with a grass understory. Historically, fire occurred frequently, and the dominant oaks are resistant to low-intensity surface fires (Allen-Diaz et al. 2007). Lightning-ignited fires are uncommon but human-ignited fires may have occurred frequently given the propensity of aboriginal cultures to burn foothill environments (Keeley 2002, Landfire 2007a). Fire history does exert some effect on fire mosaic turnover, although the effect appears to be short-lived. Also, productivity (e.g., high cover of flammable shrubs and grasses) does not seem to be as strong a control on fire occurrence as meteorology (i.e., hot, dry wind events) in these systems (Landfire 2007a).

From Sawyer et al. (2009): Large trees are exceptionally fire-resistant with the thickest bark of any California oak. They generally recover well from a fire, although severely burned crowns, trunks, and root crowns may require several years to sprout. Smaller trees are less resistant, but even low to moderately severe fires often kill seedlings and saplings. Stands may attain 80 to 100% of their pre-fire densities within 10 years after fire, though fire-return intervals in natural conditions vary widely (Steinberg 2002b, Sugihara et al. 2006).

Threats/Stressors: Conversion of this type has commonly come from residential and urban development; conversion to agriculture (clearing for rangeland and pastures). Common stressors and threats include widespread mortality of oaks from exotic pathogen sudden oak death syndrome (*Phytophthora ramorum*) (Allen-Diaz et al. 2007); land use (fire suppression, livestock grazing, herbivory, etc.). Frequent fires may create shrublands or limit oak invasion of chaparral and grasslands (Mensing 1998), while long fire-free intervals may have allowed an oak expansion (Van Dyke et al. 2001). Some studies suggest that low levels of recruitment may be related to competition from exotic grasses and forbs (Wills 2006), drought, rodent and insect damage, grazing by cattle, seedling and acorn predation by wild, and domestic animals (Landfire 2007a).

In the west central coast regions, regional climate models project mean annual temperature increases of 1.6-1.9°C by 2070. The projected impacts will be warmer winter temperatures, earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 61-188 mm by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011).

In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain (PRBO Conservation Science 2011). Potential climate change effects could include (PRBO Conservation Science 2011): deep-rooted or phreatophytic species under greater stress and death; drop in groundwater table; more and larger fires; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006); and increased competition for water from all users, and stresses on the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from (adapted from WNHP 2011): too frequent fires resulting in shrub-fields; a lack of oak regeneration due to lack of fire or seed dispersal or feral pig damage; loss of mature oaks due to fungal-induced heart rot, windthrow, or severe fires; heavy invasion of exotic plant species, displacing the native grasses and forbs; occurrences are small in size (less than 5 acres/2 ha) and surrounded by non-natural land uses; clearing activity has removed mature oaks, and remaining trees are of a single age class and younger than 100 years.

Environmental Degradation (adapted from WNHP 2011): High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; fire is no longer occurring, there is severe departure from the historic regime (FRCC = 3). Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2).

Disruption of Biotic Processes (adapted from WNHP 2011): High-severity disruption of biotic processes appears where greater than 30% absolute cover of exotic invasives; non-native species dominate understory with minor native component (native species cover in shrub and herb layers <50%); overall species richness has declined, with fewer than 4 of the expected native species occurring in the shrub or herb layers; mature oaks have been removed by clearing, logging or have fungal-induced heart rot; feral pigs are destroying regeneration layers and eating acorns. Moderate-severity appears where exotic invasives prevalent with 5-30% absolute cover; native species have 50-90% of the cover, non-natives can be codominant; overall species richness has declined, but at least 4 to 9 of the expected native species occurring in the shrub or herb layers; some of the mature oaks have been removed by clearing or logging, most oaks are <100 years of age.

CES206.936 California Lower Montane Blue Oak-Foothill Pine Woodland and Savanna

CES206.936 CLASSIFICATION

Concept Summary: This ecological system is primarily found in the valley margins and foothills of the Sierra Nevada and Coast Ranges of California from approximately 120-1200 m (360-3600 feet) in elevation on rolling plains or dry slopes. Over a century of anthropogenic changes (especially cutting of oak) have altered the density and distribution of woody vegetation. A high-quality occurrence often consists of open park-like stands of *Pinus sabiniana*, with oaks and other various broadleaf tree and shrub species, including *Quercus douglasii, Quercus wislizeni, Quercus agrifolia* (primarily central and southern Coast Ranges), *Quercus lobata, Aesculus californica, Arctostaphylos* spp., *Cercis canadensis var. texensis, Ceanothus cuneatus, Frangula californica, Ribes quercetorum, Juniperus californica*, and *Pinus coulteri* (central and southern Coast Ranges). *Pinus sabiniana* tends to drop out all together in the driest and more southerly sites, which are often dominated by *Quercus douglasii*. The California central coast region may have open stands of just *Juniperus californica*, with a grassy understory. These stands belong here due to proximity to other blue oak and gray pine stands or chaparral, and due to the heavy native or non-native grass cover. This is distinguished from Great Basin pinyon-juniper stands, which have little herbaceous understory, and *Pinus monophylla* rather than *Pinus sabiniana*. These stands of only juniper are caused by repeated removal of the oaks by humans and feral pig populations. Northern extensions of this system include *Quercus garryana* as the dominant oak, where it becomes successional to ~Mediterranean California Lower Montane Black Oak-Conifer Forest and Woodland (CES206.923)$$. *Pinus sabiniana* density also varies based on intensity or frequency of fire, being less abundant in areas of higher intensity or frequency, hence it is often more abundant on steep, rocky or more mesic north-facing slope exposures. Historically, understory vegetation included mixed chaparral to perennial bunchgrass. Currently, most occurrences have understories dominated by dense cover of annual species, both native and non-native. Variable canopy densities in existing occurrences are likely due to variation in soil moisture regime, natural patch dynamics of fire, and land use (fire suppression, livestock grazing, herbivory, etc.).

- Blue Oak Woodland (201) (Shiflet 1994) **>**

Distribution: This system occurs primarily in the valley margins and foothills of the Sierra Nevada and Coast Ranges from approximately 120-1200 m (360-3600 feet) elevation, from Shasta County to Kern and northern Los Angeles counties, California. It is unlikely to occur in the southern portion of zone 7 (Modoc Plateau), but this needs to be confirmed with California ecologists.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.936 CONCEPTUAL MODEL

Environment: Soils are shallow, low in fertility, and moderately to excessively drained with extensive rock fragments. It occurs on valley margins and foothills, rolling plains or dry slopes, and generally steeper and drier slopes than pure blue oak woodlands without foothill pine. Mediterranean climate with mild winter rain (not snow) and very hot summers. This system is extremely drought-tolerant. The upper elevational limit is 150 m in the north and 900 m in the south.

CES206.920 Central and Southern California Mixed Evergreen Woodland

CES206.920 CLASSIFICATION

Concept Summary: This system occurs from Monterey, California, south across the outer Central Coast Ranges to crests of Peninsular Ranges. It can occur on metasediments and granitics. In much of this area, conifers are relatively infrequent, *Pinus coulteri* occurs in scattered stands and *Pseudotsuga macrocarpa* picks up in Transverse Ranges south to Mexico. Characteristic tree species include *Quercus chrysolepis, Quercus agrifolia, Quercus kelloggii, Umbellularia californica, Acer macrophyllum*, and *Arbutus menziesii*. Historic fire frequency was likely higher in this system than in similar systems to the north.

CES206.923 Mediterranean California Lower Montane Black Oak-Conifer Forest and Woodland

CES206.923 CLASSIFICATION

Concept Summary: This ecological system is found throughout California's middle and inner North Coast Ranges, as well as the southern and eastern Klamath Mountains from 600-1600 m (1800-4850 feet) elevation, and the lower slopes of the western Sierra Nevada. It occurs in valleys and lower slopes on a variety of parent materials, including granitics, metamorphic and Franciscan metasedimentary parent material and deep, well-developed soils. It is characterized by woodlands or forests of *Pinus ponderosa* with one or more oaks, including *Quercus kelloggii, Quercus garryana, Quercus wislizeni*, or *Quercus chrysolepis*. *Pseudotsuga menziesii* may co-occur with *Pinus ponderosa*, particularly in the North Coast Ranges and Klamath Mountains. On most sites, the oaks are dominant, forming a dense subcanopy under a more open canopy of the conifers. On many sites, *Quercus kelloggii* is the dominant; in late-seral stands on more mesic sites, conifers such as *Pinus ponderosa* or *Pseudotsuga menziesii* will form a persistent emergent canopy over the oak. Stands may have shrubby understories (in the Klamath Mountains and Sierra Nevada) and, more rarely, grassy understories (in North Coast Ranges). Common shrubs include *Arctostaphylos viscida, Arctostaphylos manzanita, Ceanothus integerrimus*, and *Toxicodendron diversilobum*. Grasses can include *Festuca californica, Festuca idahoensis*, and *Melica* spp. Historical fire in this system was likely high frequency but of low intensity. Conifer species, such as *Pseudotsuga menziesii*, become more abundant with wildfire suppression.

Distribution: This system is found throughout California's middle and inner North Coast Ranges, as well as the Klamath Mountains from 600-1600 m (1800-4850 feet) elevation, and the lower slopes of the western Sierra Nevada.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.923 CONCEPTUAL MODEL

Environment: Mediterranean climate where winter temperatures can be from near freezing to 10°C. Snow occurs in winter at higher elevations, but does not last all season. Annual precipitation is 100 cm (Barbour et al. 2007). Low-intensity fires are frequent (every 7-10 year). Elevation ranges between 520 and 1525 m (1700-5000 feet) in the Coast Ranges, Klamath Mountains and Sierra Nevada on deep often productive soils. North-facing aspects tend to have more conifers, with more oak dominating on south, east and west exposures.

Key Processes and Interactions: LANDFIRE model information: Historical fire frequency was 5 to 30 years in this type. Fire intensities were probably low in open stands but increased in severity as woodland vegetation transitioned to a denser, closed-canopy type along watercourses. Vegetation is fire-tolerant and therefore fire severity is low. The natural fire regime was a type I regime in the upland. With the more dense vegetation and the occurrence of fuel ladders, fire severity would become mixed. The fire regime may reflect a type III in this more mesic habitat.

Insects and disease may impact individual trees (ponderosa pine) locally. Armillaria root rot, western pine beetle, western oak looper, western tent caterpillar, and the pine engraver have the greatest potential for damage.

CES206.919 Mediterranean California Mixed Evergreen Forest

CES206.919 CLASSIFICATION

Concept Summary: This ecological system occurs from the Santa Cruz Mountains (and locally in the Santa Lucia Mountains), California, north into southwestern Oregon throughout the outer and middle Coast Ranges on Franciscan Formation soils (metasedimentary sandstones, schists, and shales) with moderate to high rainfall. This system occurs just inland from the redwood belt of this region. It also occurs in southern California in more mesic, protected, cooler sites of the Transverse and Peninsular ranges. Historic fire frequency in this system was higher than for redwood-dominated systems (every 50-100 years). It is characterized by mixes of coniferous and broad-leaved evergreen trees. Characteristic trees include *Pseudotsuga menziesii, Quercus chrysolepis, Notholithocarpus densiflorus (= Lithocarpus densiflorus), Arbutus menziesii, Umbellularia californica*, and *Chrysolepis chrysophylla*. On the eastern fringe of this system, in the western Siskiyous, other conifers occur such as *Pinus ponderosa* and *Chamaecyparis lawsoniana*. In southern California (Transverse and Peninsular ranges), *Pseudotsuga macrocarpa* replaces *Pseudotsuga menziesii* but co-occurs with *Quercus chrysolepis* and sometimes *Quercus agrifolia*. *Calocedrus decurrens* is occasional. In the southern portion of the range, *Notholithocarpus densiflorus, Arbutus menziesii, Umbellularia californica*, and *Chrysolepis chrysophylla* become less important or are absent. In the Santa Lucia Mountains, stands of *Abies bracteata* are included in this system and are an unusual and unique component. These stands are a mixture of *Abies bracteata* and *Quercus chrysolepis*. The more northerly stands tend to have dense or diverse shrub understories, with *Corylus cornuta, Vaccinium ovatum, Rhododendron macrophyllum, Gaultheria shallon, Quercus sadleriana, Mahonia nervosa*, and *Toxicodendron diversilobum* being common. Southern stands are less diverse and more sparse; *Toxicodendron diversilobum* is the most constant shrub, with *Ribes* spp. occasionally present, along with much *Polystichum munitum*. Especially in the south, stands are restricted to fire-protected sites (extremely steep, northerly, mesic slopes and coves) where fires from adjacent chaparral systems do not carry.

CES206.909 Mediterranean California Mixed Oak Woodland

CES206.909 CLASSIFICATION

Concept Summary: This ecological system is found throughout the Sierra Nevada and Coast Range foothills and lower montane elevations from 600-1600 m (1800-4850 feet) on steep, rocky slopes where snow and cold temperatures occur. Fire frequency and intensity drive composition of this system, with *Quercus chrysolepis* dominant with less frequent fires. With frequent annual burning (at lower elevations and on warmer sites), this system is an open to dense woodland of large oaks with well-developed grassy understories of native perennial bunchgrass. The predominant oaks with the higher frequency fires include *Quercus kelloggii* and *Quercus garryana*, with *Quercus garryana var. garryana* codominant in the central and northern Coast Ranges and *Quercus garryana var. fruticosa* often codominant in the northwestern Coast Ranges as well as portions of the Sierra Nevada. *Quercus chrysolepis* becomes dominant with less frequent fires (but in Oregon this species is not important and occurs in a different system, either ~Mediterranean California Mixed Evergreen Forest (CES206.919)$$ or ~Mediterranean California Dry-Mesic Mixed Conifer Forest and Woodland (CES206.916)$$). The perennial bunchgrass component includes *Festuca idahoensis, Festuca californica, Elymus glaucus*, and *Danthonia californica* (close to the coast). A variety of native forbs also occur. Other characteristic species include *Toxicodendron diversilobum, Juniperus occidentalis*, and *Ceanothus cuneatus*. This system is similar to ~North Pacific Oak Woodland (CES204.852)$$ but does not include a conifer component, and *Quercus garryana* is not the only oak.

- Oregon White Oak: 233 (Eyre 1980) **><**

Distribution: This system is found throughout the Sierra Nevada and Coast Range foothills and lower montane of California and Oregon at elevations from 600-1600 m (1800-4850 feet).

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.909 CONCEPTUAL MODEL

Environment: Climate is Mediterranean, where winter temperatures can be from near freezing to 10°C. Snow occurs in winter at higher elevations, but does not last all season. Annual precipitation is 100 cm (Barbour et al. 2007). Low-intensity fires are frequent (every 7-10 years). This system occurs in the foothills of the Coast Ranges and Sierra Nevada between 600-1600 m (1970-5250 feet) in elevation on steep rocky slopes.

Key Processes and Interactions: LANDFIRE model information: Fire Regime I, primarily short-interval (e.g., <10 years) surface fires. Surface fires every 3-10 years maintained an open savanna-like structure. Fires can be mixed-severity, especially when closed-canopy conditions or additional species such as conifers and shrubs are present. Native burning was a significant factor in fire frequency of this type, but return intervals may increase significantly with a little distance from native settlements and valley bottoms.

Threats/Stressors:

Ecosystem Collapse Thresholds:

CES206.938 Southern California Oak Woodland and Savanna

CES206.938 CLASSIFICATION

Concept Summary: These oak woodlands and savannas occur in coastal plains, intermountain valleys, and low mountains (such as the San Jacinto Mountains) from Ventura County, California, south into Baja California, Mexico. *Quercus agrifolia, Quercus wislizeni, Quercus engelmannii, Quercus kelloggii*, and/or *Juglans californica* dominate a mixed closed or open canopy. Southern chaparral species such as *Adenostoma fasciculatum, Artemisia californica, Rhus integrifolia, Rhus ovata, Rhus trilobata, Ceanothus* spp., *Ribes* spp., and *Arctostaphylos* spp. are also characteristic. These woodlands may occur as remnant patches on offshore islands, where they include endemic species such as *Quercus tomentella* and *Lyonothamnus floribundus*. The California central coast region may have open stands of just *Juniperus californica*, with a grassy understory. These stands belong here due to proximity to other oak stands or chaparral, and due to the heavy native or non-native grass cover. This is distinguished from Great Basin pinyon-juniper stands, which have little herbaceous understory, and *Pinus monophylla* mixed with *Juniperus californica*. These stands of only juniper are caused by repeated removal of the oaks by humans and feral pig populations. Variable canopy densities in existing occurrences are likely due to variation in soil moisture regime, natural patch dynamics of fire, and land use (fire suppression, livestock grazing, herbivory, etc.). Most of these woodlands and savannas have been heavily altered through urban and agricultural development throughout southern California.

Related Concepts:

- California Coast Live Oak: 255 (Eyre 1980) **><**
- Coast Live Oak Woodland (202) (Shiflet 1994) **><**

Distribution: This system occurs in coastal plains and intermountain valleys from Ventura County, California, south into Baja California, Mexico.

Nations: MX, US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel and M.S. Reid

CES206.938 CONCEPTUAL MODEL

Environment: This system occurs in coastal plains, intermountain valleys, and low mountains (such as the San Jacinto Mountains). Soils are moderately to well-drained, deep, sandy or loamy with high organic matter. Elevation ranges from sea level to 2200 m, but generally at less than 1500 m elevation. It is found on variable aspects and topography with rainfall between 13-102 cm (5-40 inches).

Key Processes and Interactions: Variable canopy densities in existing occurrences are likely due to variation in soil moisture regime and natural patch dynamics of fire. Fire reduces the survivorship and growth of juvenile *Quercus engelmannii*, with seedlings especially sensitive. Stands with grassy understories tend to suffer minimal damage, but those with shrubby understories tend to top-kill the trees, which may sprout and survive (Sawyer et al. 2009). Natural fire-return intervals are 30-100 years, and occur primarily in summer to early fall. From Landfire (2007a): Typical regime is frequent, low-severity fire that likely exert positive influences on overstory productivity and canopy resilience to fire damage. Infrequent isolated areas of stand-replacement fire create gaps of grasslands that require patch-gap recruitment and edge recolonization over time. Grass fuels allow very frequent fire, up to annually. A high proportion of seedlings and saplings are top-killed in low- to moderate-severity fires. Mortality rates of different size trees decrease with increasing height and dbh. Mortality may be as much as 50-60% for trees less than 40 cm (15.7 inches) dbh. In plants that survive fires, there is a significant amount of resprouting (Lathrop and Osborne 1991, Lawson 1993, Steinberg 2002b).

Threats/Stressors: Most of these woodlands and savannas have been converted through urban and agricultural development throughout southern California. Common stressors and threats include residential development, increase and spread of exotic species, fire-suppression effects, and widespread mortality of oaks from exotic pathogen sudden oak death syndrome (*Phytophthora ramorum*). Cutting or logging and feral pigs repeatedly remove the oaks resulting in structural changes and loss of mature trees. Modified water patterns and non-native plants have affected most remaining stands. Problems facing managers include lack of sapling recruitment, loss of mature trees because of lowered water tables, and saline irrigation runoff. Mature trees are sensitive to overwatering, pruning, grade changes, and asphalt covering their root systems. Feral pigs cause considerable damage (Howard 1992).

From Landfire (2007a): Excessive burning or grazing may result in less canopy cover and more significant understory of herbs and shrubs (e.g., *Bromus* spp., *Avena* spp., *Eriogonum fasciculatum, Rhamnus ilicifolia*, and *Artemisia californica*). Research by Principe (2002 and unpubl. data) confirmed the findings of Osborne (1989) and Lathrop and Osborne (1991) that fire, even relatively frequent fire (return interval of 3 or more years), does not seem to be as important a mortality factor as others (drought and herbivory). Also, grazed areas appear to have lower numbers of juvenile oaks than ungrazed areas.

In the west central coast regions, regional climate models project mean annual temperature increases of 1.6-1.9°C by 2070. The projected impacts will be warmer winter temperatures, earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 61-188 mm by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Potential climate change effects could include (PRBO Conservation Science 2011): deep-rooted or phreatophytic species under greater stress and death; drop in groundwater table; more and larger fires; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006); and increased competition for water from all users, and stresses on the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from (adapted from WNHP 2011): cessation of regular fire resulting in dominance of conifers and loss of the dominant trees or shrubs from the occurrence; a lack of oak regeneration due to lack of fire or seed dispersal or feral pig damage; loss of mature oaks due to lowered water tables, fungal-induced heart rot, increased salinity from agricultural runoff, windthrow, or severe fires; heavy invasion of exotic plant species, displacing the native grasses and forbs; occurrences are small in size (less than 5 acres/2 ha) and surrounded by non-natural land uses; clearing activity has removed mature oaks, and remaining trees are of a single age class and younger than 100 years.

Environmental Degradation (adapted from WNHP 2011): High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; fire is no longer occurring, there is severe departure from the historic regime (FRCC = 3); water tables have dropped and soils are polluted with irrigation runoff. Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2).

Disruption of Biotic Processes (adapted from WNHP 2011): High-severity disruption of biotic processes appears where greater than 30% absolute cover of exotic invasives; non-native species dominate understory with minor native component (native species cover in shrub and herb layers <50%); conifers have >50% relative cover of the trees; overall species richness has declined, with fewer than 4 of the expected native species occurring in the shrub or herb layers; mature oaks have been lost due to lowered water tables, fungal-induced heart rot, increased salinity from agricultural runoff, windthrow, or severe fires; feral pigs are destroying regeneration layers. Moderate-severity appears where exotic invasives prevalent with 5-30% absolute cover; native species have 50-90% of the cover, non-natives can be codominant; conifers present but have not overtopped the oaks; overall species richness has declined, but at least 4 to 9 of the expected native species occurring in the shrub or herb layers; some of the mature oaks have been removed by clearing, most oaks are <100 years of age.

M015. Balconian Forest & Woodland

CES303.656 Edwards Plateau Dry-Mesic Slope Forest and Woodland

CES303.656 CLASSIFICATION

Concept Summary: This system occurs on dry to mesic, middle slopes of the rolling uplands and escarpments of the Edwards Plateau and similar sites in the adjacent Blackland Prairie region. The canopy is typically dominated or codominated by deciduous trees, including *Quercus buckleyi, Quercus sinuata var. breviloba, Ulmus crassifolia*, and/or *Celtis laevigata var. reticulata*. *Quercus fusiformis* and *Juniperus ashei* are often present and are sometimes codominant with deciduous species of this system. Canopy closure is variable, and this system can be expressed as forests or woodlands. The shrub layer may be well-represented, especially where the overstory canopy is discontinuous. Species such as *Aesculus pavia var. flavescens, Cercis canadensis var. texensis, Forestiera pubescens, Ungnadia speciosa, Ceanothus herbaceus, Sophora secundiflora, Rhus* spp., *Vitis* spp., and *Garrya ovata* may be present in the shrub layer. With the large amount of exposed rock, frequent accumulation of leaf litter, and significant canopy closure, herbaceous cover is generally sparse, with *Carex planostachys* often present. Woodland forbs such as *Tinantia anomala, Chaptalia texana, Nemophila phacelioides, Salvia roemeriana, Lespedeza texana*, and various ferns may also be present, these often being patchy in distribution.

- Edwards Plateau: Oak / Hardwood Slope Forest (904) [CES303.656.6] (Elliott 2011) **<**

Distribution: This system is expected to occur on dry-mesic slopes in the Edwards Plateau and Lampasas Cutplain.
Nations: US
Concept Source: L. Elliott and J. Teague
Description Author: J. Teague, M. Pyne and L. Elliott

CES303.656 CONCEPTUAL MODEL

Environment: This system occurs on dry-mesic, primarily north- and east-facing limestone slopes in the Edwards Plateau of Texas. In the adjacent Blackland Prairie region, it is found on limestone chalk cuestas (Elliott 2011). Stones and boulders are conspicuous on the soil surface. Soils are generally dark clay to clay loam and shallow. Steep Rocky and Steep Adobe Ecological Sites may be associated with this system (Elliot 2011).

CES303.660 Edwards Plateau Limestone Savanna and Woodland

CES303.660 CLASSIFICATION

Concept Summary: This upland system occurs primarily on soils derived from chalk or limestone of Cretaceous or Pennsylvanian origin in the Edwards Plateau; it forms the matrix within this ecoregion. It can also occur on limestone in the shortgrass regions of Texas and north into Oklahoma in areas such as the Arbuckle Mountains. This system is typified by a mosaic of evergreen oak forests, woodlands and savannas over shallow soils of rolling uplands and upper slopes within the Edwards Plateau and Lampasas Cutplain. *Quercus fusiformis* or *Juniperus ashei* typically dominate the canopy of this system. Other species may include *Quercus buckleyi, Quercus laceyi, Quercus stellata, Ulmus crassifolia, Fraxinus albicans, Quercus sinuata, Quercus vaseyana, Sophora secundiflora, Mahonia trifoliolata*, and *Diospyros texana*. Physiographic expression of this system varies from dense mottes (patches of forest where canopy cover approaches 100%) interspersed with grasslands to open savannalike woodlands with scattered individual or small groups of trees. Understories can contain various shrubs and graminoids, including *Cercis canadensis var. texensis, Forestiera pubescens, Sideroxylon lanuginosum, Diospyros texana, Rhus trilobata, Bouteloua* spp., *Schizachyrium scoparium, Nassella leucotricha, Carex planostachys, Aristida purpurea, Aristida oligantha, Liatris punctata var. mucronata, Stillingia texana, Symphyotrichum ericoides, Stenaria nigricans, Monarda citriodora*, and *Salvia texana*. Grasslands dominated by *Schizachyrium scoparium* occur in small patches within more closed woodlands and in larger patches between mottes or in open savannalike woodlands with scattered trees. Grasslands in this system tend to grade from shortgrass communities in the west to mixedgrass communities to the east. Substrate (limestone) determines the range of this system within given examples. Some disturbed areas of the western plateau are now dominated by mesquite woodland. Natural mesquite woodlands are believed to have occurred on the deeper soils of adjacent riparian systems.

Distribution: This system is found primarily within the Edwards Plateau ecoregion but can extend north into Oklahoma and into portions of the Southern Shortgrass region of Texas.

Nations: US

Concept Source: S. Menard and K. Kindscher

Description Author: S. Menard, K. Kindscher, J. Teague, M. Pyne and L. Elliott

CES303.660 CONCEPTUAL MODEL

Environment: This system is primarily found on Cretaceous limestones of the Edwards Plateau and Limestone (also referred to as Lampasas) Cutplain, but also associated with Pennsylvanian limestones of the Palo Pinto Formation and Winchell, Ranger, Home Creek limestone in the vicinity of Palo Pinto County, as well as on Cretaceous chalk formations in the northern Blackland Prairie and Cretaceous limestones of the western Crosstimbers and Rolling Plains. It ranges north into Oklahoma and is found on rolling to level upland topography, often on plateau tops, but also on gentle slopes. Soils are generally loams, clay loams, or clays, often with limestone parent material apparent. Low Stony Hill, Adobe, Clay Loam, and Shallow Ecological Sites are commonly associated with this system (Elliott 2011). Soil moisture and topography influence this system.

Key Processes and Interactions: Substrate (limestone) and topographic position primarily influence this system. Fire, grazing and browsing may also influence this system.

Threats/Stressors:

CES303.038 Edwards Plateau Mesic Canyon

CES303.038 CLASSIFICATION

Concept Summary: This ecological system is largely endemic to the Edwards Plateau ecoregion and occurs on canyon bottoms, mesic lower slopes and steep canyons, primarily in the Southern Balcones Escarpment, but also in the Eastern Balcones Escarpment. This system also includes cliff faces and lower slopes of boxed canyons occurring as narrow, sometimes long bands in areas often with seeps where moisture is consistently more available than on adjacent slopes. The tree canopy is generally closed. Common components include *Ulmus crassifolia, Juglans major, Quercus buckleyi, Quercus laceyi, Prunus serotina var. eximia* (becoming less common to the north), *Fraxinus albicans* (dominant in the northeastern plateau), *Quercus muehlenbergii*, and *Acer grandidentatum*. Canyon bottoms may have scattered *Quercus macrocarpa*. Substrate (limestone) and topographic position (north and east aspects and lower slopes) are the dominant characteristics of this system. Small seepage areas are often dominated by *Adiantum capillus-veneris*, with *Thelypteris ovata var. lindheimeri* on nearby moist habitats. Other prominent species include *Buddleja racemosa, Ungnadia speciosa*, and *Toxicodendron radicans ssp. eximium*. Fire probably plays little role in the system, while grazing and browsing (by native as well as exotic ungulates) may play an important role in recruitment and understory composition. Adjacent, drier slopes are usually dominated by various *Quercus* species and *Juniperus ashei*.

Distribution: Largely endemic to the Edwards Plateau ecoregion and occurs on canyon bottoms, mesic lower slopes and steep canyons, primarily in the Southern Balcones Escarpment, but also in the Eastern Balcones Escarpment.

Nations: US

Concept Source: L. Elliott and K.A. Schulz

Description Author: L. Elliott, K.A. Schulz, J. Teague

CES303.038 CONCEPTUAL MODEL

Environment: This system is largely endemic to the Edwards Plateau ecoregion. Examples are associated with lower Cretaceous limestones of the Edwards Plateau, often on the Glen Rose or related formations. This system occurs on mesic lower slopes (toeslopes), canyon bottoms, and onto the margins of adjacent valleys of small drainages, primarily in the Southern Balcones Escarpment, but also in the Eastern Balcones Escarpment (also on the Limestone Cutplain). Occurrences are generally found in steep canyons where insolation is minimal, or on lower positions on northern- or eastern-facing slopes. This system also includes areas of cliff faces and lower slopes of boxed canyons occurring as narrow, sometimes long bands in areas often with seeps where moisture is consistently more available than on adjacent slopes. Soils are rich loams, often very rocky, with little soil development. It includes Steep Rocky Ecological Site, in part (Elliott 2011).

Key Processes and Interactions: Substrate (limestone) and topographic position (northern and eastern aspects and lower slopes) are the dominant characteristics of this system. Fire probably plays little role in the system, while grazing and browsing (by native as well as exotic ungulates) may play an important role in recruitment and understory composition.

CES303.657 Llano Uplift Acidic Forest, Woodland and Glade

CES303.657 CLASSIFICATION

Concept Summary: This upland matrix system occurs primarily on coarse soils derived from the weathering of underlying Precambrian granites in the Llano Uplift region of Texas. The underlying intrusive granitic bedrock substrate determines the range of this system. It is composed of a mosaic of vegetation types, including closed-canopy forests, open woodlands, savannas and sparsely vegetated rock outcrops. Common trees include *Quercus marilandica, Quercus fusiformis, Quercus stellata, Carya texana, Ulmus crassifolia*, and *Prosopis glandulosa*. Subcanopy species may include *Diospyros texana, Aloysia gratissima, Ungnadia speciosa, Ziziphus obtusifolia var. obtusifolia, Eysenhardtia texana, Aesculus glabra var. arguta, Opuntia engelmannii var. lindheimeri, Yucca elata, Nolina texana*, and *Cylindropuntia leptocaulis*. Grasslands may be dominated by *Schizachyrium scoparium, Sorghastrum nutans, Panicum virgatum, Bouteloua hirsuta, Bouteloua curtipendula, Nassella leucotricha, Bothriochloa laguroides*, and *Plantago wrightiana*. Granitic glades and barrens are sparsely vegetated by crustose and foliose lichens, several ferns and fern allies, and cacti. This system also includes small (up to 16 m in diameter) shallow depressions that hold rainwater and support wetland flora including the Texas endemic, *Isoetes lithophila*.

- Llano Uplift: Post Oak Woodland (1604) [CES303.657.6] (Elliott 2011) **<**

Distribution: This system is restricted to the Llano Uplift region of Texas.
Nations: US
Concept Source: J. Teague and L. Elliott
Description Author: J. Teague and L. Elliott

CES303.657 CONCEPTUAL MODEL

Environment: This system is restricted to the Llano Uplift, also known as the central mineral region of Texas. Though named as an uplift because it is an intrusion of Precambrian metamorphic rocks and large granitic massifs, this area is generally lower in elevation than the surrounding Edwards Plateau (Walters and Wyatt 1982, Riskind and Diamond 1988). At a regional scale, it is a topographic bowl, though rock outcrops such as Enchanted Rock often produce dramatic increases in elevation at a local scale. Aside from these massif intrusions, topography is generally level to rolling. The substrate of granites, gneisses and schists determines the range of this system in central Texas. Elevation ranges from 251 to 686 m above sea level (825-2250 feet). Rainfall averages about 76 cm (30 inches), peaking in May or June and September. The central mineral region occupies approximately 1.5 million hectares in central Texas (Riskind and Diamond 1988). Mineralogy of the granitic material varies, with hornblende schist, graphite schist, quartz-feldspar gneiss and quartz-plagioclase-microcline rock common (Riskind and Diamond 1988). Soils are generally sandy loams, with gravelly soils common. They are generally acidic and coarse, resulting from weathering of the underlying granite. Many areas of exposed bedrock are present. Most frequently encountered Ecological Sites include Shallow Granite, Sandy Loam, Red Savannah, Gravelly Sandy Loam, Shallow Ridge, Granite Gravel, Sandstone Hill, and Granite Hill (Elliott 2011).
Key Processes and Interactions: This ecological system is a complex of vegetation types. The different physiognomies are maintained by an interaction between site conditions and disturbance dynamics. The forest patches, woodlands, savannas and grasslands are thought to have been maintained historically by various fire frequencies and intensities. In the absence of natural or prescribed fire, increased cover of woody vegetation has increased in some occurrences. Native grazing may have also played a role in preventing woody encroachment though the rough terrain of much of this system would have limited the extent of native grazers.
Threats/Stressors:
Ecosystem Collapse Thresholds:

M010. Madrean Lowland Evergreen Woodland

CES301.712 Guerrean Juniper Woodland

CES301.712 CLASSIFICATION

Concept Summary: Son bosques formados por árboles escuamifolios (hojas en forma de escama) del género *Juniperus* a los que se les conoce como táscate, enebro o cedro, con una altura promedio de 8 a 15 m de regiones subcálidas templadas y semifrías, siempre en contacto con los bosques de encino, pino-encino, selva baja caducifolia y matorrales de zonas áridas. Las especies más comunes y de mayor distribución son *Juniperus flaccida, Juniperus deppeana, Juniperus monosperma* y algunas especies del género *Quercus* y *Pinus*. Estas comunidades por lo regular, se encuentran abiertas como consecuencia de las actividades forestales, agrícolas y pecuarias principalmente en el norte del país. Este sistema es una variante sur de la ~Sabana de Táscate Madreana (CES301.730)$$. Ambas son templadas debido a la presencia de *Juniperus*, pero este sistema ocurre en áreas más xéricas del suroeste de México.

This system is dominated by escuamifolios trees forests (leaf-shaped flake) of the genus *Juniperus* those who are known as juniper, juniper or cedar, with an average height of 8-15 m regions warm-temperate, always in contact with the oak forests, pine-oak forest, deciduous forest and arid scrub. The most common and most widely distributed species are *Juniperus flaccida, Juniperus deppeana, Juniperus monosperma*, and some species of the genus Quercus and Pinus. In these communities, usually, are open as a result of forest, agricultural and livestock activities mainly in the north. This system is a southern variant of ~Madrean Juniper Savanna (CES301.730)$$. Both are temperate due to the presence of *Juniperus*, but this is more xeric south western Mexico.

CES301.712 CONCEPTUAL MODEL

Environment: [from M010] This type is common in foothills, mountains and plateaus in the Sierra Madre Occidentale and Sierra Madre Orientale in Mexico, Trans-Pecos Texas, southern New Mexico and Arizona, generally south of the Mogollon Rim. Stands occur on cool aspects of steep scarp slopes, in canyons (including alluvial terraces), on gently sloping alluvial fan piedmonts (bajadas), steeper colluvial slopes and ridges, as well as mesatops. Elevation generally ranges from 1300-2225 m with high-elevation stands restricted to warmer southern aspects. Pinyon and juniper woodlands extend down to 760 m elevation in Trans-Pecos ranges. Oak-dominated encinal stands may extend down along drainages to 900 m elevation in southern Sonora, but generally range from around 1350 m as woodland savannas on rolling hills intermixed with semi-desert grasslands. Encinal woodlands extend up to 1650-2200 m elevation in a mosaic within Madrean montane forests and woodlands (Brown 1982a). At the lowest elevation, encinal generally occupies the rockier substrates or is restricted to drainages within grasslands (Brown 1982a). Ground cover often has high cover of rock or bare ground. *Soil/substrate/hydrology:* Soils are variable, but are generally thin and rocky, but may include deeper clay loamy to gravelly loamy soils, especially on sites dominated by pinyon and junipers.

Key Processes and Interactions: [from M010] Dynamics are complicated by the diverse plant communities present in this macrogroup. The pinyon-juniper woodlands and savannas included in this macrogroup are represented by what Moir and Carleton (1987) classified as the High Sun Mild climate zone (summer precipitation and warm climate). Romme et al. (2003) developed a pinyon-juniper classification with three types based on canopy structure, understory composition, and historic fire regime. All three types, pinyon-juniper grass savanna, pinyon-juniper shrub woodland, and pinyon-juniper forest, are included in this macrogroup. However, the pinyon-juniper grass savanna and a new, ecologically similar type with tree canopy >10% cover (pinyon-juniper grass open woodland) have the greater aerial extent in the macrogroup (Landis and Bailey 2005, Gori and Bate 2007). Other types are the pinyon-juniper shrub woodland, represented by pinyon-juniper trees with an understory of shrubs such as *Quercus turbinella*, and the pinyon-juniper forest type that has a typically sparse understory and is restricted to dry, rocky areas or following fires (Romme et al. 2003).

Fire dynamics for these types under historic natural conditions (also called natural range of variability (NRV); for pre-1900 timeframe) are summarized as follows based on (Romme et al. 2003). The fire regime for the pinyon-juniper grass savanna/pinyon-juniper grass open woodland includes frequent, low-severity surface fires that are carried by the herbaceous layer. The low density of trees (5-20% cover) and high perennial grass cover is maintained by this fire regime. Mean fire interval is estimated to be 12-43 years (Gori and Bate 2007). The fire regime for the pinyon-juniper shrub woodland has moderately frequent, high-severity crown fires that are carried by the shrub and tree layers. After a stand replacing fire the site begins at early seral stage and returns to a moderately dense tree layer with a moderate to dense shrub layer. Succession happens relatively quickly if the shrub layer includes chaparral species that recover rapidly from fire by re-sprouting or from fire scarified seeds in a seed bank. Mixed-severity fires may alter this pattern by creating a mosaic of pinyon-juniper states (early-, mid-, and late-seral). Mean fire interval is estimated to be 23-81 years (Gori and Bate 2007). The fire regime for the pinyon-juniper forest type has very infrequent, very high-severity fires that are carried by tree crowns. The stand dynamics are stable with multi-age tree canopy and with little change in shrub or herbaceous layers.

Pinyon and juniper stands in this macrogroup have been impacted by human activities over the last century. Historical fire regimes were disrupted following the introduction of livestock (and the 1890s drought). Grazing passively suppresses fire by removing fine fuels needed to carry surface and mixed-severity fires that likely maintained the structure and composition of pinyon-juniper savannas and pinyon-juniper shrub woodlands historically. Active fire suppression was also practiced by the Federal government during the last 100 years (Swetnam and Baisan 1996b). As fire became less frequent, pinyon and juniper trees became denser and subsequent fires became more severe (Gori and Bate 2007). These impacts altered stand dynamics differently depending on stand structure. Fire dynamics under current conditions are summarized for the three major pinyon-juniper types (pinyon-juniper grass savanna/open woodland, pinyon-juniper shrub woodland, and pinyon-juniper forest) developed by Romme et al. (2003) using canopy structure, understory composition, and historic fire regime and adapted for our use as follows.

The fire regime for the pinyon-juniper grass savanna/open woodland has a fire frequency that is significantly reduced and fire severity has greatly increased from pre-1900, from low-severity surface fires towards high-severity and stand-replacing crown fires. Tree density has increased and herbaceous biomass has decreased from historic conditions with active fire suppression and livestock grazing. Currently stands have some very old trees (>300 years) present but not numerous, and are typically dominated by many young trees (<150 years). This type may also occur on sites with more rock soil and less grasses. This type is outside Historic Range of Variation (HRV) for disturbance regime, structure and composition (Gori and Bate 2007).

The fire regime for the pinyon-juniper shrub woodland has a fire frequency that is reduced and fire severity is somewhat increased from pre-1900, from low to moderately frequent, high-severity stand-replacing fires and moderately frequent mixed-severity fires that likely maintain this type, toward less frequent, higher severity fires (Gori and Bate 2007). Tree density has increased and herbaceous biomass has decreased from historic conditions with active fire suppression and livestock grazing. Currently most stands have a variable mix of tree and shrubs with few or no very old trees (>300 years) present. With fire suppression, this type maybe outside HRV for disturbance regime, and possibly for structure and composition as recent fires are likely more severe than historic fire in the late 1800s (Romme et al. 2003).

The fire regime for the pinyon-juniper forest type still has infrequent, high-severity fires that are carried by tree crowns. The stand dynamics remain relatively stable with little change in density of tree or shrub and herbaceous layers. Currently stands have numerous very old trees (>300 years) present with a multi-aged structure. Active fire suppression and livestock grazing are thought to have had little impact on fire frequency and severity and the overstory structure and composition with this type remaining within HRV for disturbance regime (Gori and Bate 2007).

Most pinyon-juniper woodlands in the southwest have high soil erosion potential. Several studies have measured present-day erosion rates in pinyon-juniper woodlands, highlighting the importance of herbaceous cover and biological soil crusts (Belnap et al. 2001) in minimizing precipitation runoff and soil loss in pinyon-juniper woodlands.

Madrean encinal stands included in this macrogroup also vary considerably under historic natural conditions in tree density ranging from very open woodlands and treed savannas (5-15% cover) with a perennial grass-dominated understory in uplands, to moderately dense oak woodlands (20-40% tree cover) in drainages and on north-facing slopes. The understory of good-condition stands generally has high cover of perennial grasses and low cover of shrubs such as *Mimosa*, and this good condition of the stand is maintained with frequent fires. Turner et al. (2003) documented a trend from more open woodlands and savannas to denser woodlands with higher cover of species of *Juniperus* and *Prosopis* over the last 150 years. Regeneration of oaks following disturbance is from resprouting rather than acorns because of the dry conditions (Germaine and McPherson 1998).

Although there is not much encinal-specific information on fire-return intervals (FRI) available, it is thought to be similar to adjacent ecosystems, primarily the semi-desert grassland (FRI of 2.5-10 years) (Wright 1980, Bahre 1985, McPherson 1995, Kaib et al. 1996) and the pine-oak woodlands (FRI of 3-7 years) (Wright 1980, Bahre 1985, Swetnam et al. 1992, McPherson 1995, Kaib et al. 1996, Swetnam and Baisan 1996b). Fire season in encinal was probably similar to that of other Madrean woodlands and grasslands, occurring predominantly before the summer monsoon between April and June when vegetation is dry and ignition sources from dry lightning strikes are common (Swetnam and Betancourt 1990). Post disturbance regeneration (such as after stand-replacing fire) mostly occurs from resprouting from trees roots. Successful regeneration from acorns is related to annual precipitation (Germaine and McPherson 1998). The understory of poor-condition stands with less frequent fires or experiencing extended drought may have significant shrub invasion by species of *Arctostaphylos* and *Juniperus* and reduction of perennial grass cover (Schussman 2006a).

Over the last century, the woody component in encinal has increased in density over time in the absence of disturbance such as fire (Burgess 1995, Gori and Enquist 2003, Turner et al. 2003, Schussman 2006a). This is correlated to a decrease in fire frequency that is related to a reduction of fine fuels that carry fire because of extensive livestock grazing. Frequent, stand-replacing fire was likely a key ecological attribute prior to 1890 (Wright 1980, Bahre 1985, McPherson 1995, Kaib et al. 1996). The oak woodlands and savannas included in this macrogroup are characterized by a strong perennial grass layer and are driven by many of the same ecological processes as semi-desert mixed grassland, primarily frequent fire and drought (USFS 2009). It is generally agreed that fire regime has been altered for encinal by passive fire suppression via removal of fine fuels through livestock grazing, as well as active suppression over the last 100 years. This has reduced the number of surface fires, permitting a buildup in woody fuels, resulting in increased fire severity when fires occur in encinal and adjacent vegetation types such as semi-desert grasslands and pine-oak woodlands across much or the southwestern U.S. and adjacent Mexico (Kaib et al. 1996, Swetnam and Baisan 1996). Reduced fire frequency is a disturbance of the natural fire regime and results in increased cover of woody plants (Barton 1999, Muldavin et al. 2002b, Gori and Enquist 2003, Turner et al. 2003). The increase in woody species in the Madrean encinal has changed species composition, in some areas, from oak-dominated woodlands or savanna to mesquite- and/or juniper-dominated woodlands (Turner et al. 2003).

Livestock grazing in encinal is currently a common practice in both the United States and Mexico, with grazing occurring in virtually all of Mexico's and in roughly 75% of the United States' oak woodlands (McPherson 1995). Livestock grazing can affect the structure and composition of Madrean oak woodlands, as well as soil structure and water infiltration (USFS 2009).

The introduction of the invasive non-native, perennial grasses *Eragrostis lehmanniana* and *Eragrostis curvula* has greatly impacted many semi-desert grasslands and encinal in this ecoregion (Cable 1971, Anable et al. 1992, Gori and Enquist 2003). Anable et al. (1992) and Cable (1971) found Lehmann lovegrass is a particularly aggressive invader and alters ecosystem processes, vegetation composition, and species diversity.

Historic fuelwood cutting for mining and domestic use and fencepost cutting was common in stands of this macrogroup in southeastern Arizona until the late 1800s, and is still common in Arizona and northern Mexico today (Bahre 1991, Bennett 1992). Although fuelwood harvesting had dramatic effects historically, its consequences were generally local and short-lived (Turner et al. 2003). More recently, chemical and mechanical treatments such as chaining and rotochopping have impacted age structure, tree density and cover of many pinyon-juniper woodlands with current demand for these products continuing to increase (Ffolliott et al. 1979, Gottfried 1987, Dick-Peddie 1993, Gottfried and Severson 1993).

Threats/Stressors: Supresión de incendios forestales, el pastoreo excesivo, introdución de especies de plantas invasoras, la recolección de leña.

Wildfire suppression, overgrazing, introduced invasive plant species, firewood collection

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra, además de: Supresión de incendios forestales, el pastoreo excesivo, introdujo especies de plantas invasoras, la recolección de leña.

Ecological collapse tends to occur from direct land conversion, plus wildfire suppression, overgrazing, introduced invasive plant species, and firewood collection.

CES305.795 Madrean Encinal

CES305.795 CLASSIFICATION

Concept Summary: Madrean Encinal occurs on foothills, canyons, bajadas and plateaus in the Sierra Madre Occidentale and Sierra Madre Orientale in Mexico, extending north into Trans-Pecos Texas, southern New Mexico and sub-Mogollon Arizona. These woodlands are dominated by Madrean evergreen oaks along a low-slope transition below ~Madrean Lower Montane Pine-Oak Forest and Woodland (CES305.796)$$ and ~Madrean Pinyon-Juniper Woodland (CES305.797)$$. Lower elevation stands are typically open woodlands or savannas where they transition into desert grasslands, chaparral or in some cases desertscrub. Common evergreen oak species include *Quercus arizonica, Quercus emoryi, Quercus intricata, Quercus grisea, Quercus oblongifolia, Quercus toumeyi*, and in Mexico *Quercus chihuahuensis* and *Quercus albocincta*. Madrean pine, Arizona cypress, pinyon and juniper trees may be present but do not codominate. Chaparral species such as *Arctostaphylos pungens, Cercocarpus montanus, Purshia* spp., *Garrya wrightii, Quercus turbinella, Frangula betulifolia*, or *Rhus* spp. may be present but do not dominate. The graminoid layer is usually prominent between trees in grassland or steppe that is dominated by warm-season grasses such as *Aristida* spp., *Bouteloua gracilis, Bouteloua curtipendula, Bouteloua rothrockii, Digitaria californica, Eragrostis intermedia, Hilaria belangeri, Leptochloa dubia, Muhlenbergia* spp., *Pleuraphis jamesii*, or *Schizachyrium cirratum*, species typical of ~Apacherian-Chihuahuan Semi-Desert Grassland and Steppe (CES302.735)$$. This system includes seral stands dominated by shrubby Madrean oaks typically with a strong graminoid layer. In transition areas with drier chaparral systems, stands of chaparral are not dominated by Madrean oaks; however, Madrean Encinal may extend down along drainages.

Este encinal se produce en colinas, cañones, bajadas y mesetas de la Sierra Madre Occidental y Sierra Madre Oriental de México, que se extiende hacia el norte en Trans-Pecos Texas, el sur de Nuevo México y sub-Mogollon Arizona. Estos bosques están dominados por encinares Madrenses a lo largo de una transición de baja pendiente por debajo del ~Bosque Montano Bajo de Pino Encino de la Sierra Madre (CES305.796)$$ y ~Madrean Pinyon-Juniper Woodland (CES305.797)$$. Rodales a baja elevación son típicamente bosques abiertos o sabanas que transicionan a los pastizales del desierto, chaparral o en algunos casos matorral desértico. Especies de roble de hoja perenne comunes incluyen *Quercus arizonica, Quercus emoryi, Quercus intricata, Quercus grisea, Quercus oblongifolia, Quercus toumeyi*, y en México *Quercus chihuahuensis* y *Quercus albocincta*. Pino madreano, ciprés de Arizona, piñoneros y enebros pueden estar presentes pero no son codominates. Especies de chaparral como *Arctostaphylos pungens, Cercocarpus montanus, Purshia* spp., *Garrya wrightii, Quercus turbinella, Frangula betulifolia*, o *Rhus* spp. pueden estar presentes pero no dominan. La capa de gramíneas suele ser prominente entre los árboles en praderas o estepas que está dominada por pastos de estación cálida tales como *Aristida* spp., *Bouteloua gracilis, Bouteloua curtipendula, Bouteloua rothrockii, Digitaria californica, Eragrostis intermedia, Hilaria belangeri, Leptochloa dubia, Muhlenbergia* spp., *Pleuraphis jamesii* o *Schizachyrium cirratum*, especies típicas del sistema de ~Pastizales Semi-desérticos y de la Estepa Apacherian-Chihuahua (CES302.735)$$. Este sistema incluye rodales suciesionales dominados por robles Madrenses arbustivos típicamente con una capa densa de gramíneas. En las zonas de transición con sistemas de chaparral más seco, se los chaparrales no están dominados por robles Madrenses, sin embargo, este encinal puede extenderse hacia abajo a lo largo de los drenajes.

CES305.795 CONCEPTUAL MODEL

Environment: Madrean Encinal occurs on foothills, canyons, bajadas and plateaus in the Sierra Madre Occidentale and Sierra Madre Orientale in Mexico, extending north into Trans-Pecos Texas, southern New Mexico and sub-Mogollon Arizona. In Texas, it is found on often rocky or gravelly soils over various substrates, including Permian limestones of the Guadalupe Mountains, Tertiary igneous formations, sandstone formations, and even colluvial/alluvial substrates at middle elevations in mountainous areas of the Trans-Pecos. It may also occur on loams and alluvial surfaces.
Key Processes and Interactions: [from M010] Dynamics are complicated by the diverse plant communities present in this macrogroup. The pinyon-juniper woodlands and savannas included in this macrogroup are represented by what Moir and Carleton (1987) classified as the High Sun Mild climate zone (summer precipitation and warm climate). Romme et al. (2003) developed a pinyon-juniper classification with three types based on canopy structure, understory composition, and historic fire regime. All three types, pinyon-juniper grass savanna, pinyon-juniper shrub woodland, and pinyon-juniper forest, are included in this macrogroup. However, the pinyon-juniper grass savanna and a new, ecologically similar type with tree canopy >10% cover (pinyon-juniper grass open woodland) have the greater aerial extent in the macrogroup (Landis and Bailey 2005, Gori and Bate 2007). Other types are the pinyon-juniper shrub woodland, represented by pinyon-juniper trees with an understory of shrubs such as *Quercus turbinella*, and the pinyon-juniper forest type that has a typically sparse understory and is restricted to dry, rocky areas or following fires (Romme et al. 2003).

Fire dynamics for these types under historic natural conditions (also called natural range of variability (NRV); for pre-1900 timeframe) are summarized as follows based on (Romme et al. 2003). The fire regime for the pinyon-juniper grass savanna/pinyon-juniper grass open woodland includes frequent, low-severity surface fires that are carried by the herbaceous layer. The low density of trees (5-20% cover) and high perennial grass cover is maintained by this fire regime. Mean fire interval is estimated to be 12-43 years (Gori and Bate 2007). The fire regime for the pinyon-juniper shrub woodland has moderately frequent, high-severity crown fires that are carried by the shrub and tree layers. After a stand replacing fire the site begins at early seral stage and returns to a moderately dense tree layer with a moderate to dense shrub layer. Succession happens relatively quickly if the shrub layer includes chaparral species that recover rapidly from fire by re-sprouting or from fire scarified seeds in a seed bank. Mixed-severity fires may alter this pattern by creating a mosaic of pinyon-juniper states (early-, mid-, and late-seral). Mean fire interval is estimated to be 23-81 years (Gori and Bate 2007). The fire regime for the pinyon-juniper forest type has very infrequent, very high-severity fires that are carried by tree crowns. The stand dynamics are stable with multi-age tree canopy and with little change in shrub or herbaceous layers.

Pinyon and juniper stands in this macrogroup have been impacted by human activities over the last century. Historical fire regimes were disrupted following the introduction of livestock (and the 1890s drought). Grazing passively suppresses fire by removing fine fuels needed to carry surface and mixed-severity fires that likely maintained the structure and composition of pinyon-juniper savannas and pinyon-juniper shrub woodlands historically. Active fire suppression was also practiced by the Federal government during the last 100 years (Swetnam and Baisan 1996b). As fire became less frequent, pinyon and juniper trees became denser and subsequent fires became more severe (Gori and Bate 2007). These impacts altered stand dynamics differently depending on stand structure. Fire dynamics under current conditions are summarized for the three major pinyon-juniper types (pinyon-juniper grass savanna/open woodland, pinyon-juniper shrub woodland, and pinyon-juniper forest) developed by Romme et al. (2003) using canopy structure, understory composition, and historic fire regime and adapted for our use as follows.

The fire regime for the pinyon-juniper grass savanna/open woodland has a fire frequency that is significantly reduced and fire severity has greatly increased from pre-1900, from low-severity surface fires towards high-severity and stand-replacing crown fires. Tree density has increased and herbaceous biomass has decreased from historic conditions with active fire suppression and livestock grazing. Currently stands have some very old trees (>300 years) present but not numerous, and are typically dominated by many young trees (<150 years). This type may also occur on sites with more rock soil and less grasses. This type is outside Historic Range of Variation (HRV) for disturbance regime, structure and composition (Gori and Bate 2007).

The fire regime for the pinyon-juniper shrub woodland has a fire frequency that is reduced and fire severity is somewhat increased from pre-1900, from low to moderately frequent, high-severity stand-replacing fires and moderately frequent mixed-severity fires that likely maintain this type, toward less frequent, higher severity fires (Gori and Bate 2007). Tree density has increased and herbaceous biomass has decreased from historic conditions with active fire suppression and livestock grazing. Currently most stands have a variable mix of tree and shrubs with few or no very old trees (>300 years) present. With fire suppression, this type maybe outside HRV for disturbance regime, and possibly for structure and composition as recent fires are likely more severe than historic fire in the late 1800s (Romme et al. 2003).

The fire regime for the pinyon-juniper forest type still has infrequent, high-severity fires that are carried by tree crowns. The stand dynamics remain relatively stable with little change in density of tree or shrub and herbaceous layers. Currently stands have numerous very old trees (>300 years) present with a multi-aged structure. Active fire suppression and livestock grazing are thought to have had little impact on fire frequency and severity and the overstory structure and composition with this type remaining within HRV for disturbance regime (Gori and Bate 2007).

Most pinyon-juniper woodlands in the southwest have high soil erosion potential. Several studies have measured present-day erosion rates in pinyon-juniper woodlands, highlighting the importance of herbaceous cover and biological soil crusts (Belnap et al. 2001) in minimizing precipitation runoff and soil loss in pinyon-juniper woodlands.

Madrean encinal stands included in this macrogroup also vary considerably under historic natural conditions in tree density ranging from very open woodlands and treed savannas (5-15% cover) with a perennial grass-dominated understory in uplands, to moderately dense oak woodlands (20-40% tree cover) in drainages and on north-facing slopes. The understory of good-condition stands generally has high cover of perennial grasses and low cover of shrubs such as *Mimosa*, and this good condition of the stand is maintained with frequent fires. Turner et al. (2003) documented a trend from more open woodlands and savannas to denser woodlands with higher cover of species of *Juniperus* and *Prosopis* over the last 150 years. Regeneration of oaks following disturbance is from resprouting rather than acorns because of the dry conditions (Germaine and McPherson 1998).

Although there is not much encinal-specific information on fire-return intervals (FRI) available, it is thought to be similar to adjacent ecosystems, primarily the semi-desert grassland (FRI of 2.5-10 years) (Wright 1980, Bahre 1985, McPherson 1995, Kaib et al. 1996) and the pine-oak woodlands (FRI of 3-7 years) (Wright 1980, Bahre 1985, Swetnam et al. 1992, McPherson 1995, Kaib et al. 1996, Swetnam and Baisan 1996b). Fire season in encinal was probably similar to that of other Madrean woodlands and grasslands, occurring predominantly before the summer monsoon between April and June when vegetation is dry and ignition sources from dry lightning strikes are common (Swetnam and Betancourt 1990). Post disturbance regeneration (such as after stand-replacing fire) mostly occurs from resprouting from trees roots. Successful regeneration from acorns is related to annual precipitation (Germaine and McPherson 1998). The understory of poor-condition stands with less frequent fires or experiencing extended drought may have significant shrub invasion by species of *Arctostaphylos* and *Juniperus* and reduction of perennial grass cover (Schussman 2006a).

Over the last century, the woody component in encinal has increased in density over time in the absence of disturbance such as fire (Burgess 1995, Gori and Enquist 2003, Turner et al. 2003, Schussman 2006a). This is correlated to a decrease in fire frequency that is related to a reduction of fine fuels that carry fire because of extensive livestock grazing. Frequent, stand-replacing fire was likely a key ecological attribute prior to 1890 (Wright 1980, Bahre 1985, McPherson 1995, Kaib et al. 1996). The oak woodlands and savannas included in this macrogroup are characterized by a strong perennial grass layer and are driven by many of the same ecological processes as semi-desert mixed grassland, primarily frequent fire and drought (USFS 2009). It is generally agreed that fire regime has been altered for encinal by passive fire suppression via removal of fine fuels through livestock grazing, as well as active suppression over the last 100 years. This has reduced the number of surface fires, permitting a buildup in woody fuels, resulting in increased fire severity when fires occur in encinal and adjacent vegetation types such as semi-desert grasslands and pine-oak woodlands across much or the southwestern U.S. and adjacent Mexico (Kaib et al. 1996, Swetnam and Baisan 1996). Reduced fire frequency is a disturbance of the natural fire regime and results in increased cover of woody plants (Barton 1999, Muldavin et al. 2002b, Gori and Enquist 2003, Turner et al. 2003). The increase in woody species in the Madrean encinal has changed species composition, in some areas, from oak-dominated woodlands or savanna to mesquite- and/or juniper-dominated woodlands (Turner et al. 2003).

Livestock grazing in encinal is currently a common practice in both the United States and Mexico, with grazing occurring in virtually all of Mexico's and in roughly 75% of the United States' oak woodlands (McPherson 1995). Livestock grazing can affect the structure and composition of Madrean oak woodlands, as well as soil structure and water infiltration (USFS 2009).

The introduction of the invasive non-native, perennial grasses *Eragrostis lehmanniana* and *Eragrostis curvula* has greatly impacted many semi-desert grasslands and encinal in this ecoregion (Cable 1971, Anable et al. 1992, Gori and Enquist 2003). Anable et al. (1992) and Cable (1971) found Lehmann lovegrass is a particularly aggressive invader and alters ecosystem processes, vegetation composition, and species diversity.

Historic fuelwood cutting for mining and domestic use and fencepost cutting was common in stands of this macrogroup in southeastern Arizona until the late 1800s, and is still common in Arizona and northern Mexico today (Bahre 1991, Bennett 1992). Although fuelwood harvesting had dramatic effects historically, its consequences were generally local and short-lived (Turner et al. 2003). More recently, chemical and mechanical treatments such as chaining and rotochopping have impacted age structure, tree density and cover of many pinyon-juniper woodlands with current demand for these products continuing to increase (Ffolliott et al. 1979, Gottfried 1987, Dick-Peddie 1993, Gottfried and Severson 1993).

Threats/Stressors: Wildfire suppression, overgrazing, introduced invasive plant species, firewood collection.

Supresión de incendios forestales, el pastoreo excesivo, introducción de especies de plantas invasoras, la recolección de leña.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct land conversion, plus: Wildfire suppression, overgrazing, introduced invasive plant species, firewood collection.

Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra, además de: Supresión de incendios forestales, el pastoreo excesivo, introdujo especies de plantas invasoras, la recolección de leña.

CES301.730 Madrean Juniper Savanna

CES301.730 CLASSIFICATION

Concept Summary: This Madrean ecological system occurs in lower foothills and plains of southeastern Arizona, southern New Mexico extending into west Texas and Mexico. These savannas have widely spaced mature juniper trees and moderate to high cover of graminoids (>25% cover). The presence of Madrean *Juniperus* spp. such as *Juniperus coahuilensis, Juniperus pinchotii*, and/or *Juniperus deppeana* is diagnostic. *Juniperus monosperma* may be present in some stands; *Juniperus deppeana* has a broader range than this Madrean system and extends north into southern stands of ~Southern Rocky Mountain Juniper Woodland and Savanna (CES306.834)$$. Stands of *Juniperus pinchotii* may be short and resemble a shrubland. Graminoid species are a mix of those found in ~Western Great Plains Shortgrass Prairie (CES303.672)$$ and ~Apacherian-Chihuahuan Semi-Desert Grassland and Steppe (CES302.735)$$, with *Bouteloua gracilis* and *Pleuraphis jamesii* being most common. In addition, these areas include succulents such as species of *Yucca, Opuntia*, and *Agave*. Juniper savanna expansion into grasslands has been documented in the last century.

Description Author: K.A. Schulz, L. Elliott and J. Teague

CES301.730 CONCEPTUAL MODEL

Environment: This ecological system occurs on a variety of substrates in rolling landscapes on gentle to level terrain. In Texas, soils are gravelly to shallow to loamy.

Key Processes and Interactions: [from M010] Dynamics are complicated by the diverse plant communities present in this macrogroup. The pinyon-juniper woodlands and savannas included in this macrogroup are represented by what Moir and Carleton (1987) classified as the High Sun Mild climate zone (summer precipitation and warm climate). Romme et al. (2003) developed a pinyon-juniper classification with three types based on canopy structure, understory composition, and historic fire regime. All three types, pinyon-juniper grass savanna, pinyon-juniper shrub woodland, and pinyon-juniper forest, are included in this macrogroup. However, the pinyon-juniper grass savanna and a new, ecologically similar type with tree canopy >10% cover (pinyon-juniper grass open woodland) have the greater aerial extent in the macrogroup (Landis and Bailey 2005, Gori and Bate 2007). Other types are the pinyon-juniper shrub woodland, represented by pinyon-juniper trees with an understory of shrubs such as *Quercus turbinella*, and the pinyon-juniper forest type that has a typically sparse understory and is restricted to dry, rocky areas or following fires (Romme et al. 2003).

Fire dynamics for these types under historic natural conditions (also called natural range of variability (NRV); for pre-1900 timeframe) are summarized as follows based on (Romme et al. 2003). The fire regime for the pinyon-juniper grass savanna/pinyon-juniper grass open woodland includes frequent, low-severity surface fires that are carried by the herbaceous layer. The low density of trees (5-20% cover) and high perennial grass cover is maintained by this fire regime. Mean fire interval is estimated to be 12-43 years (Gori and Bate 2007). The fire regime for the pinyon-juniper shrub woodland has moderately frequent, high-severity crown fires that are carried by the shrub and tree layers. After a stand replacing fire the site begins at early seral stage and returns to a moderately dense tree layer with a moderate to dense shrub layer. Succession happens relatively quickly if the shrub layer includes chaparral species that recover rapidly from fire by re-sprouting or from fire scarified seeds in a seed bank. Mixed-severity fires may alter this pattern by creating a mosaic of pinyon-juniper states (early-, mid-, and late-seral). Mean fire interval is estimated to be 23-81 years (Gori and Bate 2007). The fire regime for the pinyon-juniper forest type has very infrequent, very high-severity fires that are carried by tree crowns. The stand dynamics are stable with multi-age tree canopy and with little change in shrub or herbaceous layers.

Pinyon and juniper stands in this macrogroup have been impacted by human activities over the last century. Historical fire regimes were disrupted following the introduction of livestock (and the 1890s drought). Grazing passively suppresses fire by removing fine fuels needed to carry surface and mixed-severity fires that likely maintained the structure and composition of pinyon-juniper savannas and pinyon-juniper shrub woodlands historically. Active fire suppression was also practiced by the Federal government during the last 100 years (Swetnam and Baisan 1996b). As fire became less frequent, pinyon and juniper trees became denser and subsequent fires became more severe (Gori and Bate 2007). These impacts altered stand dynamics differently depending on stand structure. Fire dynamics under current conditions are summarized for the three major pinyon-juniper types (pinyon-juniper grass savanna/open woodland, pinyon-juniper shrub woodland, and pinyon-juniper forest) developed by Romme et al. (2003) using canopy structure, understory composition, and historic fire regime and adapted for our use as follows.

The fire regime for the pinyon-juniper grass savanna/open woodland has a fire frequency that is significantly reduced and fire severity has greatly increased from pre-1900, from low-severity surface fires towards high-severity and stand-replacing crown fires.

Tree density has increased and herbaceous biomass has decreased from historic conditions with active fire suppression and livestock grazing. Currently stands have some very old trees (>300 years) present but not numerous, and are typically dominated by many young trees (<150 years). This type may also occur on sites with more rock soil and less grasses. This type is outside Historic Range of Variation (HRV) for disturbance regime, structure and composition (Gori and Bate 2007).

The fire regime for the pinyon-juniper shrub woodland has a fire frequency that is reduced and fire severity is somewhat increased from pre-1900, from low to moderately frequent, high-severity stand-replacing fires and moderately frequent mixed-severity fires that likely maintain this type, toward less frequent, higher severity fires (Gori and Bate 2007). Tree density has increased and herbaceous biomass has decreased from historic conditions with active fire suppression and livestock grazing. Currently most stands have a variable mix of tree and shrubs with few or no very old trees (>300 years) present. With fire suppression, this type maybe outside HRV for disturbance regime, and possibly for structure and composition as recent fires are likely more severe than historic fire in the late 1800s (Romme et al. 2003).

The fire regime for the pinyon-juniper forest type still has infrequent, high-severity fires that are carried by tree crowns. The stand dynamics remain relatively stable with little change in density of tree or shrub and herbaceous layers. Currently stands have numerous very old trees (>300 years) present with a multi-aged structure. Active fire suppression and livestock grazing are thought to have had little impact on fire frequency and severity and the overstory structure and composition with this type remaining within HRV for disturbance regime (Gori and Bate 2007).

Most pinyon-juniper woodlands in the southwest have high soil erosion potential. Several studies have measured present-day erosion rates in pinyon-juniper woodlands, highlighting the importance of herbaceous cover and biological soil crusts (Belnap et al. 2001) in minimizing precipitation runoff and soil loss in pinyon-juniper woodlands.

Madrean encinal stands included in this macrogroup also vary considerably under historic natural conditions in tree density ranging from very open woodlands and treed savannas (5-15% cover) with a perennial grass-dominated understory in uplands, to moderately dense oak woodlands (20-40% tree cover) in drainages and on north-facing slopes. The understory of good-condition stands generally has high cover of perennial grasses and low cover of shrubs such as *Mimosa*, and this good condition of the stand is maintained with frequent fires. Turner et al. (2003) documented a trend from more open woodlands and savannas to denser woodlands with higher cover of species of *Juniperus* and *Prosopis* over the last 150 years. Regeneration of oaks following disturbance is from resprouting rather than acorns because of the dry conditions (Germaine and McPherson 1998).

Although there is not much encinal-specific information on fire-return intervals (FRI) available, it is thought to be similar to adjacent ecosystems, primarily the semi-desert grassland (FRI of 2.5-10 years) (Wright 1980, Bahre 1985, McPherson 1995, Kaib et al. 1996) and the pine-oak woodlands (FRI of 3-7 years) (Wright 1980, Bahre 1985, Swetnam et al. 1992, McPherson 1995, Kaib et al. 1996, Swetnam and Baisan 1996b). Fire season in encinal was probably similar to that of other Madrean woodlands and grasslands, occurring predominantly before the summer monsoon between April and June when vegetation is dry and ignition sources from dry lightning strikes are common (Swetnam and Betancourt 1990). Post disturbance regeneration (such as after stand-replacing fire) mostly occurs from resprouting from trees roots. Successful regeneration from acorns is related to annual precipitation (Germaine and McPherson 1998). The understory of poor-condition stands with less frequent fires or experiencing extended drought may have significant shrub invasion by species of *Arctostaphylos* and *Juniperus* and reduction of perennial grass cover (Schussman 2006a).

Over the last century, the woody component in encinal has increased in density over time in the absence of disturbance such as fire (Burgess 1995, Gori and Enquist 2003, Turner et al. 2003, Schussman 2006a). This is correlated to a decrease in fire frequency that is related to a reduction of fine fuels that carry fire because of extensive livestock grazing. Frequent, stand-replacing fire was likely a key ecological attribute prior to 1890 (Wright 1980, Bahre 1985, McPherson 1995, Kaib et al. 1996). The oak woodlands and savannas included in this macrogroup are characterized by a strong perennial grass layer and are driven by many of the same ecological processes as semi-desert mixed grassland, primarily frequent fire and drought (USFS 2009). It is generally agreed that fire regime has been altered for encinal by passive fire suppression via removal of fine fuels through livestock grazing, as well as active suppression over the last 100 years. This has reduced the number of surface fires, permitting a buildup in woody fuels, resulting in increased fire severity when fires occur in encinal and adjacent vegetation types such as semi-desert grasslands and pine-oak woodlands across much or the southwestern U.S. and adjacent Mexico (Kaib et al. 1996, Swetnam and Baisan 1996). Reduced fire frequency is a disturbance of the natural fire regime and results in increased cover of woody plants (Barton 1999, Muldavin et al. 2002b, Gori and Enquist 2003, Turner et al. 2003). The increase in woody species in the Madrean encinal has changed species composition, in some areas, from oak-dominated woodlands or savanna to mesquite- and/or juniper-dominated woodlands (Turner et al. 2003).

Livestock grazing in encinal is currently a common practice in both the United States and Mexico, with grazing occurring in virtually all of Mexico's and in roughly 75% of the United States' oak woodlands (McPherson 1995). Livestock grazing can affect the structure and composition of Madrean oak woodlands, as well as soil structure and water infiltration (USFS 2009).

The introduction of the invasive non-native, perennial grasses *Eragrostis lehmanniana* and *Eragrostis curvula* has greatly impacted many semi-desert grasslands and encinal in this ecoregion (Cable 1971, Anable et al. 1992, Gori and Enquist 2003). Anable et al. (1992) and Cable (1971) found Lehmann lovegrass is a particularly aggressive invader and alters ecosystem processes, vegetation composition, and species diversity.

Historic fuelwood cutting for mining and domestic use and fencepost cutting was common in stands of this macrogroup in southeastern Arizona until the late 1800s, and is still common in Arizona and northern Mexico today (Bahre 1991, Bennett 1992). Although fuelwood harvesting had dramatic effects historically, its consequences were generally local and short-lived (Turner et al. 2003). More recently, chemical and mechanical treatments such as chaining and rotochopping have impacted age structure, tree density and cover of many pinyon-juniper woodlands with current demand for these products continuing to increase (Ffolliott et al. 1979, Gottfried 1987, Dick-Peddie 1993, Gottfried and Severson 1993).

Threats/Stressors: Wildfire suppression, overgrazing, introduced invasive plant species, firewood collection.

Supresión de incendios forestales, el pastoreo excesivo, introducción de especies de plantas invasoras, la recolección de leña.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct land conversion, plus wildfire suppression, overgrazing, introduced invasive plant species, and firewood collection.

Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra, además de: Supresión de incendios forestales, el pastoreo excesivo, introdujo especies de plantas invasoras, la recolección de leña.

CES305.797 Madrean Pinyon-Juniper Woodland

CES305.797 CLASSIFICATION

Concept Summary: This system occurs on foothills, mountains and plateaus in the Sierra Madre Occidentale and Sierra Madre Orientale in Mexico, Trans-Pecos Texas, southern New Mexico and Arizona, generally south of the Mogollon Rim. Substrates are variable, but soils are generally dry and rocky. The presence of *Pinus cembroides, Pinus discolor*, or other Madrean trees and shrubs is diagnostic of this woodland system. *Juniperus coahuilensis, Juniperus deppeana, Juniperus pinchotii, Juniperus monosperma*, and/or *Pinus edulis* may be present to dominant. Madrean oaks such as *Quercus arizonica, Quercus emoryi, Quercus grisea*, or *Quercus mohriana* may be codominant. *Pinus ponderosa* is absent or sparse. If present, understory layers are variable and may be dominated by shrubs or graminoids.

Distribution: This system occurs in the Sierra Madre Occidentale and Sierra Madre Orientale of Mexico, Trans-Pecos Texas, southern New Mexico and Arizona, generally south of the Mogollon Rim. It occurs on the west side of the Sacramento Mountains but may transition into ~Southern Rocky Mountain Pinyon-Juniper Woodland (CES306.835)$$ or ~Southern Rocky Mountain Juniper Woodland and Savanna (CES306.834)$$ on the eastern side.

Nations: MX, US

CES305.797 CONCEPTUAL MODEL

Environment: This woodland system is common in foothills, mountains and plateaus in the Sierra Madre Occidentale and Sierra Madre Orientale in Mexico, Trans-Pecos Texas, southern New Mexico and Arizona, generally south of the Mogollon Rim. Elevation generally ranges from 1300-2225 m with high-elevation stands restricted to warmer southern aspects.

Climate: Climate is semi-arid with drought not uncommon. Summers are hot and winters are mild with cold periods and occasional snows. The mean annual precipitation ranges from 40-50 cm with approximately two-thirds occurring during the Arizona monsoon season from July to September, often as high-intensity convective storms. May and June are typically dry. Stands typically occur on nearly level to steep, rocky slopes.

Physiography/landform: Stands occur on cool aspects of steep scarp slopes, in canyons (including alluvial terraces), on gently sloping alluvial fan piedmonts (bajadas), steeper colluvial slopes and ridges, as well as mesatops. Pinyon and juniper woodlands extend down to 760 m elevation in Trans-Pecos ranges. At the lowest elevation, encinal generally occupies the rockier substrates or is restricted to drainages within grasslands (Brown 1982a).

Soil/substrate/hydrology: Soils are variable, but are generally shallow, rocky, calcareous, but may include deeper clay loamy to gravelly loamy soils. Parent materials include andesite, rhyolite, limestone, basalt, colluvium and alluvium (Sullivan 1993c, Pavek 1994b, Tirmenstein 1999i, Hauser 2007b).

Key Processes and Interactions: Dynamics are complicated by the variation in physiognomy and diverse plant communities present in this system. The pinyon-juniper woodlands and savannas included in this system are represented by what Moir and Carleton (1987) classified as the High Sun Mild climate zone (summer precipitation and warm climate). Romme et al. (2003) developed a pinyon-juniper classification with three types based on canopy structure, understory composition, and historic fire regime. All three types, pinyon-juniper grass savanna, pinyon-juniper shrub woodland, and pinyon-juniper forest, are included in this system. For this model an ecologically similar type, pinyon-juniper grass open woodland (with tree canopy >10% cover), was added to the pinyon-juniper grass savanna making this the more widespread type (Landis and Bailey 2005, Gori and Bate 2007). The other types are the pinyon-juniper shrub woodland, represented by pinyon-juniper trees with an understory of shrubs such as *Quercus turbinella*, and the pinyon-juniper forest type that has a typically sparse understory and is restricted to dry, rocky areas where it is protected from fires (Romme et al. 2003).

Fire dynamics for these types under historical natural conditions (also called natural range of variability (NRV) for pre-1900 timeframe) are summarized below based on (Romme et al. 2003).

The fire regime for the pinyon-juniper grass savanna/pinyon-juniper grass open woodland includes frequent, low-severity surface fires that are carried by the herbaceous layer. The low density of trees (5-20% cover) and high perennial grass cover is maintained by this fire regime. Mean fire interval is estimated to be 12-43 years (Gori and Bate 2007).

The fire regime for the pinyon-juniper shrub woodland is described as moderately frequent, high-severity crown fires that are carried by the shrub and tree layers. After a stand-replacing fire the site begins at early-seral stage and returns to a moderately dense tree layer with a moderate to dense shrub layer. Succession happens relatively quickly if the shrub layer includes chaparral species that recover rapidly from fire by re-sprouting or from fire-scarified seeds in a seed bank. Mixed-severity fires may alter this pattern by creating a mosaic of pinyon-juniper states (early-, mid-, and late-seral). Mean fire interval is estimated to be 23-81 years (Gori and Bate 2007).

The fire regime for the pinyon-juniper forest type is characterized by very infrequent, very high-severity fires that are carried by tree crowns. The stand dynamics are stable with a multi-age tree canopy and with little change in shrub or herbaceous layers.

The historical fire season was probably similar to that of other Madrean woodlands and grasslands, occurring predominantly before the summer monsoon between April and June when vegetation is dry and ignition sources from dry lightning strikes are common (Swetnam and Betancourt 1990).

Other important ecological processes include climate, drought, insect infestations, pathogens, herbivory and seed dispersal by birds and small mammals.

Juniper berries and pinyon nut crops are primarily utilized by birds and small mammals (Johnsen 1962, McCulloch 1969, Short et al. 1977, Salomonson 1978, Balda 1987, Gottfried et al. 1995, Tirmenstein 1999i). Large mammals, such as mule deer (*Odocoileus hemionus*), white-tailed deer (*Odocoileus virginianus*) and elk (*Cervus elaphus*), eat leaves and seeds of both species and browse woodland grasses, forbs and shrubs, including *Artemisia tridentata, Cercocarpus montanus, Quercus gambelii*, and *Purshia stansburiana* (Short and McCulloch 1977). The most important dispersers of juniper and pinyon seeds are birds. Juniper seeds that pass through the digestive tract of birds and other herbivores germinate faster than uneaten seeds (Johnsen 1962, Tirmenstein 1999i). The primary dispersers of pinyon seeds, i.e., scrub jays (*Aphelocoma californica*), pinyon jays (*Gymnorhinus cyanocephalus*), Steller's jays (*Cyanocitta stelleri*) and Clark's nutcrackers (*Nucifraga columbiana*), cache hundreds of thousands of pinyon seeds during mast crop years, many of which are never recovered (Balda and Bateman 1971, Vander Wall and Balda 1977, Ligon 1978, Pavek 1994b). This seed dispersal mechanism is a good example of a co-evolved, mutualistic, plant-vertebrate relationship (Vander Wall et al. 1981, Evans 1988, Lanner 1996) and would be at risk with loss of trees or dispersers. In addition, small mammals, such as cliff chipmunk (*Neotamias dorsalis*) and rock squirrel (*Otospermophilus variegatus*), compete with birds (Christensen and Whitham 1993).

There are many insects, pathogens, and plant parasites that attack pinyon and juniper trees (Gottfried et al. 1995, Rogers 1995, Weber et al. 1999). For pinyon, there are at least seven insects, plus a fungus (black stain root disease (*Leptographium wageneri*), and pinyon dwarf mistletoe (*Arceuthobium divaricatum*). These insects are normally present in these woodland stands, and during drought-induced water stress outbreaks may cause local to regional mortality (Wilson and Tkacz 1992, Gottfried et al. 1995, Rogers 1995). Most insect-related pinyon mortality in the West is caused by pinyon ips beetle (*Ips confusus)* (Rogers 1993).

Most pinyon-juniper woodlands in the Southwest have high soil erosion potential. Several studies have measured present-day erosion rates in pinyon-juniper woodlands, highlighting the importance of herbaceous cover and biological soil crusts (Belnap et al. 2001) in minimizing precipitation runoff and soil loss in pinyon-juniper woodlands.

Threats/Stressors: The Madrean pinyon-juniper woodland ecological system has been impacted by human activities over the last century. Historical fire regimes were disrupted following the introduction of livestock (and the 1890s drought). Fire suppression has increased woody species, led to changes in woody species composition and led to an uncharacteristic fire regime in many stands (Barton 1999, Gori and Bate 2007, Muldavin et al. 2002b, Turner et al. 2003). Grazing passively suppresses fire by removing fine fuels needed to carry surface and mixed-severity fires that likely maintained the structure and composition of pinyon-juniper savannas and pinyon-juniper shrub woodlands historically. Active fire suppression was also practiced by the Federal government during the last 100 years (Swetnam and Baisan 1996a). As fire became less frequent, pinyon and juniper trees became denser and subsequent fires became more severe (Gori and Bate 2007).

These impacts altered stand dynamics differently depending on stand structure. Fire dynamics under current conditions are summarized below for the three major pinyon-juniper types (pinyon-juniper grass savanna/open woodland, pinyon-juniper shrub woodland, and pinyon-juniper forest) developed by Romme et al. (2003) using canopy structure, understory composition, and historical fire regime.

The fire regime for the pinyon-juniper grass savanna/ open woodland has a fire frequency that is significantly reduced and fire severity has greatly increased from pre-1900, from low-severity surface fires towards high-severity and stand-replacing crown fires. Tree density has increased and herbaceous biomass has decreased from historical conditions with active fire suppression and livestock grazing. Currently stands have some very old trees (>300 years) present but not numerous, but are typically dominated by many young trees (<150 years). This type may also occur on sites with more rock soil and less grasses. This type is outside Historical Range of Variation (HRV) for disturbance regime, structure and composition (Gori and Bate 2007).

The fire regime for the pinyon-juniper shrub woodland has a fire frequency that is reduced and fire severity is somewhat increased from pre-1900, from low to moderately frequent, high-severity stand-replacing fires and moderately frequent mixed-severity fires that likely maintain this type, toward less frequent, higher severity fires (Gori and Bate 2007). Tree density has increased and herbaceous biomass has decreased from historical conditions with active fire suppression and livestock grazing. Currently most stands have a variable mix of tree and shrubs with few or no very old trees (>300 years) present. With fire suppression, this type may be outside HRV for disturbance regime, and possibly for structure and composition as recent fires are likely more severe than historical fire in late 1800s (Romme et al. 2003).

The fire regime for the pinyon-juniper forest type still has infrequent, high-severity fires that are carried by tree crowns. The stand dynamics remain relatively stable with little change in density of tree or shrub and herbaceous layers. Currently stands have numerous very old trees (>300 years) present with a multi-aged structure. Active fire suppression and livestock grazing are thought to have had little impact on fire frequency and severity and the overstory structure and composition with this type remains within HRV for disturbance regime (Gori and Bate 2007).

Historic fuelwood cutting for mining and domestic use and fencepost cutting was common in stands of this system until the late 1800s, and is still common in Arizona, New Mexico and northern Mexico today (Bahre 1991, Bennett 1992). Although fuelwood harvesting had dramatic effects historically, its consequences were generally local and short-lived (Turner et al. 2003). More recently, chemical and mechanical treatments such as chaining and rotochopping have impacted age structure, tree density and cover of many pinyon-juniper woodlands with current demand for these products continuing to increase (Ffolliott et al. 1979, Gottfried 1987, Dick-Peddie 1993, Gottfried and Severson 1993).

Fragmentation from a variety of sources such as construction of roads and secondary homes has occurred in many areas of pinyon-juniper woodlands (Gori and Bate 2007). Additional roads from oil and gas exploration and development is important in some areas. The introduction of non-native species is a threat to this ecosystem and needs to be further investigated (Gori and Bate 2007). Non-native species invasion is an important issue in the Great Basin pinyon-juniper woodlands which has led to increased fire frequency and size in that type (Miller and Tausch 2001). In Mesa Verde National Park, invasive non-native species dominate pinyon-juniper woodland areas post-fire (Romme et al. 2003). Post-fire succession may be altered if invasive non-native species colonize and prevent native grasses and forbs from establishing (Floyd et al. 2006).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct land conversion, plus wildfire suppression, overgrazing, introduced invasive plant species, and firewood collection.

Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra, además de: Supresión de incendios forestales, el pastoreo excesivo, introdujo especies de plantas invasoras, la recolección de leña.

High-severity environmental degradation appears where occurrences tend to be relatively small (<5000 acres) for this type. Stands are surrounded primarily by urban or agricultural landscape, with <25% landscape cover of natural or semi-natural vegetation. The fire regime has high departure (VCC 3) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed high woody fuel load buildup. Surficial disturbances occur on more than 50% of the area (e.g., mines or ranch activities and buildings; off-road vehicle use). Up to 50% of the stand may have been "chained" and re-seeded. Microbiotic crusts are >75% removed, occurring only in small pockets naturally protected from livestock and off-road vehicle use. Soil erosion may be severe in places.

Moderate-severity environmental degradation appears where occurrences are moderate (5000-10,000 acres) in size for this large-patch type. Landscape is a mosaic of agricultural or semi-developed areas and natural or semi-natural vegetation, the latter composing 25-80% of the landscape. The fire regime has moderate departure (VCC 2) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed moderate woody fuel load buildup. Surficial disturbances occur on more than 20% of the area. Up to 50% of the stand may have been "chained" and re-seeded. There are more than a few roads found within the occurrence. Microbiotic crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence. Soil erosion and gullying may be observed in patches (up to 30%) within the stand.

High-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) present and abundant throughout much of the stand. Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) may be present and even dominant in spots, but not throughout the stand. Connectivity is moderately hampered by fragmentation from roads and/or agriculture that restrict natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

A poor condition/non-functioning ecosystem is highly fragmented, or much reduced in size from its historical extent and the fire regime is functioning outside the historical range of variation. Density of tree canopy is too high and outside the historical range of variation. The surrounding landscape is in poor condition, either with highly eroding soils, many non-native species or a large percentage of the surrounding landscape has been converted to pavement or highly maintained agriculture (row crops, irrigated crops, etc.); the biotic condition is at the limit or beyond natural range of variation. Characteristic birds, mammals, reptiles, and insect species are not present at expected abundances or the ratio of species shows an imbalance of predator to prey populations; abiotic condition is poor with evidence of high soil erosion, rill and gullies present or exposed soil sub horizons. Cryptogamic soil crusts, if present, have been disturbed or destroyed leading to increased soil erosion and loss of topsoil to both wind and water erosional processes.

M011. Madrean Montane Forest & Woodland

CES305.282 Madrean Ponderosa Pine Woodland

CES305.282 CLASSIFICATION

Concept Summary: This is a Madrean variant of the widespread and well-studied ~Southern Rocky Mountain Ponderosa Pine Woodland (CES306.648)$$ common throughout the cordillera of the Rocky Mountains. It is also found primarily in the Sierra Madre Occidental. These woodlands occur at the lower treeline/ecotone between dry deciduous forests and pine-oak forests typically in warm, dry, exposed sites. Elevations range from less than 400 to 1500 m. Occurrences are found on all slopes and aspects; however, moderately steep to very steep slopes or ridgetops are most common. Much like the Rocky Mountain system, this system likely occurs on igneous, metamorphic, and sedimentary material derived soils, with characteristic features of good aeration and drainage, coarse textures, circumneutral to slightly acidic pH, an abundance of mineral material, rockiness, and periods of drought during the growing season. Mixed fire regimes and surface fires of variable return interval likely maintain these woodlands, depending on climate, degree of soil development, and understory density. The following species are diagnostic for this system: *Pinus ponderosa, Abies concolor*.

Related Concepts:

Distribution: This system is found in the Sierra Madre Occidental and Sierra Madre Oriental of Mexico, Trans-Pecos Texas, southern New Mexico and Arizona, generally south of the Mogollon Rim.

Nations: MX

Concept Source: C. Josse

Description Author: C. Josse

CES305.282 CONCEPTUAL MODEL

Environment: These woodlands occur at the lower treeline/ecotone between dry deciduous forests and pine-oak forests, typically in warm, dry, exposed sites. Elevations range from less than 400 to 1500 m. Occurrences are found on all slopes and aspects; however, moderately steep to very steep slopes or ridgetops are most common. Much like the Rocky Mountain system, this system likely occurs on igneous, metamorphic, and sedimentary material derived soils, with characteristic features of good aeration and drainage, coarse textures, circumneutral to slightly acidic pH, an abundance of mineral material, rockiness, and periods of drought during the growing season.

Key Processes and Interactions: Mixed fire regimes and surface fires of variable return interval likely maintain these woodlands, depending on climate, degree of soil development, and understory density.

Threats/Stressors: Deforestation, wildfire suppression

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

CES305.281 Madrean Pine-Alder Forest and Woodland

CES305.281 CLASSIFICATION

Concept Summary: This system occurs on high mountains and plateaus throughout Mexico. These forests and woodlands are composed of Madrean pines, alder, intermingled with patchy shrublands and bunchgrasses on many mid- to high-elevation slopes (2700-3500 m elevation). Some stands have moderate cover of perennial graminoids in the form of bunchgrasses and forbs. Fires are frequent, with perhaps more crown fires than ponderosa pine woodlands, which tend to have more frequent surface fires on gentle slopes. Alder likely plays a similar ecological role to species of aspen in Rocky Mountain forests, with fire and wind providing frequent canopy openings, and this alder species exploiting disturbance, especially on soils with high moisture-holding capacity. The following list of species is diagnostic for this system: *Pinus montezumae, Pinus michoacanus, Pinus oocarpa, Alnus firmifolia, Arbutus glandulosa, Buddleia paryflora, Penstemon gentianoides, Senecio cineraroides, Symphoricarpos microphyllus, Muhlenbergia macroura, Festuca tolucensis, Alchemilla procumbens*, and *Arenaria lycopodioides*.

Related Concepts:

Nations: MX

Concept Source: C. Josse

Description Author: C. Josse

CES305.281 CONCEPTUAL MODEL

Environment: These woodlands occur above pine-oak forests on dissected landscapes with rolling-to-steep slopes, and on lava flows, between 2700-3500 m elevation. Soils tend to be shallow with gravelly sandy loam textures.

Key Processes and Interactions: Mixed fire regimes and surface fires of variable return interval likely maintain these woodlands, depending on climate, degree of soil development, and understory density.

Threats/Stressors:

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

CES305.796 Madrean Lower Montane Pine-Oak Forest and Woodland

CES305.796 CLASSIFICATION

Concept Summary: This ecological system occurs on mountains and plateaus in the Sierra Madre Occidental and Sierra Madre Oriental in Mexico, Trans-Pecos Texas, southern New Mexico and Arizona, generally south of the Mogollon Rim. These forests and woodlands are composed of Madrean pines (*Pinus arizonica, Pinus engelmannii, Pinus leiophylla*, or *Pinus strobiformis*) and evergreen oaks (*Quercus arizonica, Quercus emoryi*, or *Quercus grisea*) intermingled with patchy shrublands on most mid-elevation slopes (1500-2300 m elevation). Other tree species include *Hesperocyparis arizonica, Juniperus deppeana, Pinus cembroides, Pinus discolor, Pinus ponderosa* (with Madrean pines or oaks), and *Pseudotsuga menziesii*. Subcanopy and shrub layers may include typical encinal and chaparral species such as *Agave* spp., *Arbutus arizonica, Arctostaphylos pringlei, Arctostaphylos pungens, Garrya wrightii, Nolina* spp., *Quercus hypoleucoides, Quercus rugosa*, and *Quercus turbinella*. Some stands have moderate cover of perennial graminoids such as *Muhlenbergia emersleyi, Muhlenbergia longiligula, Muhlenbergia straminea*, and *Schizachyrium cirratum*. Fires are frequent with perhaps more crown fires than ponderosa pine woodlands, which tend to have more frequent surface fires on gentle slopes.

Distribution: This system is found in the Sierra Madre Occidental and Sierra Madre Oriental of Mexico, Trans-Pecos Texas, southern New Mexico and Arizona, generally south of the Mogollon Rim.
Nations: MX, US
Concept Source: P. Comer
Description Author: L. Elliott and J. Teague

CES305.796 CONCEPTUAL MODEL

Environment: This system is found on mountains and plateaus, on gently rolling landscapes or rugged slopes. In the Davis Mountains of Texas, it occurs on Tertiary igneous substrates, but may also occur on sandstone and limestone substrates, such as in the Guadalupe Mountains region. Soils are often rocky but also include mountain loams.
Key Processes and Interactions: [from M011] Under historic natural conditions (also called natural range of variability, NRV), lower to mid-elevation stands in this macrogroups varied from open woodlands (10-20% cover) with pines dominating the overstory and perennial bunch grass dominating the understory to moderately dense woodlands (20-40% tree cover) with less dense herbaceous layer and more tree and shrub cover. Lower elevation tree line of pines is primarily controlled by dry season water stress (Barton 1993). Fire and drought are the primary disturbances of this ecosystem (USFS 2009).

Information on fire return intervals is varied depending on elevation zone with fires frequently starting at lower elevations and burning upslope into the montane zone. Lower montane elevation pine-oak stands had frequent, low intensity surface fires (mean fire return every 6-14 years) as a result of lightning ignitions primarily between early spring and summer (Bahre 1985, Swetnam et al. 1992, 2001, Kaib et al. 1996, Schussman and Gori 2006, Swetnam and Baisan 1996b). However, minimum fire-free periods of 20-30 years are necessary for pines to establish and become resistant (thick bark) to surface fires (Barton et al. 2001). More frequent fire favors oaks and other sprouting species over pines and other conifers, which can alter stand composition. Less frequent fire (FRI >50 years) results in more conifer recruitment and denser vegetation that can lead to higher intensity, mixed-severity and patches of stand-replacing fires that also favors oaks and other sprouting species (Danzer et al. 1996, Barton 1999, Barton et al. 2001, Schussman and Gori 2006). For stands with inclusions of Ponderosa Pine Woodland in the Madrean Conifer-Oak Forest and Woodland, the historic mean fire-return interval is similar (Smith 2006). In Arizona and New Mexico, Swetnam and Baisan (1996b) found the historic mean fire-return interval ranges from 2 to 17 years for fires scarring one or more trees, and 4 to 36 years for fires scarring between 10% and 25% of trees between the years of 1700 and 1900. However, in the more mesic subalpine fir communities a fire return interval of up to 400 years is not uncommon.

Herbivory by native herbivores in the Madrean montane conifer-oak forests and woodlands is variable in this type. For more open stands with grass-dominated understory herbivores are similar to semi-desert grasslands. Large herbivores include browsers like Coues' white-tailed deer (*Odocoileus virginianus couesi*), mule deer (*Odocoileus hemionus*), elk (*Cervus elaphus*), and rodents such as yellow nosed cotton rat (*Sigmodon ochrognathus*), white-throated wood rat (*Neotoma albigula*), southern pocket gopher (*Thomomys umbrinus*), Apache squirrel (*Sciurus nayaritensis*), Arizona gray squirrel (*Sciurus arizonensis*), porcupine (*Erethizon dorsatum*), Bailey's pocket mouse (*Chaetodipus baileyi*), and eastern cotton tail (*Sylvilagus floridanus*) are common in the Madrean pine-oak woodlands (Schussman and Gori 2006, Majka et al. 2007). Southwestern forest trees have been host to several species of insects, pathogenic fungi, and parasitic plants, however there are no accounts of historic insect outbreak, fungi or parasitic plant periodicity (Dahms and Geils 1997).

A good condition/proper functioning occurrence of Madrean Montane Conifer-Oak Forest and Woodland ecosystem is large and uninterrupted; the surrounding landscape is also in good condition with soils that have not been excessively eroded. Weeds are few. There is a diversity of stand age and size classes in response to a functioning natural fire regime. For the majority of the type (lower montane pine-oak woodlands) that is frequent (mean fire return every 6-14 years), low-intensity surface fires with occasional fire free periods of 20-30 years minimum to allow for conifers to establish and become resistant (thick bark) to surface fires. For upper montane conifer oak and mixed conifer forests, the historical fire regime would have less frequent fires, mixed-severity and occasional stand-replacing fires.

A poor condition/non-functioning occurrence is highly fragmented, or much reduced in size from its historic extent; the surrounding landscape is in poor condition either with highly eroding soils, many non-native species or a large percentage of the surrounding landscape has been converted to exurban development. Over time passive (livestock grazing) and active fire suppression would result high density of trees and heavy fuel loading that would lead to large, high-severity, stand-replacing fires in stands of the montane conifer-oak forests.
Threats/Stressors:
Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct land conversion.

Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

CES305.798 Madrean Upper Montane Conifer-Oak Forest and Woodland

CES305.798 CLASSIFICATION

Concept Summary: This ecological system occurs at the upper elevations in the Sierra Madre Occidental and Sierra Madre Oriental of Mexico with disjunct and limited occurrences at the highest elevations of the Chisos and Guadalupe mountains in Texas. In the U.S., it is restricted to north and east aspects at high elevations (1980-2440 m) in the Sky Islands (Chiricahua, Huachuca, Pinaleno, Santa Catalina, and Santa Rita mountains) and along the Nantanes Rim. It is more common in Mexico and does not occur north of the Mogollon Rim. The vegetation is characterized by large- and small-patch forests and woodlands dominated by *Pseudotsuga menziesii, Abies coahuilensis*, or *Abies lowiana* and Madrean oaks such as *Quercus arizonica, Quercus emoryi, Quercus grisea, Quercus hypoleucoides, Quercus rugosa*, and *Quercus toumeyi*. If *Quercus gambelii* is prominent in the shrub layer, then other Madrean elements are present. This system may include stands of *Quercus gravesii* woodlands. It is similar to ~Southern Rocky Mountain Dry-Mesic Montane Mixed Conifer Forest and Woodland (CES306.823)$$ which typically lacks Madrean elements.

Related Concepts:
- Trans-Pecos: High Mountain Conifer Forest and Woodland (12601) [CES305.798.1] (Elliott 2012) **<**
- Trans-Pecos: High Mountain Evergreen Shrubland (12605) [CES305.798.2] (Elliott 2012) **<**
- Trans-Pecos: High Mountain Mixed Conifer - Oak Forest and Woodland (12603) [CES305.798.2] (Elliott 2012) **<**

Distribution: This system is found in the Sierra Madre Occidental and Sierra Madre Oriental of Mexico. In the U.S., it is restricted to north and east aspects at high elevations (1980-2440 m) in the Sky Islands (Chiricahua, Huachuca, Pinaleno, Santa Catalina, and Santa Rita mountains) and along the Nantanes Rim. It also has limited distribution in Texas on the highest mountain areas of the Guadalupe and Chisos mountains, but is lacking from high elevations of the Davis Mountains.

Nations: MX, US

Concept Source: P. Comer

Description Author: L. Elliott and J. Teague

CES305.798 CONCEPTUAL MODEL

Environment: In Texas, this system occurs on Permian limestone in the Guadalupe Mountains, and in the Chisos Mountains, it primarily occurs on Tertiary igneous formations and associated colluvial and alluvial deposits from these formations. In the Chisos Mountains, it occurs on Igneous Hill and Mountain soils; in the Guadalupe Mountains in occurs on Victorio-Lorenz-Rock outcrop complex.

Key Processes and Interactions: [from M011] Under historic natural conditions (also called natural range of variability, NRV), lower to mid-elevation stands in this macrogroups varied from open woodlands (10-20% cover) with pines dominating the overstory and perennial bunch grass dominating the understory to moderately dense woodlands (20-40% tree cover) with less dense herbaceous layer and more tree and shrub cover. Lower elevation tree line of pines is primarily controlled by dry season water stress (Barton 1993). Fire and drought are the primary disturbances of this ecosystem (USFS 2009).

Information on fire return intervals is varied depending on elevation zone with fires frequently starting at lower elevations and burning upslope into the montane zone. Lower montane elevation pine-oak stands had frequent, low intensity surface fires (mean fire return every 6-14 years) as a result of lightning ignitions primarily between early spring and summer (Bahre 1985, Swetnam et al. 1992, 2001, Kaib et al. 1996, Schussman and Gori 2006, Swetnam and Baisan 1996b). However, minimum fire-free periods of 20-30 years are necessary for pines to establish and become resistant (thick bark) to surface fires (Barton et al. 2001). More frequent fire favors oaks and other sprouting species over pines and other conifers, which can alter stand composition. Less frequent fire (FRI >50 years) results in more conifer recruitment and denser vegetation that can lead to higher intensity, mixed-severity and patches of stand-replacing fires that also favors oaks and other sprouting species (Danzer et al. 1996, Barton 1999, Barton et al. 2001, Schussman and Gori 2006). For stands with inclusions of Ponderosa Pine Woodland in the Madrean Conifer-Oak Forest and Woodland, the historic mean fire-return interval is similar (Smith 2006). In Arizona and New Mexico, Swetnam and Baisan (1996b) found the historic mean fire-return interval ranges from 2 to 17 years for fires scarring one or more trees, and 4 to 36 years for fires scarring between 10% and 25% of trees between the years of 1700 and 1900. However, in the more mesic subalpine fir communities a fire return interval of up to 400 years is not uncommon.

Herbivory by native herbivores in the Madrean montane conifer-oak forests and woodlands is variable in this type. For more open stands with grass-dominated understory herbivores are similar to semi-desert grasslands. Large herbivores include browsers like Coues' white-tailed deer (*Odocoileus virginianus couesi*), mule deer (*Odocoileus hemionus*), elk (*Cervus elaphus*), and rodents such as yellow nosed cotton rat (*Sigmodon ochrognathus*), white-throated wood rat (*Neotoma albigula*), southern pocket gopher (*Thomomys umbrinus*), Apache squirrel (*Sciurus nayaritensis*), Arizona gray squirrel (*Sciurus arizonensis*), porcupine (*Erethizon dorsatum*), Bailey's pocket mouse (*Chaetodipus baileyi*), and eastern cotton tail (*Sylvilagus floridanus*) are common in the Madrean pine-oak woodlands (Schussman and Gori 2006, Majka et al. 2007). Southwestern forest trees have been host to several species of insects, pathogenic fungi, and parasitic plants, however there are no accounts of historic insect outbreak, fungi or parasitic plant periodicity (Dahms and Geils 1997).

A good condition/proper functioning occurrence of Madrean Montane Conifer-Oak Forest and Woodland ecosystem is large and uninterrupted; the surrounding landscape is also in good condition with soils that have not been excessively eroded. Weeds are few. There is a diversity of stand age and size classes in response to a functioning natural fire regime. For the majority of the type (lower montane pine-oak woodlands) that is frequent (mean fire return every 6-14 years), low-intensity surface fires with occasional fire free periods of 20-30 years minimum to allow for conifers to establish and become resistant (thick bark) to surface fires. For upper montane conifer oak and mixed conifer forests, the historical fire regime would have less frequent fires, mixed-severity and occasional stand-replacing fires.

A poor condition/non-functioning occurrence is highly fragmented, or much reduced in size from its historic extent; the surrounding landscape is in poor condition either with highly eroding soils, many non-native species or a large percentage of the surrounding landscape has been converted to exurban development. Over time passive (livestock grazing) and active fire suppression would result high density of trees and heavy fuel loading that would lead to large, high-severity, stand-replacing fires in stands of the montane conifer-oak forests.

Threats/Stressors:

Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct land conversion.

Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

1.B.2.Na. Eastern North American Forest & Woodland

M883. Appalachian-Interior-Northeastern Mesic Forest

CES202.593 Appalachian (Hemlock)-Northern Hardwood Forest

CES202.593 CLASSIFICATION

Concept Summary: This forested system of the eastern U.S. ranges from central New England west to Lake Erie and south to the higher elevations of Virginia and West Virginia. It is one of the matrix forest types in the northern part of the Central Interior and Appalachian Division. Northern hardwoods such as *Acer saccharum, Betula alleghaniensis*, and *Fagus grandifolia* are characteristic, either forming a deciduous canopy or mixed with *Tsuga canadensis* (or in some cases *Pinus strobus*). Other common and sometimes dominant trees include *Quercus* spp. (most commonly *Quercus rubra*), *Liriodendron tulipifera, Prunus serotina, Acer rubrum*, and *Betula lenta*. It is of more limited extent and more ecologically constrained in the southern part of its range in northern parts of Virginia and West Virginia.

Distribution: This system is found from southern New Hampshire south to Virginia and West Virginia, and possibly in adjacent Kentucky.
Nations: US
Concept Source: S.C. Gawler, R. White, R. Evans, M. Pyne
Description Author: S.C. Gawler, R. White, R. Evans, M. Pyne, L.A. Sneddon

CES202.593 CONCEPTUAL MODEL

Environment: This system occurs predominantly on mesic sites over a broad range of topographic conditions, such as protected low and midslopes and valley bottoms, at elevations from 305 to 1360 m. Soils are usually acidic and retain some moisture except during severe droughts. They are moderately well-drained to well-drained loamy or silty soils, and are rocky and usually deep in depressions among boulders. Forests in this system are also associated with high-elevation periglacial boulderfields. In the Central Appalachian center of its range, its ecological amplitude is somewhat broader, and it becomes the matrix forest in some areas of Pennsylvania, Maryland, West Virginia. At Shenandoah National Park, this system spans a broad range of environmental settings from steep west-facing slopes to south-facing gentle slopes.
Key Processes and Interactions: In general, this system is dominated by long-lived, mesophytic species that form multi-layered uneven-aged forests. Canopy dynamics are dominated by single and multiple disturbances encouraging gap phase regeneration (Abrams and Orwig 1996). Larger disturbances include windthrow, insect attack and icestorms. Although stand-replacing wind events are rare, small to medium blowdown events are more common and occur at greater frequency on the plateau and exposed sideslopes (Ruffner and Abrams 2003).This system is currently being devastated in large parts of its range by the hemlock woolly adelgid (*Adelges tsugae*). This sucking insect is continuing to cause close to 100% mortality in some areas as it spreads from the north into the southern United States. The insect will most likely cause canopy hemlocks to be replaced by other canopy trees. Historically, this system was probably only subject to occasional fires. Fires that did occur may have been catastrophic and may have led to even-aged stands of pine and hemlock. Fire suppression appears to have increased the extent of this system at the expense of oak-pine systems.

Fire Regime Description (from Landfire 2007a): Historically, this system was probably only subject to occasional fires. Fires that did occur may have been catastrophic and may have led to even-aged stands of pine and hemlock. Due to the predominance of cool, moist site conditions, surface and replacement fires are extremely rare, occurring at 700- to 1000-year intervals. Most protected sites are essentially fire-free. The principal cause of fuel formation leading to fire in northern hardwood ecosystems is broad-scale, storm-driven windthrow of catastrophic proportions (Hough 1936, Runkle 1982). The importance of red maple, sweet birch, northern red oak, and especially black cherry in contemporary Central Appalachian examples of this community group reflects secondary succession following catastrophic logging and fire disturbances in the early part of the twentieth century. Sugar maple and beech, both abundant in understory layers and locally codominant in the overstory, appear positioned to assume dominance as current secondary stands mature. However, beech bark disease and excessive deer browsing are serious threats to the future viability of the largest stands on Allegheny Mountain (VDNH 2007).
Threats/Stressors: This system is currently being impacted in large parts of its range by losses or declines of several dominant tree species. *Tsuga canadensis* is heavily impacted by hemlock woolly adelgid (*Adelges tsugae*), a sucking insect that is continuing to cause close to 100% mortality in hemlocks; Orwig and Foster (1998) documented high mortality or high foliar loss by *Tsuga canadensis*; changes in forest composition resulted in rapid understory responses to canopy openings such as prolific establishment of *Betula lenta*, as well as invasion by *Ailanthus altissima, Microstegium vimineum*, and others). Other important trees in this system impacted by insect damage include *Fraxinus americana* by the emerald ash borer (*Agrilus planipennis*) and *Fagus grandifolia* by the insect *Cryptococcus fagisuga*, which causes fungal infections known as beech bark disease. A number of tree species of this system are also damaged by Asian long-horned beetle (*Anoplophora glabripennis*). Past logging in many areas has altered this system by creating a predominantly even-aged structure that contains a much higher proportion of shade-intolerant species. In many areas, this change in species composition is further aggravated by decades of overbrowsing by deer (Runkle 1982, Abrams and Orwig 1996), which has significantly reduced the hemlock component and reduced species and structural diversity in many areas. Loss of foundation tree species changes the local environment and associated ecosystem processes; those forests dominated by a few foundation species are dependent on a small number of strong interactions that may be susceptible to fluctuation among unstable states (Ellison et al. 2005). Additional threats include logging, development, overbrowsing, and road construction, which fragments large patches (Fike 1999, NYNHP 2013b). Climate change also threatens to allow expansion of woolly adelgid beyond its current restrictions in cooler climates (Paradis et al. 2007). Another threat is acid deposition due to high precipitation in the mountains

downwind from coal power plants. Combined with repeated logging cycles which remove carbon and calcium sinks, this may cause soil cations to be leached and depleted and toxic elements to accumulate (Connolly et al. 2007).

Ecosystem Collapse Thresholds: Ecosystem collapse would occur as a result of the loss of key tree species to insect predation or pathogens, opening the tree canopy to allow significant invasion of exotic species and early-successional tree species. Commercial and residential development has reduced patch size such that wildlife populations have decreased significantly.

CES202.887 South-Central Interior Mesophytic Forest

CES202.887 CLASSIFICATION

Concept Summary: These high-diversity, predominately deciduous forests occur on deep and enriched soils (in some cases due to, or enhanced by, the presence of limestone or related base-rich geology), in non-montane settings and usually in somewhat protected landscape positions such as coves or lower slopes. The core distribution of this system lies in the Cumberland and Allegheny plateaus, extending into the adjacent southern Ridge and Valley and portions of the Interior Low Plateau where it is located entirely south of the glacial boundary. Dominant species include *Acer saccharum, Fagus grandifolia, Liriodendron tulipifera, Tilia americana, Quercus rubra, Magnolia acuminata*, and *Juglans nigra*. The abundance of *Tsuga canadensis*, which may be a component of some stands, is being rapidly reduced by the hemlock woolly adelgid (*Adelges tsugae*). The canopy trees may grow very large in undisturbed areas. The herb layer is very rich, often with abundant spring ephemerals. Many examples may be bisected by small streams.

Related Concepts:

- Yellow-Poplar - Eastern Hemlock: 58 (Eyre 1980) **<**
- Yellow-Poplar: 57 (Eyre 1980) **<**

Distribution: This system occurs in southeastern Ohio east to Virginia, West Virginia, Kentucky, Tennessee, Georgia, and Alabama, with disjunct occurrences in unglaciated southwestern Pennsylvania and southwestern New York. This range is more-or-less consistent with the "Mixed Mesophytic" and "Western Mesophytic" (non-coastal plain portion only) forest regions of Braun (1950) and Greller (1988), although it does extend into unglaciated portions of the "Beech-Maple" region to the north. Thus, this system is most extensive in the Cumberland and Allegheny plateaus, as well as the unglaciated Interior Low Plateau, and becomes relatively limited in extent towards its western limit in the Ozark Hills of Illinois, and towards its northern limit in southwestern New York.. It is replaced in the Upper East Gulf Coastal Plain by other systems. Its range also includes the southern Ridge and Valley from Tennessee (and adjacent southwestern Virginia) to Alabama. Parts of the Cumberland Mountains (EPA 69 in Kentucky and Tennessee) are

instead occupied by ~Southern and Central Appalachian Cove Forest (CES202.373)$$. ~North-Central Interior Beech-Maple Forest (CES202.693)$$ replaces this one in EPA 72b of Indiana.

CES202.373 Southern and Central Appalachian Cove Forest

CES202.373 CLASSIFICATION

Concept Summary: This system consists of mesophytic hardwood or hemlock-hardwood forests of sheltered topographic positions in the Southern Blue Ridge and central Appalachian Mountains. Examples are generally found on concave slopes that promote moist conditions. The system includes acidic and "rich" coves that may be distinguished by individual plant communities based on perceived differences in soil fertility and species richness (rich examples have higher diversity and density in the herbaceous layer). Both acidic and rich coves may occur in the same site, with the acidic coves potentially creeping out of the draw-up to at least midslope on well-protected north-facing slopes. Characteristic species in the canopy include *Aesculus flava, Acer saccharum, Fraxinus americana, Tilia americana, Carya cordiformis, Liriodendron tulipifera, Halesia tetraptera, Tsuga canadensis, Fagus grandifolia, Magnolia acuminata*, and *Magnolia fraseri*.

Distribution: This system occurs in the southern and central Appalachian Mountains, ranging into the Cumberland Mountains of Kentucky and Tennessee. This range is more-or-less consistent with the "Oak-Chestnut" forest region of Braun (1950) and Greller

(1988), versus the "Mixed Mesophytic" and "Western Mesophytic" forest regions to the west. In West Virginia and north, the Allegheny front is the boundary between this and ~South-Central Interior Mesophytic Forest (CES202.887)$$.

Nations: US

Concept Source: M. Schafale, M. Pyne, R. White, R. Evans

CES202.373 CONCEPTUAL MODEL

Environment: This mixed mesophytic forest system occurs on moist, topographically protected areas such as coves, V-shaped valley bottoms and ravines, and north- and east-facing toeslopes in a dissected landscape. It generally occurs below 1525 m (5000 feet) elevation. The dissected topography creates strong gradients in microclimate and soil moisture and fertility at the local (watershed) scale (Hutchins et al. 1976, Iverson et al. 1997, Morris and Boerner 1998). This forest type developed primarily on mesic, sheltered landscape positions (e.g., lower concave slopes, coves, ravines) but also occurred on some dry-mesic slopes, where presumably fire was infrequent (Wade et al. 2000). This system has two primary components, an acidic cove of lower soil fertility that ranges from the lowest slope positions up the slope on north-facing protected slopes, and a rich, high-fertility cove forest that tends to occur only at the lowest slope positions. Both are sheltered from wind and may be shaded by concave topography, which promotes moist conditions. Local slopes are usually concave. Bedrock may be of numerous types. Acidic rocks, such as felsic igneous and metamorphic rocks, support rich cove forests in a more limited range of sites than do basic rocks, such as mafic metamorphic rocks or marble. Soils may be rocky or fine-textured, and may be residual, alluvial, or colluvial. In the southern Appalachians, the hemlock "phase" of this ("acidic cove forest") often occurs between "richer" examples of ~Southern and Central Appalachian Cove Forest (CES202.373)$$ in the lowest areas and ~Southern Appalachian Oak Forest (CES202.886)$$ on the midslopes.

Key Processes and Interactions: This system is naturally dominated by stable, uneven-aged forests, with canopy dynamics dominated by gap-phase regeneration on a fine scale. Occasional extreme wind or ice events may disturb larger patches. In the absence of frequent or catastrophic disturbance, environmental gradients formed by the dissected topography determine forest composition (Hutchins et al. 1976, Muller 1982, Iverson et al. 1997, Dyer 2001). Most of the component species are among the less fire-tolerant in the region. The mixed-mesophytic forest type is fire regime class III, surface fires with return intervals 30-100+ years (Wade et al. 2000). Mixed-severity fires may occur approximately every 500 years opening the canopy with increased mortality. Straight-line winds or microbursts may cause blowdowns on a scale of one to 100 acres. Stand-replacement fires happen very infrequently. Current composition and structure of this system is influenced by the absence of fire, deer herbivory, and non-native invasive species (plants, animals, insects and disease). The absence of fire is causing an expansion of some of the characteristic mesic taxa out of coves, potentially replacing previous oak-dominated vegetation on drier and more exposed sites than those typically associated with "mesic" vegetation.

CES202.029 Southern Appalachian Northern Hardwood Forest

CES202.029 CLASSIFICATION

Concept Summary: This ecological system consists of hardwood forests of the higher elevation zones of the Southern Appalachians, generally above 1372 m (4500 feet) elevation within its primary range. Included are classic northern hardwood forests, dominated by various combinations of mesophytic hardwoods, which interfinger with high-elevation oak forests downslope or on more exposed aspects. The combination of elevation and aspect provides habitat for this system. Included in this system are limited areas locally known as "beech gaps" and "boulderfields." Stands are dominated by various combinations of Appalachian mesophytic trees, including *Acer saccharum, Aesculus flava, Betula alleghaniensis, Fagus grandifolia*, and *Tsuga canadensis*. In addition, *Prunus serotina* and *Tilia americana var. heterophylla* are occasionally abundant. *Quercus rubra* may be present but is not dominant. In Kentucky, this system is of extremely limited extent, being restricted to areas on Black Mountain (the highest mountain in the state) above about 915-1100 m (3000-3600 feet) elevation. Black Mountain is apparently higher in elevation than adjacent areas in Tennessee and Virginia.

Related Concepts:

- Northern Hardwood Forest (Schafale and Weakley 1990) **>**
- Sugar Maple - Beech - Yellow Birch: 25 (Eyre 1980) **?**

Distribution: This system is primarily found in the Southern Blue Ridge, where it ranges from northwestern Georgia, western North Carolina and eastern Tennessee northward to southern Virginia. In Kentucky, this system is restricted to the Cumberland Mountains in the extreme southeastern corner of that state.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, M. Pyne and S. Gawler

CES202.029 CONCEPTUAL MODEL

Environment: The habitat for this system in the Southern Blue Ridge includes cooler, moister slopes and more-or-less concave landforms, at elevations from 1220-1680 m (4000-5500 feet), occasionally extending up to nearly 1830 m (6000 feet). It is most prevalent on north- to east-facing slopes, but can occur on a variety of landforms and aspects within this elevational range, tending to be more predominant towards its upper limits, where it transitions to spruce- or spruce-hardwood-dominated types. Elevation and orographic effects make the climate cool and wet, with significant moisture input from fog as well as high rainfall. Strong winds, ice glaze, and extreme cold may occur but are less important than in ~Central and Southern Appalachian Spruce-Fir Forest (CES202.028)$$. Soils are generally very rocky, with the matrix ranging from well-weathered parent material to coarse colluvial boulder deposits. Soils are probably moist but not saturated most of the time. Any kind of bedrock may be present. Limited areas support boulderfields. In related areas of Kentucky, this system is of extremely limited extent. It is found as low as about 915 m (3000 feet) on exposed northwest-facing slopes on Black Mountain, the highest mountain in the state. Its elevational range here is lower than in the Southern Blue Ridge. Black Mountain is higher in elevation than adjacent areas in Tennessee and Virginia, which apparently lack examples of this system.

Key Processes and Interactions: This system is naturally dominated by stable, uneven-aged forests, with canopy dynamics dominated by gap-phase regeneration on a fine to medium scale. Occasional extreme wind or ice events disturb larger patches on exposed slopes. Fire appears to be uncommon under natural conditions, perhaps extremely rare in the more mesic portions. In contrast, fire may be important in regeneration of *Quercus rubra* in stands of ~Central and Southern Appalachian Montane Oak Forest (CES202.596)$$, and may be crucial in maintaining its dominance in these drier sites. Many *Quercus rubra* forests now appear to be succeeding to mesophytic hardwoods in the absence of fire. Little is known about natural fire behavior. Fires are likely to be low in intensity because of limited flammability of the vegetation and prevailing moist conditions, but most of the component tree species are probably not very tolerant of fire.

CES202.342 Southern Piedmont Mesic Forest

CES202.342 CLASSIFICATION

Concept Summary: This system encompasses mixed deciduous hardwood or occasionally hardwood-pine forests of mesic sites in the Piedmont of the southeastern United States. Most examples occur on lower or north-facing slopes where topography creates mesic moisture conditions. A mix of a small number of mesophytic trees is usually dominant, with *Fagus grandifolia* most prominent. Both acidic and basic substrates are currently included in this concept, as are certain heath bluffs, where dense shrub layers of mesophytic ericaceous shrubs may occur beneath an open tree canopy. Fire is naturally infrequent in this system, due to the slopes and moist conditions. If fire does penetrate, it is likely to be low in intensity and may not have significant ecological effects. Vegetation consists of forests dominated by combinations of trees that include a significant component of mesophytic species. *Fagus grandifolia* is almost always abundant and is often strongly dominant. *Quercus rubra, Liriodendron tulipifera*, and *Acer rubrum* may be abundant. In basic soil examples, *Fraxinus americana* and *Acer floridanum* are also abundant. A well-developed understory is usually present. Herbs range from fairly dense in basic examples to sparse in acidic examples, and may be nearly absent in a few. The composition of all lower strata varies substantially with soil acidity.

Distribution: This ecological system ranges throughout the southern Piedmont, from Virginia to Alabama.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, C.W. Nordman

CES202.342 CONCEPTUAL MODEL

Environment: Examples occur on lower slopes or on north-facing slopes, where topography creates mesic moisture conditions. This system may occur on any kind of rock type, with rock chemistry being an important determinant of variation. Most soils are acidic, but those formed on mafic rocks often are circumneutral to basic. The moist conditions and slope limit natural fire intensity and frequency.

Key Processes and Interactions: Fire is naturally infrequent in this system, due to the slopes and moist conditions. If fire does occur, it is likely to be low in intensity and may not have significant ecological effects. These forests generally exist naturally as old-growth forests, with canopy dynamics dominated by gap-phase regeneration. Small to occasional medium-sized canopy gaps created by wind are likely the primary form of natural disturbance, though infrequent fires might create gaps. Most of the prevailing species are shade-tolerant. Most are not very fire-tolerant. The mesophytic forest type is fire regime class III, surface fires with return intervals of 20 to 70 years (Landfire 2007a). Mixed-severity fires may occur approximately every 100 years depending on climatic conditions. Disturbance may also occur by recurrent, severe insect defoliations or droughts. Ice, straight-line winds or microbursts may cause blow-downs on a scale of 1 to 10 acres. Stand-replacement fires happen very infrequently. Low-intensity surface fires, whether natural or set by Native Americans, would have maintained the more fire-resistant *Castanea dentata* and oak species.

Threats/Stressors: Conversion of this type has primarily resulted from repeated canopy removal through logging, which is also the most critical anthropogenic threat. These sites were historically less frequently logged than the adjacent pine-dominated uplands, with more desirable species being removed in preference to *Fagus grandifolia*, which is less desirable in the lumber trade. In addition, some mesic hardwood forests in more moderately dissected terrain have been converted to pine plantations or impacted (destroyed or fragmented) by agriculture. Bluff habitats are often prime sites for development, especially along major rivers. Complete devastation by natural agents was probably very rare in this forest type (Batista and Platt 1997). These forests also suffer the effects of ozone and acidic atmospheric deposition.

Aside from actual site conversion, feral hogs represent one of the greatest threats to biodiversity in these forests (Engeman et al. 2007). They can be especially difficult to control in sensitive slope forests (Edwards et al. 2013). In addition, invasive exotic species including *Elaeagnus umbellata, Hedera helix, Ligustrum sinense, Lonicera japonica*, and *Wisteria sinensis* can become dominant in the ground and shrub layers following canopy disturbance (Edwards et al. 2013). For mesic hardwood forests containing *Fraxinus* species, emerald ash borer (recently found in Georgia) may also be a significant stressor.

The most significant potential climate change effects over the next 50 years include periods of drought, which has affected parts of the coastal plain. Droughts will affect the health and survival of the moisture-requiring trees, as well as increase the probability of damaging wildfire.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (including *Fagus grandifolia*) to regenerate. Periods of drought will also affect the health and survival of the moisture-requiring trees. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Ecological collapse can also result from such severe fragmentation (as in remnant patches left scattered among developments and roads) that wildlife is driven out and natural processes are lacking. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and other disturbance. Feral hogs and other non-native species can significantly impact forest composition and structure (Engeman et al. 2007, Edwards et al. 2013).

M502. Appalachian-Northeastern Oak - Hardwood - Pine Forest & Woodland

CES202.359 Allegheny-Cumberland Dry Oak Forest and Woodland

CES202.359 CLASSIFICATION

Concept Summary: This system encompasses dry hardwood forests on predominately acidic substrates in the Allegheny and Cumberland plateaus, as well as acidic sandstone ridges in the southern Ridge and Valley. Its range is more-or-less consistent with the "Mixed Mesophytic Forest Region" of Braun (1950) and Greller (1988), although it is not a mesic forest type. These forests are typically dominated by *Quercus alba, Quercus falcata, Quercus montana, Quercus coccinea*, with lesser amounts of *Acer rubrum, Carya glabra*, and *Carya tomentosa*. Small inclusions of *Pinus echinata* and/or *Pinus virginiana* may occur, particularly adjacent to escarpments or following fire. In addition, *Pinus strobus* may be prominent in some stands in the absence of fire. It occurs in a variety of situations, including on nutrient-poor or acidic soils. Sprouts of *Castanea dentata* can often be found where it was formerly a common tree.

CES202.598 Appalachian Shale Barrens

CES202.598 CLASSIFICATION

Concept Summary: This system encompasses the distinctive shale barrens of the Central and Southern Appalachians at low to mid elevations. The exposure and lack of soil create extreme conditions for plant growth. Vegetation is mostly classified as woodland, overall, but may include large open areas of sparse vegetation. Dominant trees are primarily *Quercus montana* and *Pinus virginiana*, although on higher-pH substrates the common trees include *Juniperus virginiana* and *Fraxinus americana*. Shale barren endemics are diagnostic in the herb layer. The substrate includes areas of solid rock as well as unstable areas of shale scree, usually steeply sloped. The fully exposed areas are extremely dry. These barrens are high in endemic species.

Related Concepts:

- Chestnut Oak: 44 (Eyre 1980) **<**
- Virginia Pine: 79 (Eyre 1980) **<**

Distribution: This system is found from southern Pennsylvania south to Virginia and extreme eastern Tennessee. Application of the concept south of Virginia is uncertain. It is not attributed to Kentucky.

CES202.598 CONCEPTUAL MODEL

Environment: This system is found at low to mid elevations in the Central and Southern Appalachians. Most shale barrens occur between 305 and 610 m (1000-2000 feet) elevation and have a generally southern exposure. Slopes are steep and often undercut by a stream at the base. Soils are thin, with a layer weathered rock fragments covering the surface. The exposure and lack of soil create extreme conditions for plant growth. The chemistry and pH vary somewhat from site to site, and this variability may be reflected in the vegetation. The substrate includes areas of solid rock as well as unstable areas of shale scree, usually steeply sloped.

CES202.596 Central and Southern Appalachian Montane Oak Forest

CES202.596 CLASSIFICATION

Concept Summary: This generally oak-dominated system is found in the central and southern Appalachian Mountains. These high-elevation deciduous forests occur on exposed sites, including ridgecrests and south- to west-facing slopes, mostly between 915 and 1372 m (3000-4500 feet) elevation, less commonly ranging up to 1680 m (5500 feet). In most associations attributed to this system, the soils are thin, weathered, nutrient-poor, low in organic matter, and acidic. The forests are dominated by *Quercus* spp. (most commonly *Quercus rubra* and *Quercus alba*), with the individual trees in high-elevation red oak examples often stunted or wind-flagged. *Castanea dentata* sprouts are also common, but the importance of chestnut in these forests has been dramatically altered by chestnut blight. *Ilex montana, Hamamelis virginiana*, and *Rhododendron prinophyllum* (in Virginia and West Virginia) are characteristic shrubs.

Distribution: This system is found at higher elevations of the central and southern Appalachian Mountains, Virginia and West Virginia to Georgia. In Kentucky, this system is restricted to the Cumberland Mountains in the extreme southeastern corner of that state. In West Virginia, this system is found in the Ridge and Valley.

Nations: US

Concept Source: R. White, M. Pyne, R. Evans, M. Schafale, S.C. Gawler

Description Author: R. White, M. Pyne, R. Evans, M. Schafale, S. Gawler, L. Sneddon, C. Nordman

CES202.596 CONCEPTUAL MODEL

Environment: The habitat for this system includes high ridgelines and exposed upper slopes, primarily on south- to west-facing aspects, mostly between 915 and 1372 m (3000-4500 feet) elevation, and less commonly ranging up to 1680 m (5500 feet).It generally occurs as a transition between ~Southern Appalachian Oak Forest (CES202.886)$$ and more mesic ~Southern Appalachian Northern Hardwood Forest (CES202.029)$$ that occurs on less-exposed ridgetops and cooler, moister upper slopes (e.g., north- and east-facing aspects). At high elevations (e.g., above 1372 m [4500 feet]), this system is generally less common than ~Southern Appalachian Northern Hardwood Forest (CES202.029)$$, since the habitat on most slopes at this elevation tends to favor those species adapted to a more mesic environment. Rockslides occur periodically due to the steep slopes, and severe rockslides can cause stand replacement. Ice storms occur frequently and cause extensive damage to older dwarfed trees. Fire occurs at moderate frequency and probably needed in the long run to promote growth of fire tolerant *Quercus* and maintain their dominance. Some rare examples may be too rocky to burn, and even these have mostly closed canopies and produce a substantial leaf litter layer in most places (M. Schafale pers. comm. 2013).

Key Processes and Interactions: The communities of this system occur on exposed high ridges in the Appalachians. They are subject to frequent ice in winter, wind storms in the summer and high winds throughout the year. Natural old-growth forest examples have trees reproducing in small to medium-sized canopy gaps created by the death of individual or small groups of trees. Wind and ice storms are the main cause of tree mortality. Breakage of trees and of branches by ice storms can additionally produce partial canopy opening over large areas (M. Schafale pers. comm.). In addition, lightning-caused fires may create surface fires that change the understory composition and inhibit some ericaceous shrub species in some areas. Fire is naturally at moderate or low frequency, but appears to be important in structuring the vegetation. In many locations, fire exclusion and competing understory vegetation are factors in poor oak regeneration, with replacement by more mesophytic species such as *Acer saccharum* (Fleming et al. 2005). Fire likely was crucial for reducing the competitive advantage of these species. Presettlement forests are likely to have experienced lightning-caused fires every 40-60 years (Fleming et al. 2005). Fires likely were more frequent than this farther south. Rockslides cause severe disturbance in occasional locations, initiating a primary succession that may last many years. Despite the high elevation, *Castanea dentata* had been a fairly substantial component of this system and can still be seen as rotting stumps in the forest.

Threats/Stressors: The most evident threat to this system is the decline and subsequent mortality of the dominant and characteristic canopy *Quercus* species, particularly *Quercus rubra* (Greenberg et al. 2011). High oak mortality rates and widespread oak regeneration failure threaten the long-term survival of these forests. Oak decline will continue to be a forest health problem, particularly on national forest lands. Oaks will not be eliminated from affected areas, but their numbers and diversity will be reduced. Red maple, blackgum, and other relatively shade-tolerant species are likely to replace the oaks (Southern Group of State Foresters 2013). Oak decline results from a number of stress factors, including the low-quality site conditions (rocky and shallow soils), drought (intensified by climate change), defoliation by insect pests, root diseases, unusual late frosts (again perhaps made more frequent by climate change), and stand disturbances (Greenberg et al. 2011). In the Northern Blue Ridge, gypsy moth (*Lymantria dispar*) infestations have caused widespread tree mortality and pose a threat to these systems (Fleming et al. 2005). This threat is likely to continue spreading southward and is a potential threat throughout the range of this system. These are higher elevation forests where development and fragmentation pressures are less than at moderate to low elevations. Climate change is likely somewhat of a threat. Warmer temperatures are likely to cause vegetation zones to shift upward in elevation, which will reduce the area of available habitat for this system in many places.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from loss or severe deterioration of the canopy, through timber removal by logging or through a slow loss of the oak component and replacement by other more mesophytic species.

CES202.591 Central Appalachian Dry Oak-Pine Forest

CES202.591 CLASSIFICATION

Concept Summary: These oak and oak-pine forests cover large areas in the low- to mid-elevation Central Appalachians and middle Piedmont. The topography and landscape position range from rolling hills to steep slopes, with occasional occurrences on more level, ancient alluvial fans. In the highly dissected fall zone of Maryland and the District of Columbia, where the Piedmont and Coastal Plain meet, it is also found on dry knolls capped with Pleistocene- and Tertiary-aged fluvial cobble and gravel terrace deposits. Soils are typically coarse and infertile; they may be deep (on glacial deposits in the northern and terrace deposits in the southern parts of the system's range), or more commonly shallow, on rocky slopes of acidic rock (shale, sandstone, other acidic igneous or metamorphic rock). The well-drained soils and exposure create dry conditions. The forest is mostly closed-canopy but can include patches of more open woodlands. It is dominated by a variable mixture of dry-site oak and pine species, most typically *Quercus montana, Pinus virginiana*, and *Pinus strobus*, but sometimes *Quercus alba* and/or *Quercus coccinea*. The system may include areas of oak forest, pine forest (usually small), and mixed oak-pine forest. Heath shrubs such as *Vaccinium pallidum, Gaylussacia baccata*, and *Kalmia latifolia* are common in the understory and often form a dense layer. Embedded submesic ravines and concave landforms support slightly more diverse forests characterized by mixtures of oaks, several hickories, *Cornus florida*, and sometimes *Liriodendron tulipifera*. Small hillslope pockets with impeded drainage may support small isolated wetlands with *Acer rubrum* and *Nyssa sylvatica* characteristic. Disturbance agents include fire, windthrow, and ice damage. Increased site disturbance generally leads to secondary forest vegetation with a greater proportion of *Pinus virginiana* and weedy hardwoods such as *Acer rubrum*.

CES202.600 Central Appalachian Pine-Oak Rocky Woodland

CES202.600 CLASSIFICATION

Concept Summary: This system encompasses open or patchily wooded hilltops and outcrops or rocky slopes in the Central Appalachians, High Allegheny Plateau, and Lower New England / Northern Piedmont. It occurs mostly at lower elevations, but occasionally up to 1220 m (4000 feet) in West Virginia. The substrate rock is generally granitic or of other acidic lithology, although near the northern limit of its range in New England, examples can also occur on intermediate, base-rich, or mafic bedrock including traprock. The vegetation is patchy, with woodland as well as open portions. *Pinus rigida* (and within its range *Pinus virginiana*) is diagnostic and often mixed with xerophytic *Quercus* spp. and sprouts of *Castanea dentata*. In New England, some examples lack pine and feature *Juniperus virginiana* or *Ostrya virginiana* as important codominants with oak. Some areas have a fairly well-developed heath shrub layer, others a graminoid layer, the latter particularly common under oaks or other deciduous trees. Conditions are dry and for the most part nutrient-poor, and at many, if not most, sites, a history of fire is evident. In the Central Appalachians ecoregion, this system is rarely found on sandy soils rather than rock.

Distribution: This system occurs from central New England south to Virginia and West Virginia, with peripheral occurrences in southeastern Ohio and easternmost Kentucky.
Nations: US
Concept Source: S.C. Gawler
Description Author: S.C. Gawler and L.A. Sneddon

CES202.600 CONCEPTUAL MODEL

Environment: This system occurs mostly at lower elevations, but occasionally up to 1220 m (4000 feet) in West Virginia. The substrate rock is generally granitic or of other acidic lithology, although near the northern limit of its range in New England, examples can also occur on intermediate, base-rich, or mafic bedrock including traprock.

This system contains species-poor, fire-influenced, mixed woodlands of xeric, exposed montane habitats. They are typically located on convex, south to west facets of steep spur ridges, narrow rocky crests, and cliff tops. Pine - oak / heath woodlands are widespread throughout both the Ridge and Valley and Blue Ridge provinces in western Virginia. They occur at elevations from below 305 m (1000 feet) to more than 1220m (4000 feet) on various substrates, but most commonly on acidic, sedimentary and metasedimentary substrates, e.g., sandstone, quartzite, and shale. A few stands occur on Piedmont monadnocks and foothills. Soils are very infertile, shallow, and droughty (VDNH 2007).

The type is restricted to poor, dry sites which have been disturbed in the recent past by heavy cutting, fire, or both. It is found on thin, rocky soils in the mountainous areas. Soils are strongly acidic and devoid of nutrients. Precipitation is low in the shale barrens of eastern West Virginia and adjacent states (Eyre 1980).

Key Processes and Interactions: Periodic fire is an important ecological process that provides opportunities for regeneration of both pines and less competitive herbaceous species, while setting back successional encroachment of potential overstory oaks (especially chestnut oak). On cliffs and other very rocky sites, the vegetation is self-perpetuating due to extreme edaphic conditions. (VDNH 2007). Fire is the most common disturbance type, but frost pockets and late-spring frosts have been also documented. If disturbances occur very frequently (every 2-3 years), *Quercus ilicifolia* may be replaced by low shrubs, grasses, ferns, and other herbs. If disturbances are infrequent, canopy trees can outgrow the shade-intolerant *Quercus ilicifolia*. Suppression of white pine and increase in Virginia pine were accomplished through low-intensity fires in shortleaf pine - oak forests in Georgia (Hubbard et al. 2004).

CES202.592 Northeastern Interior Dry-Mesic Oak Forest

CES202.592 CLASSIFICATION

Concept Summary: These oak-dominated forests are one of the matrix forest systems in the northeastern and north-central U.S. Occurring in dry-mesic settings, they are typically closed-canopy forests, though there may be areas of patchy-canopy woodlands. They cover large expanses at low to mid elevations, where the topography is flat to gently rolling, occasionally steep. Soils are mostly acidic and relatively infertile but not strongly xeric. Local areas of calcareous bedrock, or colluvial pockets, may support forests typical of richer soils. Oak species characteristic of dry-mesic conditions (e.g., *Quercus rubra, Quercus alba, Quercus velutina*, and *Quercus coccinea*) and *Carya* spp. (particularly *Carya tomentosa, Carya glabra, Carya ovalis, Carya ovata*, and *Carya pallida*) are dominant in mature stands. *Quercus montana* may be present but is generally less important than the other oak species. *Castanea dentata* was a prominent tree before chestnut blight eradicated it as a canopy constituent. *Acer rubrum, Betula lenta*, and *Betula alleghaniensis* may be common associates; *Acer saccharum* is occasional. With a long history of human habitation, many of the forests are early- to mid-successional, where *Pinus strobus, Pinus virginiana*, or *Liriodendron tulipifera* may be dominant or codominant. Within these forests, hillslope pockets with impeded drainage may support small isolated wetlands, including non-forested seeps or forested wetlands with *Acer rubrum, Quercus bicolor*, or *Nyssa sylvatica* characteristic.

Distribution: This system is found from southern New York west through Ohio and Pennsylvania and south to Virginia. It does not extend to the southernmost part of Virginia, except in the Ridge and Valley.
Nations: US
Concept Source: S.C. Gawler
Description Author: S.C. Gawler and L.A. Sneddon

CES202.592 CONCEPTUAL MODEL

Environment: These oak-dominated forests are one of the matrix forest systems in the northeastern and north-central U.S. Occurring in dry-mesic settings, they are typically closed-canopy forests, though there may be areas of patchy-canopy woodlands. They cover large expanses at low to mid elevations, where the topography is flat to gently rolling, occasionally steep. The typical landscape position is midslope to toeslope, transitioning to more xeric systems on the upper slopes and ridges. Soils are acidic and relatively infertile but not strongly xeric.

Key Processes and Interactions: This system is naturally dominated by stable, uneven-aged forests, with canopy dynamics dominated by gap-phase regeneration. Most oaks are long-lived, with typical age of mortality ranging from 200 to 400 years. *Quercus coccinea* and *Quercus velutina* are shorter-lived with typical ages being approximately 50 to 100 years, while *Quercus alba* can live as long as 600 years. Extreme wind or ice storms occasionally create larger canopy openings.

This forest system is characterized by low-severity surface fires that cause variable structure and composition based on fire frequency and intensity. The great majority of historical fires were generated by Native Americans.

Open woodlands developed within a moderate burning regime, (fire-return intervals of 5 to 15 years), and canopy closure occurred with greater fire-return intervals. Shade-tolerant, fire-sensitive trees such as *Acer saccharum* regenerated beneath oak-hickory canopies when fire was excluded over several decades. With continued fire exclusion, *Acer saccharum* and other late-successional species gradually replaced overstory oaks and hickories as forest gaps closed (Sutherland et al. 2003), generating a mosaic of vegetation types formed with varying fire history (Cutter and Guyette 1994). A recent study on fire history of a *Quercus rubra* stand in West Virginia revealed that fire intervals ranged from 7 to 32 years from 1846 to 2002, in contrast to intervals of 7 to 15 years prior to the fire control era. These results were consistent with previous research in the oak forests of Ohio, Maryland, and Missouri (Schuler and McClain 2003).

CES202.590 Northeastern Interior Pine Barrens

CES202.590 CLASSIFICATION

Concept Summary: These pine barrens occur on glacial sandplains of the inland regions of the northeastern U.S., with a disjunction to the distinctive till plain shrublands in the Poconos of eastern Pennsylvania. Substrates include outwash plains, stabilized sand dunes, and glacial till. The soils are consequently coarse-textured, acidic, mostly well-drained to xeric, and low in nutrients. *Pinus rigida* is the usual dominant, and cover may range from closed-canopy forest to (more typically) open woodlands. *Quercus rubra, Pinus strobus*, and *Betula populifolia* are common associates. A tall-shrub layer of *Quercus ilicifolia* and/or *Quercus prinoides* is commonly present, although portions of some barrens (or occasionally the entire barrens) lack the scrub oak component. A well-developed low-shrub layer is typical, with lowbush *Vaccinium* spp., *Gaylussacia baccata*, and *Comptonia peregrina* characteristic, with *Rhododendron canadense* characteristic on the slightly more mesic microsites of the Poconos. The system is often a physiognomic patchwork, ranging from nearly closed-canopy forest to open pine woodlands, to scrub oak shrublands, to herbaceous/dwarf-shrub frost pockets. Grassy areas dominated by *Schizachyrium scoparium* with *Lupinus perennis, Lespedeza capitata*, and other forbs provide habitat for several rare invertebrates. Small changes in elevation can create pockets with saturated soil, where shrubs such as *Corylus americana, Cephalanthus occidentalis, Vaccinium corymbosum*, and *Alnus* spp. form dense cover. These barrens always have a history of recurrent fires, and fire is required to maintain them.

- Bear Oak: 43 (Eyre 1980) **<**
- Eastern White Pine: 21 (Eyre 1980) **<**
- Pitch Pine: 45 (Eyre 1980) **<**

Distribution: This system is restricted to interior south-central New England; Colchester, Vermont; eastern New York; and the Pennsylvania Poconos.

Nations: US

Concept Source: D.S. Schweitzer and T.J. Rawinski (1988)

Description Author: S.C. Gawler and L.A. Sneddon

CES202.590 CONCEPTUAL MODEL

Environment: This system is confined to flat to gently rolling plains with sandy soils that are coarse-textured, acidic, mostly well-drained to xeric, and low in nutrients.

Key Processes and Interactions: Fire regime includes frequent stand-replacing events and lower intensity surface fires. Periodic severe wildfires with 40- to 100-year intervals have produced oak-pine mixtures over extensive areas of uplands, while more frequent severe fires have created mixtures of pitch pine and shrub oaks. Pitch pine younger than 20-40 years may produce stump

sprouts after top-killing fire (Andresen 1959). If not top-killed, pines may recover from fire by sprouting from branches and trunk. Pitch pine has. Additionally, pitch pine is quick to maturity and to produce seeds. Frequent fires of moderate to high intensity/severity eventually eliminate all other tree species except for scrub oak and pitch pine, which has thick, fire-resistant bark and is a prolific seed producer. Fires, especially large wildfires, have been a major factor in the development of the present differences among forest stands on similar sites in the Pine Barrens. Abandoned upland sites generally progress from a grass or shrubland (MFRI of 2-3? years) to pitch pine/scrub oak woodland (5-25 years) to pure pitch pine forest with heath/oak scrublands (30-60 years) to pitch pine/tree-sized oak forest (60-100 years) to oak-hickory forest (100-200 years) (Landfire 2007a).
Threats/Stressors: This system has faced widespread conversion to agriculture. Motzkin et al. (1999) note that areas currently occupied by pitch pine - scrub oak communities in central Massachusetts likely represent less than 10% of the area that supported this vegetation in the early historical period. Agricultural activity has been documented since the mid-19th century at Waterboro Barrens in Maine (Copenheaver et al. 2000), in addition to other land uses such as logging, charcoal production, and sand mining. Urban and commercial development continues to be a threat to this system, and as remaining patches become smaller and surrounded by development, they can no longer support the fire regime required to maintain the mosaic of vegetation types that make up this system. Other threats include invasive species and irresponsible recreation activities (Gray and Dawson 2004). Another threat is the degradation in ecological integrity that results from re-establishment of barrens following cessation of agriculture. Motzkin et al. (1999) note that those barrens with soils that have been plowed are depauperate and differ in their composition and structure. [Note: With increasing temperatures and decreased drying projected in the coming decades, it is possible that these effects of climate change may foster continued existence of pine barrens if sufficient protection measures are put in place.]
Ecosystem Collapse Thresholds: Ecological collapse results from reduction in patch size to 10 ha or less, surrounded by development and other areas that cannot support a fire management. Resulting fire suppression reduces the number of patches and patch types (*Pinus rigida / Quercus ilicifolia* woodlands, *Quercus ilicifolia* shrublands, grassland patches characterized by native grasses and forbs) and associated species; invasive species (*Wisteria sinensis, Polygonum cuspidatum (= Fallopia japonica)*) form 40% or more cover; absence or very low cover of species indicative of absence of soil disturbance (*Quercus ilicifolia, Gaultheria procumbens, Quercus prinoides)* (Motzkin et al. 1999); woodland patches lacking significant shrub layer of either scrub oaks or heaths; predominance of deciduous early-successional species such as *Betula populifolia, Populus tremuloides*.

CES203.069 Northern Atlantic Coastal Plain Calcareous Ravine

CES203.069 CLASSIFICATION

Concept Summary: This system occurs on dry to mesic slopes and saturated bottoms of dissected ravine systems in the northern Atlantic Coastal Plain where erosion has exposed Tertiary-aged shell deposits, limesands, or aboriginal shell middens. These calcium-bearing sediments produce soils that range from slightly acidic to circumneutral and moderately to very strongly calcareous. The fertile soils support a rich diversity of plant species that distinguishes this system from the more widespread dry-mesic, acidic (poor) ravines. This system includes mostly deciduous upland forests and woodlands on slopes and low interfluves and forested seepage wetlands found in saturated stream valley bottoms. Species composition varies with the environmental setting , but all habitats are characterized by species indicative of high base status soils. The communities of this system often contain species that are disjunct from their primary ranges in the mountains or Piedmont, such as Erigeron pulchellus, *Actaea pachypoda, Caltha palustris, Pedicularis lanceolata, Solidago flexicaulis, Quercus muehlenbergii, Verbesina virginica var. virginica, Hexalectris spicata, Corallorhiza wisteriana, Campanulastrum americanum, Celastrus scandens, Muhlenbergia sobolifera, Muhlenbergia tenuiflora, Sanicula marilandica*, and *Thalictrum revolutum*.

Related Concepts:

- Beech - Sugar Maple: 60 (Eyre 1980) **<**

Distribution: This system is known from the northern Atlantic Coastal Plain of Virginia and Maryland, possibly ranging north into Delaware and New Jersey.
Nations: US
Concept Source: NCR Review Team
Description Author: G. Fleming, J. Teague, L.A. Sneddon

CES203.069 CONCEPTUAL MODEL

Environment: This system occurs on dry to mesic slopes and saturated bottoms of dissected ravine systems in the northern Atlantic Coastal Plain where erosion has exposed Tertiary-aged shell deposits, limesands or aboriginal shell middens that have been exposed by downcutting streams or on river fronting bluffs along the northern Atlantic Coastal Plain of Virginia, Maryland, Delaware and New Jersey. It includes mesic and dry uplands and groundwater-saturated wetlands associated with these fertile, base-rich soils. Occurrences are typically linear or small patch and uncommon.
Key Processes and Interactions: Natural erosion of steep bluffs exposed by downcutting streams.
Threats/Stressors: Habitat destruction; tree removal degrades this community by allowing additional light and aggressive growth of invasive alien plant species, which thrive in well-lit, high-calcium environments.
Ecosystem Collapse Thresholds: Loss of most canopy trees, high cover by invasive species and low cover or absence of characteristic species.

CES203.475 Northern Atlantic Coastal Plain Hardwood Forest

CES203.475 CLASSIFICATION

Concept Summary: This ecological system comprises dry hardwood forests largely dominated by oaks, ranging from sandy glacial and outwash deposits of Cape Cod, Massachusetts, and Long Island, New York, south to the Coastal Plain portions of Maryland and Virginia south to about the James River. *Quercus alba, Quercus montana (= Quercus prinus), Quercus coccinea*, and *Quercus rubra* are typical, and *Ilex opaca* is sometimes present. *Pinus* species may be codominant in some areas, for example the mixture of oaks with *Pinus virginiana* or *Pinus echinata* on very xeric, relict inland dunes. In the northern half of the range, conditions can grade to dry-mesic, reflected in the local abundance of *Fagus grandifolia*. These forests occur on acidic, sandy to gravelly soils with a thick duff layer, often with an ericaceous shrub layer. From New Jersey south to Virginia, this system also includes oak-beech/heath forests on steep slopes.

CES203.302 Northern Atlantic Coastal Plain Maritime Forest

CES203.302 CLASSIFICATION

Concept Summary: This system encompasses a range of woody vegetation present on barrier islands, maritime shores and near-coastal strands, from Fisherman's Island, Virginia (the northern range limit of *Quercus virginiana* and the southernmost tip of the Delmava Peninsula) northward to the extent of the Atlantic Coastal Plain. It includes forests and shrublands whose structure and composition are influenced by proximity to marine environments, including both upland and wetland. Vegetation includes narrow bands of forests with often stunted trees with contorted branches and dense vine layers. A range of trees may be present depending upon actual location and degree of protection from most extreme maritime influences. Common trees include *Prunus serotina, Pinus taeda, Ilex opaca, Quercus stellata, Juniperus virginiana, Pinus rigida, Pinus virginiana, Amelanchier canadensis*, and *Celtis occidentalis*. These trees are also found in less extreme or non-maritime settings; this system is distinguished as much by the structure of the vegetation as its composition. *Morella pensylvanica* is a characteristic shrub, and *Smilax rotundifolia* and *Vitis rotundifolia* are characteristic vines. *Morella cerifera* is often present south of central New Jersey.

- White Oak - Black Oak - Northern Red Oak: 52 (Eyre 1980) **<**
- White Oak: 53 (Eyre 1980) **<**

Distribution: This system ranges from Fisherman's Island, Virginia northward to Massachusetts along the extent of the Atlantic Coastal Plain.
Nations: US
Concept Source: R. Evans, G. Fleming, P. Coulling, L. Sneddon
Description Author: R. Evans, G. Fleming, P. Coulling, L.A. Sneddon, M. Pyne

CES203.302 CONCEPTUAL MODEL

Environment: This system occurs in marine coastal areas on sandy soils, usually in low interdunal areas behind primary or secondary dunes. In the glaciated portion of the range, it also occurs on till or morainal bluffs fronting the ocean, or on drowned drumlins on coastal islands. Examples also occur on sill or sand deposits in salt marsh islands. Soils range from well-drained on higher topographic positions to mesic in lower positions.

Key Processes and Interactions: Salt spray, high winds, dune deposition, sand shifting and blasting, and occasional overwash during extreme disturbance events.

Threats/Stressors: Widespread land clearance removed heavier-seeded late-successional trees, resulting in disclimax early-successional trees that are dispersed by birds; continued land conversion; sea-level rise and increased severity of storms exacerbates erosion of coastal bluffs. Dynamic coastal processes have maintained maritime forests through migration upslope following postglacial sea-level rise (Clark 1986b). Invasive plants are dispersed by birds into areas disturbed by human activity as well as natural dune blowouts. Exotic species such as *Lonicera morrowii, Rosa multiflora, Rhamnus cathartica, Phragmites australis*, and others can overwhelm native vegetation, particularly in the understory. Continued coastal development is a major threat. Indirect threats include hardening shoreline imposed by adjacent human habitation, causing alteration of natural shoreline deposition and erosion processes. Deer browse can impact regeneration through the removal of seedlings and saplings (NYNHP 2013a).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur when the dynamic nature of coastal processes are interrupted by coastal development, hardened shorelines, and a lack of sufficient buffer to allow for dune migration.

CES203.269 Northern Atlantic Coastal Plain Pitch Pine Barrens

CES203.269 CLASSIFICATION

Concept Summary: This system comprises a group of dry pitch pine woodlands and forests of deep sandy soils ranging from Cape Cod (Massachusetts) south through Long Island (New York) and the famous Pine Barrens of the New Jersey Coastal Plain, with occasional occurrences north to southernmost Maine and south to the Anacostia watershed (Maryland). The vegetation is characterized by a tree canopy of *Pinus rigida* with a tall-shrub layer dominated by *Quercus ilicifolia* and a low-shrub layer characterized by *Vaccinium pallidum* and/or *Vaccinium angustifolium*. The system is heavily influenced by fire, the composition and structure of its components varying with fire frequency. In general, tree oaks are more prevalent in those stands having a longer fire-return interval; fire frequencies of 8-10 years foster the growth of "pine plains," i.e., dwarf pine stands 1 m in height. Pine barrens with a history of more-or-less biennial burns for lowbush blueberry production may have very few trees and be characterized as sandplain grasslands. Dwarf-shrubs such as *Arctostaphylos uva-ursi, Vaccinium angustifolium, Vaccinium pallidum*, and *Hudsonia ericoides* typify the field layer of pine plains and sandplain grasslands. *Schizachyrium scoparium* is the most common grass (in close proximity to the coast, it may be represented by its close relative *Schizachyrium littorale*).

Scrub oak stands may occur without pine cover, particularly in low-lying areas that do not intersect the water table, where cold-air drainage inhibits pine growth. North of the glacial boundary, heathlands characterized by *Arctostaphylos uva-ursi, Corema conradii*, and *Morella pensylvanica*, and grasslands characterized by *Schizachyrium littorale, Schizachyrium scoparium*, and *Danthonia spicata* occur as small (or occasionally large) patches. The Pine Barrens of New Jersey are very similar in structure and composition to those north of the glacial boundary but are characterized by additional species, such as *Quercus marilandica,* *Quercus stellata, Pyxidanthera barbulata, Leiophyllum buxifolium*, and others. Where the water table is close to the surface, pitch pine lowland vegetation (described as a separate system) occurs.

Description Author: R. Evans, S.C. Gawler and L.A. Sneddon

CES203.269 CONCEPTUAL MODEL

Environment: This system typically occurs on deep well-drained sand deposits. In the coastal regions of the glaciated Northeast, it occurs on outwash plains and morainal deposits. In New Jersey, it occurs on Cohansey sand, which is sometimes overlain with hilltop gravel deposits.

Key Processes and Interactions: Different fire frequencies and intensities interrupt succession, accounting for variations in forest composition. Periodic severe wildfires with 40- to 100-year intervals have produced oak-pine mixtures over extensive areas of uplands, while more frequent severe fires have created mixtures of pitch pine and shrub oaks. The most frequent and severe fires have created the pine plains (Landfire 2007a).

Threats/Stressors: Fire suppression, urban and agricultural land conversion and landscape fragmentation effecting fire behavior, limiting management options, and introducing invasive plants species. On Long island, New York, pine barrens were noted to have decreased in size to 45% of their original extent (Jordan et al. 2003). The New Jersey Pine Barrens has a complex land-use history; used originally as a source of raw materials for iron smelting, ship building, transitioning over time to severe threats of conversion to residential and commercial development. Walker and Solecki (1999) documented a loss of 317 km2 of pine barrens between 1975 and 1986 to urban and agricultural uses. This represents an annual conversion rate of 0.6%, comparable to the rate of tropical deforestation conversion between 1980 and 1990.

Ecosystem Collapse Thresholds: Ecological collapse results from reduction in patch size to 10 ha or less, surrounded by development and other areas that cannot support a fire management. Resulting fire suppression reduces the number of patches and patch types (*Pinus rigida / Quercus ilicifolia* woodlands, *Quercus ilicifolia* shrublands, heathlands, pine plains) and associated species.

CES202.331 Southern Appalachian Montane Pine Forest and Woodland

CES202.331 CLASSIFICATION

Concept Summary: This system consists of predominantly evergreen woodlands (or more rarely forests) occupying very exposed, convex, often rocky south- and west-facing slopes, ridge spurs, crests, and clifftops in the Central Appalachians, Southern Ridge and Valley and Southern Blue Ridge. They occur at moderate to upper elevations (450-1200 m [1500-4000 feet]), with the more southerly examples at the higher elevations. In the Southern Blue Ridge, this system is best developed above 700 m (2300 feet) in elevation. The underlying rock is acidic and sedimentary or metasedimentary (e.g., quartzites, sandstones and shales). The soils are very infertile, shallow and droughty. A thick, poorly decomposed duff layer, along with dead wood and highly volatile ericaceous shrubs, creates a strongly fire-prone habitat. Most examples are dominated by *Pinus pungens*, often with *Pinus rigida* and/or *Pinus virginiana*, and occasionally *Tsuga caroliniana*. The canopy is usually patchy to open, but areas of closed canopy may be present, especially where *Tsuga caroliniana* is prominent. Fire is a very important ecological process in this system. Pines may be able to maintain dominance due to edaphic conditions, such as very shallow soil or extreme exposure in some areas which can produce sustained drought conditions, but most sites appear eventually to succeed to oak dominance in the absence of fire. Fire is also presumably a strong influence on vegetation structure, producing a more open woodland canopy structure and more herbaceous ground cover.

Distribution: This system is centered on the Southern Blue Ridge, from northern Georgia and South Carolina north through Virginia, with outlying occurrences north through the Central Appalachians to a small incursion in the northern Blue Ridge of south-central Pennsylvania.

Nations: US

Concept Source: M. Schafale, R. Evans, M. Pyne, R. White

Description Author: M. Schafale, R. Evans, M. Pyne, R. White, S.C. Gawler

CES202.331 CONCEPTUAL MODEL

Environment: This system occurs on ridgetops, usually only on the sharpest and narrowest spur ridges, and adjacent convex upper slopes. These sites are the extreme of convex landforms. Rapid drainage of rainfall and exposure to wind, sun and lightning are probably the important characteristics. Bedrock may be of any acidic type, including felsic igneous and metamorphic rocks, sandstone and quartzite. Soils are shallow and rocky residual soils. Fire appears to be an important factor.

Key Processes and Interactions: Fire is apparently a very important process in this system (Harrod and White 1999). Pines may be able to maintain dominance due to shallow soils and extreme exposure in some areas, but most sites appear eventually to succeed to oak dominance in the absence of fire. Fire is also presumably a strong influence on vegetation structure, producing a more open woodland canopy structure and more herbaceous ground cover. Occurrence in highly exposed sites may make this system more prone to ignition, but most fires probably spread from adjacent oak forests. Fires could be expected to show more extreme behavior in this system than in oaks forests under similar conditions, due to the flammability of the vegetation and the dry, windy and steep location. Both high-intensity fires and lower-intensity fires probably occurred naturally. Natural stands probably include both even-aged and uneven-aged canopies.

Southern pine beetle outbreaks are an important disturbance in this system, at least under present conditions. Beetle outbreaks can kill all the pines without creating the conditions for the pines to regenerate. If the pines are lost, the distinction between this system and ~Southern Appalachian Oak Forest (CES202.886)$$ or ~Central Appalachian Pine-Oak Rocky Woodland (CES202.600)$$ becomes blurred.

CES202.886 Southern Appalachian Oak Forest

CES202.886 CLASSIFICATION

Concept Summary: This system consists of predominantly dry-mesic (to dry) forests occurring on open and exposed topography at lower to mid elevations in the Southern Blue Ridge and Southern Ridge and Valley ecoregions. This is the upland forest that characterizes much of the lower elevations of these areas. The geology and soils can range from acidic to circumneutral or basic, and the vegetation varies accordingly. Soils are usually deep residual soils but are often rocky. Some shallow soils and colluvium may be present locally, but shallow soil environments are more extreme and have more pine. These forests are typically dominated by oaks, especially *Quercus montana, Quercus alba, Quercus rubra, Quercus velutina*, and *Quercus coccinea*, with varying amounts of *Carya* spp., *Nyssa sylvatica, Acer rubrum*, and other species such as *Pinus strobus* and *Fraxinus americana*. Historically, *Castanea dentata* was a dominant or codominant in many of these communities until its virtual elimination by the chestnut blight fungus (*Cryphonectria parasitica*) during the early 1900s. Some areas (usually on drier sites) now have dense evergreen heath shrub layers of *Kalmia latifolia*, with *Rhododendron maximum* on more mesic sites. Some other areas have deciduous heath-dominated layers, sometimes consisting of *Vaccinium* spp. or *Gaylussacia* spp. This system concept also includes many successional communities that have been impacted by logging or agriculture, such as types dominated by *Liriodendron tulipifera, Pinus* spp., and *Robinia pseudoacacia*. This system is naturally dominated by stable, uneven-aged forests, with canopy dynamics dominated by gap-phase regeneration. Most oaks are long-lived with typical age of mortality ranging from 200 to 400 years. Scarlet and black oaks are shorter lived with typical ages being approximately 50 to 100 years, while white oaks can live as long as 600 years.

Distribution: This system ranges throughout the southern Appalachians, from northern Georgia and South Carolina north into the Southern Blue Ridge of Virginia to the Roanoke River in the Blue Ridge, and slightly farther south in the Ridge and Valley. It occurs in very limited montane outliers in the Piedmont, and possibly on Pine/Black Mountain in Kentucky.

Nations: US

Concept Source: M. Schafale, R. Evans, M. Pyne, R. White

Description Author: M. Schafale, R. Evans, M. Pyne, R. White, S.C. Gawler

CES202.886 CONCEPTUAL MODEL

Environment: This system occurs on open slopes, ridgetops, lower elevation peaks, and higher parts of broad valley bottoms, at low to moderate elevations. Soils are usually deep residual soils, but are often rocky. Some shallow soils, colluvium, and other soils may be present locally within the system, but shallow soil environments are more extreme and have more *Pinus* spp. than this system. Moisture levels are intermediate for the region. Soil chemistry and topography are important determinants of different associations within the system. Topography, elevation, and soil depth are the most important factors separating this system from others.

Key Processes and Interactions: This system is naturally dominated by stable, uneven-aged forests. Extreme wind or ice storms occasionally create larger canopy openings. Natural old-growth forest examples have trees reproducing in small to medium-sized canopy gaps created by the death of individual or small groups of trees. Fire occurred fairly frequently in presettlement times, though there is some dispute whether most of the fires were natural or anthropogenic in origin (Abrams 1992, Delcourt and Delcourt 1997). Fires were usually low-intensity surface fires. The dominant species are fairly fire-tolerant, making most fires non-catastrophic. Fire may be important for favoring oak dominance over more mesophytic tree species within some of the topographic range of this system. Fire also can be expected to have a moderate effect on vegetation structure, producing a somewhat more open canopy and less dense understory and shrub layer than currently seen in most examples. Fire frequency or intensity may be important for determining the boundary between this system and both the more mesic and the drier systems. Virtually all examples have been strongly affected by the introduction of the chestnut blight, which killed all of the *Castanea dentata* trees, eliminating it as a canopy dominant. Past logging affected most occurrences. Regenerated forest canopies are even-aged, or have a more even-aged structure. Extreme wind or ice storms occasionally create larger canopy openings, which may provide particularly good sites for *Quercus* regeneration. Virtually all examples have been strongly affected by introduction of chestnut blight (*Cryphonectria parasitica*), which killed *Castanea dentata* trees, eliminating it as a canopy dominant. The introduction, and now widespread establishment, of gypsy moth (*Lymantria dispar*) that favors oaks as food has also affected these forests by causing widespread mortality of overstory trees depending on topographic position and precipitation amounts around defoliation events. Past logging, and now lack of fire, has affected most occurrences by changing canopies to an even-aged, or more even-aged, structure with an understory of shade-tolerant but fire-intolerant species such as *Pinus strobus, Acer rubrum*, and *Acer pensylvanicum*. The removal of

Castanea dentata from the overstory of these forests is thought to have benefited *Carya* spp., and their persistence and continued recruitment in contemporary oak-hickory forests may reflect fire exclusion in recent decades.

CES202.457 Southern Ridge and Valley / Cumberland Dry Calcareous Forest

CES202.457 CLASSIFICATION

Concept Summary: This system includes dry to dry-mesic calcareous forests of the Southern Ridge and Valley region of Alabama and Georgia, extending north into Tennessee, Kentucky, Virginia and adjacent West Virginia. It includes calcareous forests on lower escarpments of the Cumberland Plateau and other related areas. Examples occur on a variety of different landscape positions and occur on generally deeper soils than glade systems of the same regions. This system is distinguished from those farther north in the Ridge and Valley by its relatively southern location in the region, in an area which is transitional to the "Oak-Pine-Hickory" region. High-quality and historic examples are typically dominated by combinations of *Quercus* species and *Carya* species, sometimes with *Pinus* species and/or *Juniperus virginiana* as a significant component in certain landscape positions and with particular successional histories. These forests occur in a variety of habitats and are the matrix vegetation type that covers portions of the landscape under natural conditions. Examples can occur on a variety of topographic and landscape positions including valley floors, sideslopes, and lower to midslopes. Fire frequency and intensity are factors determining the relative mixture of deciduous hardwood versus evergreen trees in this system. Much of this system is currently composed of successional forests that have arisen after repeated cutting, clearing, and cultivation of the original forests. The range of this system is primarily composed of circumneutral substrates, which exert an expected influence on the composition of the vegetation.

- White Oak: 53 (Eyre 1980) **<**

Distribution: This system is endemic to the Southern Ridge and Valley and the Cumberland Plateau escarpment in Alabama, Georgia, Tennessee, Kentucky, and southwestern Virginia.

Nations: US

Concept Source: R. Evans and M. Pyne

Description Author: R. Evans and M. Pyne

CES202.457 CONCEPTUAL MODEL

Environment: Examples of this forest and woodland system occur usually on dry sites, on a variety of topographic and landscape positions, including sideslopes (particularly south- and west-facing ones), ridges, and knobs, as well as valley floors, depending on where the base-rich rock is present or crops out, and where the soils are influenced by calcareous/circumneutral geology. Elevation is generally between 200 and 500 m. In some landscapes, the ridges and ridgetops will more likely be composed of sandstones and other more weather-resistant and acidic materials.

Key Processes and Interactions: Fire frequency and intensity are factors determining the relative mixture of deciduous hardwood versus evergreen trees in this system. Presettlement fire-return intervals are believed to have ranged from 3 to 14 years from both lightning and Native American ignitions. These frequent surface fires maintained the grassy understory and kept hardwoods and shrubs from dominating the understory and forming a midstory layer. These fires occurred in the dormant season with occasional growing-season mosaic fires (most likely occurring infrequently once or twice every 20 to 25 years) (Landfire 2007a). Occasionally, during extensive droughts, mixed-severity or stand-replacement fires could occur, especially in drier stands or those containing *Juniperus virginiana*. In addition, local thunderstorm-caused blowdowns and windthrow created gaps on a small but continual basis. More extensive regional disturbances included winter ice storms. Dense stands of middle to older aged pines (where present) were susceptible to periodic mortality from bark beetle epidemics, and younger *Juniperus virginiana* trees were killed by periodic droughts.

Threats/Stressors: The most critical anthropogenic threats include removal of the characteristic dominant hardwoods and a lack of fire. Removal of the characteristic dominant hardwoods (primarily *Quercus* species and *Carya* species) through logging may result in a stand dominated by wind-blown or bird-dispersed tree species, including *Acer rubrum, Celtis* spp., *Fraxinus americana, Juglans nigra, Juniperus virginiana, Liquidambar styraciflua, Liriodendron tulipifera, Prunus serotina, Robinia pseudoacacia, Sassafras albidum, Ulmus americana*, and the exotic *Ailanthus altissima*. Lack of fire in the system leads to a closing of the subcanopy, and consequent loss of ground layer diversity. Patches dominated by *Juniperus virginiana* (or rarely with *Pinus taeda* and/or *Pinus echinata*) are artifacts of past disturbance and succession in the absence of fire. These are likely to eventually succumb to drought, fire or insect damage (in the case of *Pinus* species, which are generally atypical due to the high base status in the soils). Another major threat is conversion to human-created land uses, including residential development, quarries, industrial development, and infrastructure development (TNC 1996c).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (*Quercus* species and *Carya* species) to regenerate. When this deterioration of the canopy is combined with the absence of fire, the floristic characters of the stand are lost entirely. Ecological collapse can result from conversion to human-created land uses, including residential development, quarries, industrial development, and infrastructure development (TNC 1996c).

M882. Central Midwest Mesic Forest

CES202.693 North-Central Interior Beech-Maple Forest

CES202.693 CLASSIFICATION

Concept Summary: This system is found primarily along the southern Great Lakes ranging from central Indiana to southern Ontario. It is typically found on flat to rolling uplands to steep slopes with rich loam soils over glacial till. This system is characterized by a dense tree canopy that forms a thick layer of humus and leaf litter leading to a dense and rich herbaceous layer. *Acer saccharum* and *Fagus grandifolia* comprise up to 80% of the canopy. Canopy associates can include *Quercus rubra, Tilia americana*, and *Liriodendron tulipifera* with *Carpinus caroliniana* and *Ostrya virginiana* common in the understory and subcanopy. The relative dominance of sugar maple compared to other tree species varies across the range of this system based on regional climate and microclimate. The herbaceous layer is very diverse and typically includes spring ephemerals. Some common species include *Arisaema triphyllum, Osmorhiza claytonii, Polygonatum biflorum*, and *Trillium grandiflorum*. The primary natural disturbance influencing this system includes wind-driven gap dynamics. Conversion to agriculture has significantly decreased the range of this system, and very few large stands remain intact.

- Sugar Maple - Beech - Yellow Birch: 25 (Eyre 1980) **<**

Distribution: This system is located in the southern Great Lakes from central Indiana north into southern Ontario, and east to northwestern Pennsylvania and western New York.

Nations: CA, US

Concept Source: S. Menard

Description Author: S. Menard, S.C. Gawler and J. Drake

CES202.693 CONCEPTUAL MODEL

Environment: This system is typically found on flat to rolling uplands to steep slopes with rich loam soils over glacial till. It occurs principally on medium- or fine-textured ground moraine, medium- or fine-textured end moraine, and silty/clayey glacial lakeplains. Sand dunes and sandy lakeplains can support these systems where proximity to the Great Lakes modifies local climate (within 10-20 miles of the shore, evapotranspiration conditions are suitable for mesic forest). Prevalent topographic positions of this community are gentle to moderate slopes and level areas with moderate to good drainage. Where mesic southern forest occurs on steeper slopes, it is often associated with northern to eastern exposures which receive low amounts of direct sunlight and are characterized by a cool, moist microclimate.

It can occur on a variety of soil types, but loam is the predominant texture. The diversity of soils which can support this system include sand, sandy loam, loamy sand, loam, silt loam, silty clay loam, clay loam, and clay. Soils are typically well-drained with high water-holding capacity and high nutrient and soil organism content. High soil fertility is maintained by nutrient inputs from the decomposition of deciduous leaves which enrich the top layer of soil (Cohen 2004).

Key Processes and Interactions: Small-gap development and replacement due to tree death is the prevalent disturbance factor influencing this system. Catastrophic fire and/or wind can impact this system over long return intervals but are rare. Tree canopy tends to be closed so understory plants receive little light after leaf-out in the spring. This system could form large stands or be part of a large forested landscape in conjunction with other forested types, resulting in a relatively high proportion of forest interior to forest edge.

Threats/Stressors: The greatest impacts on this system are due to conversion of the surrounding landscape to agriculture, logging, and grazing. This system occurs on relatively fertile soils and many areas have been converted to or affected by agricultural uses. Other sites have been subject to selective or clearcut logging. Outright conversion to crops or clearcut logging destroys the affected area and has greatly reduced the range of this system. Remaining stands are also impacted by these activities on the surrounding landscape. Agricultural and urban development, road construction, and logging create gaps in formerly large blocks of forest. These serve as vectors or preferred habitat for invasive and aggressive native species, some of which thrive in the forest edge habitat but do not favor the interior of large forested stands (e.g., brown-headed cowbird (*Molothrus ater*)) (Howell et al. 2005). The structure and composition of stands near the edge is different from the interior (Palik and Murphy 1990). White-tailed deer (*Odocoileus virginianus*) populations have increased significantly due to their preference for fragmented landscapes and elimination of top carnivores. Browse pressure at these high population levels can have significant effects on forest composition and structure (Rooney and Waller 2003).

Many of the remaining stands are farm woodlots that have been subject to continual anthropogenic pressures. The structure and composition of the remnants have been altered by selective logging, grazing, removal of snags and logs for firewood, deer herbivory, exotic species invasion, and human-introduced diseases (e.g., Dutch elm disease and chestnut blight) (Cain 1935, Curtis 1959, Brewer 1980, Parker et al. 1985, Donnelly and Murphy 1987, Robertson and Robertson 1995). Many fragments are dominated solely by *Acer saccharum*, which was often left to provide maple syrup and is favored in gaps created by selective logging. In addition, *Fagus grandifolia* was often culled because of its poor timber value. Conversely, many stands that were high-graded of valuable timber (i.e., sugar maple and red oak) are now beech-dominated (Cohen 2004).

Invasive species often spread after fragmentation and repeated disturbance (i.e., logging). Invasive plant species that threaten the diversity and structure of this system include *Acer platanoides, Alliaria petiolata, Berberis thunbergii, Celastrus orbiculata, Elaeagnus umbellata, Frangula alnus (= Rhamnus frangula), Hesperis matronalis, Ligustrum vulgare, Lonicera japonica, Lonicera maackii, Lonicera morrowii, Lonicera sempervirens, Lonicera tatarica, Lonicera x bella, Lonicera xylosteum, Rhamnus cathartica, Rosa multiflora*, and *Viburnum opulus* (Kost el al. 2007).

Beech bark disease can be a threat to the health of this system. This fungal disease can kill up to 50% of *Fagus grandifolia* trees in newly infected stands and reduces the vigor of remaining trees (Witter et al. 2005).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the landscape surrounding this system is converted to agricultural or urban use and the remaining stands are small. Invasive and aggressive native species increase with deleterious effects on the diversity and ecological function of the stands.

CES202.696 North-Central Interior Maple-Basswood Forest

CES202.696 CLASSIFICATION

Concept Summary: This system is primarily found in the prairie forest border region of Minnesota, Wisconsin, and Iowa, but it can range north into northern Minnesota and Wisconsin and south to central Illinois, central Missouri, and eastern Kansas. This forest system is distinguished by underlying mesic soils and the predominance of mesic deciduous species forming a moderately dense to dense canopy. Examples of this system occur on valley slopes and bottoms often with northern or eastern aspects. Soils are moderately well-drained, fertile, and medium to deep loams that have developed from glacial till or loess parent material. *Acer saccharum* typifies this system, with *Tilia americana, Quercus rubra*, and *Ostrya virginiana* as common associates. The dense canopy allows for a rich mixture of shrub and herbaceous species in the understory. Examples of common herbaceous species include *Anemone quinquefolia, Adiantum pedatum, Arisaema triphyllum*, and *Sanicula* spp. Spring ephemeral herbaceous species are characteristic of this system, including *Aplectrum hyemale, Cardamine* spp., *Claytonia virginica, Dicentra cucullaria, Diplazium pycnocarpon, Erythronium americanum, Hydrastis canadensis, Phlox divaricata*, and *Trillium flexipes*. Dynamic processes such as wind and fire can impact this system over long return cycles; however, the most immediate threats to remaining examples of this system are grazing, unsustainable logging, and conversion to agriculture.

Distribution: This system ranges from northern Minnesota and Wisconsin south to eastern Kansas and Nebraska and southeast to central Illinois, Missouri, and possibly western Indiana.

Nations: US

Concept Source: S. Menard and K. Kindscher

Description Author: S. Menard, K. Kindscher, J. Drake

CES202.696 CONCEPTUAL MODEL

Environment: This system is found primarily on mesic soils that are moderately well-drained and fertile. These are mostly moderate to deep loams that have developed from glacial till or loess. This system occurs near the prairie-forest border, and the closer to this border, the stronger the association this system has with natural firebreaks. These sites are typically on the east and north sides of rivers, lakes, and wetlands and topographically protected areas on valley slopes and bottoms often with northern or eastern aspects (Kucera and McDermott 1955, Grimm 1984, Moran n.d.).

Key Processes and Interactions: Wind and fire can impact this system over long return intervals but are rare. Small-gap development and replacement due to tree death is more frequent than catastrophic fire or wind (Bray 1956, Grimm 1984). Tree canopy tends to be closed so understory plants receive little light after leaf-out in the spring. Old-growth stands may not vary greatly in species composition from mature managed forest but have different structural characteristics, including more snags, coarse woody debris, and large trees (McHale et al. 1999). This provides different habitats for wildlife and other non-plant species. This system could form large stands or be part of a large forested landscape in conjunction with other forested types, resulting in a relatively high proportion of forest interior to forest edge.

Threats/Stressors: The greatest impacts on this system are due to conversion to agriculture, logging, and grazing. This system occurs on relatively fertile soils and many areas have been converted to or affected by agricultural uses. Other sites have been subject to selective or clearcut logging. Outright conversion to crops or clearcut logging destroys the affected area and has greatly reduced the range of this system. Remaining stands are also impacted by these activities on the landscape. Agricultural and urban development, road construction, and logging create gaps in formerly large blocks of forest. These serve as vectors or preferred habitat for invasive and aggressive native species, some of which thrive in the forest edge habitat but do not favor the interior of large forested stands (e.g., brown-headed cowbird (*Molothrus ater*)) (Howell et al. 2005)). White-tailed deer (*Odocoileus virginianus*) populations have increased significantly due to their preference for fragmented landscapes and elimination of top carnivores. Browse pressure at these high population levels can have significant effects on forest composition and structure (Rooney and Waller 2003).

Despite the abundance of maple-basswood forests in Wisconsin, old-growth stands are almost nonexistent. In addition, very few rich mesic hardwood forests with diverse herbaceous floras have been protected. Note that some formerly common associates are now scarce or absent (e.g., *Ulmus rubra*), and others may be on the brink of major declines (*Fraxinus* spp.).

Non-native European earthworms of the families *Acanthodrilidae, Lumbricidae*, and *Megascloedidae* can also have dramatic impacts on forest floor properties by greatly reducing organic matter (Hale et al. 2005), microbial biomass (Groffman et al. 2004), nutrient availability (Bohlen et al. 2004, Suárez et al. 2004), and fine-root biomass (Groffman et al. 2004). These physical changes in the forest floor reduce densities of tree seedlings and rare herbs (Gundale 2002) and can favor non-native invasive plants (Kourtev et al. 1999). Changes in ground layer plant community composition due to non-native earthworms are more severe in stands with high white-tailed deer densities (Wiegmann and Waller 2006).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the landscape surrounding this system is converted to agricultural or urban use and the remaining stands are small. Invasive and aggressive native species increase with deleterious effects on the diversity and ecological function of the stands. Moderate invasive species impacts occur with 2-10% cover by invasive species. Severe invasive species impacts occur with >10% cover by invasive species. Moderate deer impacts occur with 4-11 deer/square km (Alverson et al. 1988, Augustine and Frelich 1998). Severe deer impacts occur with >11 deer/square km (Alverson et al. 1988, Augustine and Frelich 1998).

CES202.043 Ozark-Ouachita Mesic Hardwood Forest

CES202.043 CLASSIFICATION

Concept Summary: This system is found on lower slopes, toeslopes and valley bottoms within the Ozark and Ouachita regions, as well as on north slopes. In the Ozarks, *Quercus rubra* increases in abundance compared to dry-mesic habitats, and *Acer saccharum* is sometimes a leading dominant. On more alkaline moist soils, *Quercus muehlenbergii, Tilia americana*, and *Cercis canadensis* may be common. In the Boston Mountains, mesic forests may also be common on protected slopes and terraces next to streams. Here, *Fagus grandifolia* may be the leading dominant, with codominants of *Acer saccharum, Liquidambar styraciflua, Tilia americana, Magnolia acuminata, Magnolia tripetala*, and others. Similar habitats occur in the western Ouachita Mountains.

Distribution: This system is found within the Ozarks and Ouachita Mountains of Missouri, Arkansas, and Oklahoma.

Nations: US

Concept Source: R. Evans, D. Faber-Langendoen

Description Author: R. Evans, D. Faber-Langendoen, M. Pyne

CES202.043 CONCEPTUAL MODEL

Environment: This system may be found on a wide range of topographic positions. It includes mixed mesophytic forests, seeps/springs and smaller riparian areas. This system is found on primarily north- and east-facing aspects, lower slopes, toeslopes, small valley bottoms and terraces, as well as other protected slopes and ravines along intermittent and/or ephemeral streams. Distribution is influenced by local conditions affecting moisture, aspect, elevation and soil productivity. Closed conditions are multiple canopy usually late-seral forests. Stands of this system are generally small, isolated, and/or disjunct and are generally "embedded" in a larger landscape matrix. These communities are maintained primarily through naturally occurring circumstances such as aspect, elevation, soil moisture conditions, and soil productivity, except for mortality or other disturbance-induced openings or gaps.

Key Processes and Interactions: This type has a lower fire frequency than drier (uphill) types and experiences primarily low-intensity surface fire with occasional mosaic (mixed-severity) or replacement fire. Mean fire-return interval (MFI) is about 25 years with wide year-to-year and within-type variation related to moisture cycles, degree of sheltering and proximity to more fire-prone types. Anthropogenic fire is considered and contributes to within-type MFRI variation. Drought and moisture cycles play a strong role interacting with fire and insect and disease damage. Other natural disturbances may include wind and ice (Landfire 2007a).

Threats/Stressors: The most critical anthropogenic threat range-wide is invasive exotic species including *Microstegium vimineum* and *Ailanthus altissima*, which can become dominant in the ground and shrub layers following canopy disturbance. In more developed regions, *Euonymus alatus, Euonymus fortunei, Ligustrum sinense, Lonicera japonica*, and *Lonicera maackii* are taking over the understory at the landscape scale. For mesic hardwood forests containing *Fraxinus* species, emerald ash borer (which as of October 2013 has been reported from southeastern Missouri) may also be (or become) a significant stressor. Feral hogs also represent one of the greatest threats to biodiversity in these forests (Engeman et al. 2007). They can be especially difficult to control in sensitive slope forests. Conversion of this type has also resulted from repeated canopy removal through logging, which is a threat on private lands, but less so on public land, particularly in Arkansas, where many examples are known from national forests. Sites for this type were historically less frequently logged than the adjacent uplands, with more desirable species being removed in preference to *Fagus grandifolia*, which is less desirable in the lumber trade. In addition, some mesic hardwood forests in more moderately dissected terrain have been converted to pine plantations or impacted (destroyed or fragmented) by agriculture. Bluff habitats are often prime sites for development, especially along major rivers. The threat of development is exacerbated by the current surge in population in northwestern and north-central Arkansas. Urban and exurban sprawl into previously forested lands outside the major communities is expected to continue to increase (Arkansas Forestry Commission 2010). This will lead to the conversion of sites to human-created land uses.

The most significant potential climate change effects over the next 50 years include an increase in storms, which would contribute to erosion of the substrate and loss of canopy. Climate change may also bring increased periods of drought, which will affect the health and survival of the moisture-requiring trees, as well as increase the probability of damaging wildfire.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from removal of the canopy due to logging. It also results from fragmentation, in that smaller stands will not function ecologically, and will not provide habitat for characteristic animal species. Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (including *Fagus grandifolia*) to regenerate. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Ecological collapse can also result from such severe fragmentation (as in remnant patches left scattered among developments and roads) that wildlife is driven out and natural processes are lacking. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and other disturbance. Feral hogs can also significantly impact forest composition and structure (Engeman et al. 2007).

M012. Central Midwest Oak Forest, Woodland & Savanna

CES202.047 North-Central Interior Dry Oak Forest and Woodland

CES202.047 CLASSIFICATION

Concept Summary: This system is found throughout the glaciated regions of the Midwest, typically in gently rolling to flat landscapes. It can occur on uplands within the prairie matrix or within the context of dry-mesic oak-hickory forests and oak savannas. These are common on rolling glacial moraines and outwash plains. Soils are typically well-drained to excessively drained Mollisols or Alfisols that range from sand to sandy loam in texture. Historically, this type was quite extensive in Michigan, Indiana, Illinois, Missouri, Iowa, Wisconsin, and Minnesota. It is distinguished from other forested systems within the region by a dry edaphic condition that is transitional between dry prairies, oak barrens, or savannas and dry-mesic oak-hickory forests and woodlands. Forest cover can range from dense to moderately open canopy. Fire-resistant oak species, in particular *Quercus velutina, Quercus macrocarpa, Quercus coccinea*, and *Quercus ellipsoidalis*, dominate the overstory. *Carya glabra, Prunus serotina*, and *Sassafras* *albidum* are also common in portions of the range of this system. Depending on range of distribution and overstory canopy density, the understory may include species such as *Gaylussacia baccata* (in Michigan, Wisconsin, and Minnesota), *Vaccinium angustifolium*, and *Rhus aromatica*, and/or a mixture of woodland and grassland species, including *Schizachyrium scoparium, Deschampsia flexuosa*, and *Carex pensylvanica*. Extreme drought, along with periodic ground and crown fire events, constitute the main natural processes for this type and likely maintained a more open canopy structure that supported oak regeneration. In fact, many current examples of this type have resulted from long-term fire suppression and conversion of oak barrens to these forests and woodlands. Fire suppression may also account for examples of this system with the more dry-mesic understory. It likely has allowed for other associates such as *Quercus rubra* and *Fraxinus americana* to become more prevalent. Extensive conversion for agriculture in the surrounding landscape with more productive soils has fragmented and isolated examples of this system. It is found primarily within the "corn belt" of the United States, and remaining large areas of this system are likely under considerable pressure due to conversion to pastureland and urban development.

CES202.047 CONCEPTUAL MODEL

Environment: This system can occur on uplands within the prairie matrix or within the context of dry-mesic oak-hickory forests and oak savannas. These are common on rolling glacial moraines and outwash plains and, less frequently, old dunes. Soils are typically well-drained to excessively drained Mollisols or Alfisols that range from sand to sandy loam in texture. Dry soils or landscape position (steep slopes, upper slopes, south- or west-facing aspect) favor the formation of this system. Historically, this type was quite extensive in Michigan, Indiana, Illinois, Missouri, Iowa, Wisconsin, and Minnesota. It is distinguished from other forested systems within the region by a dry edaphic condition that is transitional between dry prairies, oak barrens, or savannas and dry-mesic oak-hickory forests and woodlands.

Key Processes and Interactions: Extreme drought, along with periodic ground and crown fire events, constitute the main natural processes for this type and likely maintained a more open canopy structure that supported oak regeneration. In fact, many current examples of this type have resulted from long-term fire suppression and conversion of oak barrens to these forests and woodlands. Frequency of fires necessary to maintain this system varied, largely depending on soil fertility and drainage, with more fertile and mesic sites requiring more frequent fires. Fire-return intervals of 5-20 years would typically maintain a woodland or oak grub shrubland, while fire-return intervals of 20-50 years would typically maintain a closed canopy oak forest (Landfire 2007a). Fire suppression may also account for examples of this system with the more dry-mesic understory. It likely has allowed for other associates such as *Quercus rubra* and *Fraxinus americana* to become more prevalent.

Threats/Stressors: Fire suppression and conversion to agricultural or urban uses are the major threats to this system. Fire suppression has resulted in more closed-canopy forests with little or no oak regeneration and invasion by fire-intolerant trees, such as *Acer* spp., *Celtis occidentalis, Fagus grandifolia, Liriodendron tulipifera, Prunus serotina*, and *Sassafras albidum*, and understory species (Nowacki and Abrams 2008). Extensive conversion for agriculture in the surrounding landscape with more productive soils has fragmented and isolated examples of this system. It is found primarily within the "corn belt" of the United States, and many remaining large areas of this system are under considerable pressure due to conversion to pastureland and urban development. Stands can be significantly affected by insect defoliators gypsy moth (*Lymantria dispar*) and forest tent caterpillar (*Malacosoma disstria*). Long-term effects from these have been limited in this system, but significant mortality in *Quercus*-dominated stands in the northeastern U.S. has been noted due to gypsy moth defoliation (Davidson et al. 2001). Heavy deer browsing is not as common as in more mesic systems but can affect the understory and tree seedlings, reducing many native forbs and tree seedlings (Healy 1997, Rooney 2001). White-tailed deer have been shown to browse oak seedling over maple seedlings (Stroke and Anderson 1992). Invasive plant species that threaten the diversity and structure include *Alliaria petiolata, Celastrus orbiculata, Cynanchum louiseae (= Vincetoxicum nigrum), Cynanchum rossicum (= Vincetoxicum rossicum), Elaeagnus umbellata, Lonicera japonica, Lonicera maackii, Lonicera morrowii, Lonicera sempervirens, Lonicera tatarica, Lonicera x bella, Lonicera xylosteum, Rhamnus cathartica*, and *Rosa multiflora* (Kost el al. 2007).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from prolonged fire suppression and invasion by more mesophytic tree species or fragmentation or partial or outright conversion of stands by agricultural or other human uses. Selective logging can also affect areas. Moderate fire suppression results when fire-return intervals are 20-50 years. Severe fire suppression results from fire-return intervals of >50 years. As mesophytic species, especially *Acer* spp., *Celtis occidentalis, Fagus grandifolia, Liriodendron tulipifera*, and invasive shrubs, come to dominate the sapling or canopy layers, the system becomes more mesic which perpetuates the change. Fragmentation by road building or destruction of parts of the forest by development impacts natural fire regimes and reduces the amount of interior forest area. This, as well as partial conversion for human use, including pasturing or selective logging, usually brings invasion by weedy species which degrades the system. Excessive, prolonged deer browse can eliminate sensitive understory and regeneration of overstory species, including *Quercus* spp.

CES202.046 North-Central Interior Dry-Mesic Oak Forest and Woodland

CES202.046 CLASSIFICATION

Concept Summary: This system is found throughout the glaciated regions of the Midwest, typically in gently rolling landscapes. It can occur on uplands within the prairie matrix and near floodplains, or on rolling glacial moraines and among kettle-kame topography. Soils are typically well-drained Mollisols or Alfisols that range from loamy to sandy loam or even coarse sands in texture. Historically, this type was quite extensive in Michigan, Indiana, Illinois, Missouri, Iowa, Wisconsin, and Minnesota. Well over 700,000 hectares likely occurred in southern Michigan alone (ca. 1800). It is distinguished from other forested systems within the region by a dry-mesic edaphic condition that is transitional between dry oak forests and woodlands and mesic hardwood forests, such as maple-basswood forests. Forest cover can range from a dense to moderately open canopy and there is commonly a dense shrub layer. Fire-resistant oak species, in particular *Quercus macrocarpa, Quercus rubra*, and/or *Quercus alba*, dominate the overstory. *Carya* spp., including *Carya ovata, Carya cordiformis*, and *Carya tomentosa*, are diagnostic in portions of the range of this system. Depending on site location and overstory canopy density, the understory may include species such as *Amelanchier* spp., *Aralia nudicaulis, Corylus americana, Desmodium glutinosum, Maianthemum stellatum, Osmunda claytoniana, Phryma leptostachya, Trillium grandiflorum*, and *Viburnum acerifolium*. Occasionally, prairie grasses such as *Andropogon gerardii* and *Panicum virgatum* may be present. Fire constitutes the main natural process for this type and likely maintained a more open canopy structure to support oak regeneration. Historic fire frequency was likely highest in the prairie-forest border areas. Fire suppression may account for the more closed oak forest examples of this system with the more mesic understory. It likely has allowed for other associates, such as *Acer saccharum, Acer rubrum, Celtis occidentalis, Liriodendron tulipifera, Ostrya virginiana*, and *Juglans nigra*, to become more prevalent, especially in upland areas along floodplains. Periodic drought, intensified by local conditions, such as slope, southern exposure, or sandy soil, also inhibit growth of mesophytic trees. Extensive conversion for agriculture has fragmented this system. Continued fire suppression has also resulted in succession to mesic hardwoods, such that in many locations, no oak species are regenerating. Remaining large areas of this system are likely under considerable pressure due to conversion to agriculture, pastureland, and urban development.

CES202.046 CONCEPTUAL MODEL

Environment: This system can occur on uplands within the prairie matrix and near floodplains, or on rolling glacial moraines and kettle-kame topography. Soils are typically well-drained Mollisols or Alfisols that range from loamy to sandy loam or even coarse sands in texture. Historically, this type was quite extensive in Michigan, Indiana, Illinois, Missouri, Iowa, Wisconsin, and Minnesota. Well over 700,000 hectares likely occurred in southern Michigan alone (ca. 1800). It is distinguished from other forested systems within the region by a dry-mesic edaphic condition that is transitional between dry oak forests and woodlands and mesic hardwood forests, such as maple-basswood forests.

Key Processes and Interactions: Fire constitutes the main natural process for this type and frequent surface fires combined with uncommon crown fires maintained a more open canopy and subcanopy structure to allow oak regeneration. Historic fire frequency was highest in the prairie-forest border areas and declined further from prairies and behind natural firebreaks. Frequency of fires necessary to maintain this system varied, largely depending on soil fertility and drainage, with more fertile and mesic sites requiring more frequent fires. Fire-return intervals of 15-25 years would typically maintain a woodland, while fire-return intervals of 25-50 years would typically maintain a closed-canopy oak forest (Landfire 2007a). Fire suppression accounts for many of the more closed oak forest examples of this system with the more mesic understory (Abrams 1992, Lorimer 2001). Fire suppression has allowed for other associates, such as *Acer saccharum, Celtis occidentalis, Juglans nigra, Liriodendron tulipifera, Ostrya virginiana*, and invasive shrubs, to become more prevalent, especially in more mesic upland areas or along floodplains (Rogers et al. 2008). Periodic drought, intensified by local conditions like slope, southern exposure, or sandy soil, also inhibit growth of mesophytic trees. Some stands currently in this system were more open savanna stands but fire suppression has allowed them to succeed to the more close-canopy oak woodland or forest. A continued lack of fire in many of those stands will result in succession to more mesophytic forest types. Gap-phase dynamics producing multi-structured, uneven-aged stands operate most noticeably in ~North-Central Interior Beech-Maple Forest (CES202.693)$$ but also influence succession in this system. Canopy gap formation originates through localized stem breakage resulting from wind (Runkle 1982), glaze or ice storms (Lemon 1961), attack by oak wilt fungus (*Chalara quercina*), and episodic defoliation caused by insects such as gypsy moth (*Lymantria dispar*).

Threats/Stressors: Fire suppression, logging, and conversion to agricultural or urban uses are the major threats to this system. Fire suppression has resulted in more closed-canopy forests with little or no oak regeneration and invasion by fire-intolerant trees, such as *Acer* spp., *Celtis occidentalis, Fagus grandifolia*, and *Liriodendron tulipifera*, and understory species (Nowacki and Abrams 2008), especially invasive shrubs. Extensive conversion for agriculture has fragmented this system and the landscape in which it exists and the resulting increase in edge-to-interior ratio has encouraged invasion by weedy species. Even where the tree canopy is maintained in a moderately closed condition, invasion by exotic shrubs, particularly *Rhamnus cathartica* and *Lonicera* spp., can form nearly continuous shrub canopies in some stands, shading out regeneration of all but the most shade-tolerant species. Stands can be significantly affected by insect defoliators gypsy moth (*Lymantria dispar*) and forest tent caterpillar (*Malacosoma disstria*). Long-term effects from these have been limited in this system, but significant mortality in *Quercus*-dominated stands in the northeastern U.S. has been noted due to gypsy moth defoliation (Davidson et al. 2001). Deer browsing can affect the understory and tree seedlings, reducing many native forbs and tree seedlings (Healy 1997, Rooney 2001). White-tailed deer have been shown to browse oak seedling over maple seedlings (Stroke and Anderson 1992). Grazing by livestock can have impacts on sensitive understory species. Impacts of logging can include shift in species composition (especially where overstory species are high-graded) and decrease in species diversity.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from prolonged fire suppression and invasion by more mesophytic species or fragmentation or partial or outright conversion of stands by agricultural or other human uses. Selective logging can also affect areas. Moderate fire suppression results when fire-return intervals for surface fires are 25-50 years. Severe fire suppression results from fire-return intervals for surface fires of >50 years. As mesophytic species, especially *Acer* spp., *Celtis occidentalis, Fagus grandifolia*, and *Liriodendron tulipifera*, come to dominate the sapling and canopy layers, the system becomes more mesic which perpetuates the change. Fragmentation by road building, destruction of parts of the forest by development, or logging impacts natural fire regimes and reduces the amount of interior forest area. This, as well as partial conversion for human use, including pasturing, selective logging, and residential development, usually brings invasion by weedy species which degrades the system. Excessive, prolonged deer browse can eliminate sensitive understory species and regeneration of overstory species, including *Quercus* spp.

CES202.698 North-Central Interior Oak Savanna

CES202.698 CLASSIFICATION

Concept Summary: This system is found primarily in the northern glaciated regions of the Midwest with the largest concentration in the prairie-forest border ecoregion. It is typically found on rolling outwash plains, hills and ridges. Soils are typically moderately well- to well-drained deep loams. This system is typified by scattered trees over a continual understory of prairie and woodland grasses and forbs. *Quercus macrocarpa* is the most common tree species and can range from 10-60% cover. The understory is dominated by tallgrass prairie species such as *Andropogon gerardii* and *Schizachyrium scoparium* associated with several forb species. Historically, frequent fires maintained this savanna system within its range and would have restricted tree canopies to 10-30%. Fire suppression in the region has allowed trees to establish more dense canopies. Periodic, strong wind disturbances and browsing also impact this system. Much of this system has also been converted to urban use or agriculture, and thus its range has decreased considerably.
Related Concepts:
Distribution: This system is found throughout the northern glaciated regions of the Midwest. Its main concentration, where it was likely the matrix type, is within the Prairie Forest Border of Minnesota, Wisconsin, Iowa, and Illinois. Conversion to urban uses and agriculture and fire suppression have significantly impacted the range of this system.
Nations: US
Concept Source: S. Menard
Description Author: S. Menard and J. Drake

CES202.698 CONCEPTUAL MODEL

Environment: This system is typically found on rolling tillplains, hills, and ridges in the glaciated Midwest. Soils are typically moderately well- to well-drained deep loams and fertile. Because fire is critical to maintaining this system, it is not found in fire-protected portions of the landscape.
Key Processes and Interactions: Historically, frequent fires maintained this savanna system within its range and would have restricted tree canopies to 10-30% cover with some portions having up to 60% tree canopy. On average, surface fires were very frequent (1- to 5-year return intervals) and maintained the open, herbaceous understory. Canopy trees were replaced when periodic longer fire-return intervals, due to chance, multi-year wet climatic cycles, or lack of burning by Native Americans, allowed oak seedlings to grow large enough to survive surface fires when they returned. If fire is absent for more than about 20-40 years, a site will transition to oak woodland/forest (Cottam 1949, Curtis 1959, Grimm 1981). Fire suppression in the region has allowed trees to establish more consistent dense canopies. Periodic, strong wind disturbances and browsing/grazing also impact this system through modification to the herbaceous layer and tree seedlings.
Threats/Stressors: Before European settlement, oak savanna, essentially this system and ~North-Central Oak Barrens (CES202.727)$$, was estimated to have covered 11-13 million ha in the Midwest. The extent in 1985 was estimated at just over 2600 ha and all but 40 ha was on dry or rocky sites (Nuzzo 1986) and likely ~North-Central Oak Barrens (CES202.727)$$. Fire suppression and conversion to agriculture or urban development have nearly eliminated this system from the landscape. Fire suppression for more than a few years allows woody species to proliferate. This system was most common on flat to rolling fertile sites in the "corn belt" of the United States, so many sites were used for agricultural and the landscape they were in was fragmented. Agricultural grazing can degrade sites, especially when combined with fire suppression, and other agricultural uses can outright destroy them. Conversion to urban uses was also common in the industrial and agricultural Midwest. A lack of fire allows native woody species to expand but also allows exotic species into the shrub and herbaceous strata. *Rhamnus cathartica* and *Lonicera* spp. are particularly common invaders. In Michigan, invasive species that threaten the diversity and structure of this system include *Berteroa incana, Celastrus orbiculata, Centaurea biebersteinii (= Centaurea maculosa), Cynanchum louiseae (= Vincetoxicum nigrum), Cynanchum rossicum (= Vincetoxicum rossicum), Elaeagnus umbellata, Hieracium* spp., *Hypericum perforatum, Leucanthemum vulgare (= Chrysanthemum leucanthemum), Lonicera japonica, Lonicera maackii, Lonicera morrowii, Lonicera sempervirens, Lonicera tatarica, Lonicera x bella, Lonicera xylosteum, Poa compressa, Poa pratensis, Rhamnus cathartica, Rosa multiflora, Rumex acetosella*, and *Saponaria officinalis*. Due to their high edge-to-area ratio, savannas are susceptible to exotic species invasion by such aggressive shrubs as buckthorns and honeysuckles (Apfelbaum and Haney 1991), which create dense shade that depresses or eliminates graminoid species that provide fine fuels for surface fires (Anderson and Bowles 1999). Ground layer vegetation of savanna remnants has been inhibited by low levels of light filtering through the dense overstories and impenetrable understories (often

dominated by exotic shrubs) and by the thick litter layers that have accumulated from over a century of fire suppression (Bowles and McBride 1994, Abella et al. 2001) (from Cohen 2004).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from prolonged fire suppression or conversion due to agricultural or urban development. Moderate fire suppression results when fire-return intervals are 5-20 years. Severe fire suppression results when fire-return intervals are 20-40 years (Landfire 2007a). As the canopy of shrubs and trees increases, sites become less flammable and the process becomes difficult to reverse. Stands reduced in size by landscape fragmentation also suffer from a reduction in fire frequency and increased opportunities for weed invasion.

CES202.727 North-Central Oak Barrens

CES202.727 CLASSIFICATION

Concept Summary: This system occurs on well-drained, coarse-textured sandy soils derived from glacial outwash, end moraine formations, lakeplain dune systems, and broad sandy river terraces in the north-central U.S. into Ontario, Canada. Soils range from almost pure sand, to loamy sand, to sandy loam. The soils have low fertility, organic matter, and moisture-retention capacity. Factors which affect seasonal soil moisture are strongly related to variation in this type. This oak barrens system is a scrubby, open-treed system dominated by graminoids and shrubs. Canopy structure varies from a dominant herbaceous ground layer with sparse, scattered "savanna" canopy (5-30%), through oak-dominated scrub, to a more closed woodland canopy (30-80%). The canopy layer is dominated by *Quercus velutina*, with some *Quercus ellipsoidalis, Quercus macrocarpa*, and *Quercus alba* (the latter more common eastward and in woodland conditions). Occasional *Pinus banksiana* can occur in the northern parts of the range. Species found in the herb layer include *Ambrosia psilostachya, Amphicarpaea bracteata, Artemisia ludoviciana, Andropogon gerardii, Calamovilfa longifolia, Carex pensylvanica, Carex* spp., *Comandra umbellata, Dichanthelium* spp., *Hesperostipa spartea, Koeleria macrantha, Lupinus perennis, Schizachyrium scoparium, Sorghastrum nutans*, and *Tephrosia virginiana*. Fire was an important factor in maintaining this system. Oak wilt, droughts and, in some northern sites, frosts during the growing season also reduce tree cover.

Related Concepts:

- White Oak - Black Oak - Northern Red Oak: 52 (Eyre 1980) **<**

Distribution: This system is found in the north-central U.S. from North Dakota to western New York and westernmost Pennsylvania (mostly historic there) and into Ontario, Canada.

Nations: CA, US

Description Author: D. Faber-Langendoen and J. Drake

CES202.727 CONCEPTUAL MODEL

Environment: This system occurs on well-drained, coarse-textured sandy soils derived from glacial outwash, end moraine formations, lakeplain dune systems, broad sandy river terraces, and sometimes on colluvium below sandstone bluffs. Soils range from almost pure sand, to loamy sand, to sandy loam. The soils have low fertility, organic matter, and moisture-retention capacity. Factors which affect seasonal soil moisture are strongly related to variation in this type.

Key Processes and Interactions: Fire was an important factor in maintaining this system. Oak wilt and droughts also reduce tree cover. For more fertile sites, surface fires were very frequent (1- to 5-year return intervals) and important for maintaining the open canopy and herbaceous understory. This system was not as fire-dependent as more mesic savannas and woodlands, due to the relatively infertile and often droughty soils on which it occurred. Some examples retained an open canopy without frequent fires (Whitford and Whitford 1971). Canopy trees were replaced when periodic longer fire-return intervals, due to chance, multi-year wet climatic cycles, or lack of burning by Native Americans, allowed oak seedlings to grow large enough to survive surface fires when they returned. If fire is absent for more than about 20-40 years, a site will transition to oak woodland/forest (Curtis 1959).

Threats/Stressors: Before European settlement, oak savanna, essentially a combination of this system and ~North-Central Interior Oak Savanna (CES202.698)$$, was estimated to have covered 11-13 million ha in the Midwest. The extent in 1985 was estimated at just over 2600 ha and all but 40 ha was on dry or rocky sites (Nuzzo 1986) and likely ~North-Central Oak Barrens (CES202.727)$$. Fire suppression and conversion to agriculture or urban development have nearly eliminated this system from the landscape. Fire suppression for more than a few years allows woody species to proliferate. This system was most common on infertile, drought-prone, acidic sites, so conversion to agriculture is not as common as other Midwest oak systems, but pasturing and conversion to pine plantations or urban uses still occurs. Livestock grazing can degrade sites, especially when combined with fire suppression. Conversion to urban uses was also common in the industrial and agricultural Midwest. A lack of fire allows native woody species to expand but also allows exotic species into the shrub and herbaceous strata. In Michigan, invasive species that threaten the diversity and structure include *Berteroa incana, Celastrus orbiculata, Centaurea biebersteinii (= Centaurea maculosa), Cynanchum louiseae (= Vincetoxicum nigrum), Cynanchum rossicum (= Vincetoxicum rossicum), Elaeagnus umbellata, Hieracium* spp., *Hypericum perforatum, Leucanthemum vulgare (= Chrysanthemum leucanthemum), Lonicera japonica, Lonicera maackii, Lonicera morrowii, Lonicera sempervirens, Lonicera tatarica, Lonicera x bella, Lonicera xylosteum, Poa compressa, Poa pratensis, Rhamnus cathartica, Rosa multiflora, Rumex acetosella*, and *Saponaria officinalis*.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from prolonged fire suppression or conversion due to agricultural or urban development. Moderate fire suppression results when fire-return intervals are 5-20 years. Severe fire suppression results when fire-return intervals are 20-40 years (Landfire 2007a). As the canopy of shrubs and trees increases, sites become less flammable and the reduction in flammability becomes difficult to reverse. Stands reduced in size by landscape fragmentation also suffer from a reduction in fire frequency and increased opportunities for weed invasion.

M014. Laurentian-Acadian Mesic Hardwood - Conifer Forest

CES201.565 Acadian Low-Elevation Spruce-Fir-Hardwood Forest

CES201.565 CLASSIFICATION

Concept Summary: This system represents the Acadian and northern Appalachian red spruce-fir forest that extends to the southern boreal region of southeastern Canada. The low- to mid-elevation forests are dominated by *Picea rubens* and *Abies balsamea*. *Picea mariana* and *Picea glauca* may be present. *Betula alleghaniensis* is the most common codominant, and *Acer rubrum, Acer saccharum*, and *Fagus grandifolia* are sometimes present. The upland soils are acidic and usually rocky, mostly well- to moderately well-drained but with some somewhat poorly drained patches at the slope bottoms. This is the matrix forest type in the lower-elevation northern portions of this division. This system may include earlier successional patches in which *Populus* spp. and *Betula* spp. are dominant or mixed with *Picea* and *Abies* that will develop into spruce-fir forests. Blowdowns with subsequent gap regeneration are the most frequent form of natural disturbance, with large-scale fires important at longer return intervals.

CES201.566 Acadian-Appalachian Montane Spruce-Fir Forest

CES201.566 CLASSIFICATION

Concept Summary: This is the matrix forest system in the montane spruce-fir region of the northern Appalachian Mountains, extending east through the Canadian Maritimes. It occurs mostly upwards of 457 m (1500 feet) elevation and is restricted to progressively higher elevations southward. Northward, it is often contiguous with ~Acadian Low-Elevation Spruce-Fir-Hardwood Forest (CES201.565)$$. This system often forms a mosaic of strongly coniferous patches and mixed patches, with occasional smaller inclusions of northern hardwoods, but is overall more than 50% coniferous. *Picea rubens* and *Abies balsamea* are the dominant conifers. Gaps formed by wind, snow, ice, and harvesting are the major replacement agents; fires may be important but only over a long return interval.

CES202.028 Central and Southern Appalachian Spruce-Fir Forest

CES202.028 CLASSIFICATION

Concept Summary: This system consists of forests in the highest elevation zone of the Blue Ridge and parts of the Central Appalachians, generally dominated by *Picea rubens, Abies fraseri*, or by a mixture of spruce and fir. *Abies fraseri* is the constituent fir from Mount Rogers in Virginia southward. Examples occur above 1676 m (5500 feet) in the Southern Blue Ridge, but as low as 975 m (3200 feet) at the northern range in West Virginia, and may range up to the highest peaks. Elevation and orographic effects make the climate cool and wet, with heavy moisture input from fog as well as high rainfall. Strong winds, extreme cold, rime ice, and other extreme weather are periodically important.

Related Concepts:

- Red Spruce - Yellow Birch: 30 (Eyre 1980) **<**
- Red Spruce: 32 (Eyre 1980) **<**

Distribution: This system ranges from the Balsam Mountains and Great Smoky Mountains of North Carolina and Tennessee northward to the mountains of western Virginia and eastern West Virginia.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, S.C. Gawler and M. Pyne

CES202.028 CONCEPTUAL MODEL

Environment: This system occurs at elevations typically above about 1300 m (4300 feet), up to the highest peaks. Species distribution follows an elevational gradient, with *Picea rubens*-dominated stands occurring between 1370 and 1675 m, mixed stands between 1675 and 1890 m, and *Abies fraseri* stands above 1890 m (Whittaker 1956 cited in Nicholas and Zedaker 1989). Examples occur on most of the landforms that are present in this elevational range; most sites are strongly exposed and convex in shape. Elevation and orographic effects make the climate cool and wet, with heavy moisture input from fog as well as high rainfall. Strong winds, extreme cold, rime ice, and other extreme weather are periodically important factors in the structure and dynamics of this vegetation. Concentration of air pollutants has been implicated as an important anthropogenic stress in recent years. In recent decades, the balsam woolly adelgid (*Adelges piceae*), an introduced insect, has killed almost all of the mature *Abies fraseri*. The saplings are not susceptible, resulting in many dense stands of young trees. Soils are generally very rocky, with the matrix ranging from well-weathered parent material to organic deposits over boulders. Soils may be saturated for long periods from a combination of precipitation and seepage. Any kind of bedrock may be present, but most sites have erosion-resistant felsic igneous or metamorphic rocks (White et al. 1993).

Key Processes and Interactions: This system is naturally dominated by stable, uneven-aged forests, with canopy dynamics dominated by gap-phase regeneration on a fine scale, as well as larger disturbances resulting primarily from ice storms (Nicholas and Zedaker 1989). Despite the extreme climate, *Picea rubens* is long-lived (300-400 or more years) (White et al. 1993). Both *Picea* and *Abies* seedlings are shade-tolerant, and advanced regeneration is important in stand dynamics. Natural disturbances are primarily wind and ice storms, but may include debris avalanches or very rarely lightning fires (White 1984b, Nicholas and Zedaker 1989, White et al. 1993). Occasional extreme wind events disturb larger patches on the most exposed slopes. Fire is a very rare event under natural conditions, due to the wetness and limited flammability of the undergrowth (Korstian 1937 cited in White et al. 1993), and return intervals have been estimated between 500 and 1000 years or more. If fires do occur, they are likely to be catastrophic, because few of the species are at all fire-tolerant. Anthropogenic fires fueled by logging slash were extremely destructive, turning large expanses of this system into grass-shrub-hardwood scrub (e.g., Dolly Sods, Graveyard Fields) that has not recovered to conifer dominance after 100 years.

Estimates of the loss in extent of the Southern Appalachian spruce-fir forest range from 50% (White 1984c) to 90% (Korstian 1937 cited in Nicholas and Zedaker 1989). The primary disturbances are weather-related, including ice storms and windthrow, occurring at intervals of 100 to 200 years. There have been multiple events of wind and ice damage in single- and multiple-tree patches that have cumulatively damaged a lot of the canopy in spruce forests (M. Schafale pers. comm. 2013). Rare extreme weather events are also important large-scale disturbances. In contrast to northern stands of *Picea-Abies* vegetation, insect outbreaks are not important disturbances (M. Schafale pers. comm. 2013). Windthrow produces dense *Abies* seedlings if overstory is mature (Eyre 1980). In general, fire is extremely rare in Southern Appalachian *Picea-Abies* vegetation, and fire is not a primary factor in its successional dynamics.

Threats/Stressors: Anthropogenic disturbances and stresses, beyond the effects of logging, have had major effects on dynamics in these systems in recent decades. Anthropogenic fires fueled by logging slash were extremely destructive, turning large expanses of this system into grass-shrub-hardwood scrub (e.g., Dolly Sods, Graveyard Fields) that has not recovered to conifer dominance after 100 years. An introduced insect, the balsam woolly adelgid (*Adelges piceae*), has killed almost all of the mature *Abies fraseri*. Saplings are not susceptible, and dense stands have established from advanced regeneration in some areas. Other areas were converted to long-term successional vegetation dominated by deciduous trees such as *Sorbus americana, Betula alleghaniensis*, and *Prunus pensylvanica* (White and Cogbill 1992), as well as *Rubus* and/or shrubs. It is unclear if the young fir stands will establish seedlings before they too are killed. Stress caused by concentrated air pollutants on the mountaintops has been suggested as an important anthropogenic stress and as a cause of observed growth declines in *Picea rubens*. Climate changes may severely affect this system. Global warming can be expected to raise the lower elevational limit and greatly reduce the land area available to this system.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe stress from the effects of concentrated air pollutants at high elevations, combined with the effects of insect pests, particularly the balsam woolly adelgid (*Adelges piceae*), which has killed almost all of the mature *Abies fraseri*. Loss of overstory trees results in increased densities of *Abies fraseri* seedlings but also *Sorbus americana, Betula alleghaniensis*, and *Prunus pensylvanica* (White and Cogbill 1992), perhaps leading to a forest dominated by these three deciduous taxa if the *Abies fraseri* cannot attain maturity in the future. If the younger *Abies fraseri* trees do not reach cone-bearing age and if the adelgid populations do not decline, *Abies* will cease to be a component of natural forests in the region (White et al. 1993). Stands in which *Abies* is not regenerating can be considered collapsed. Those with young *Abies* may be recovering, but their prognosis is uncertain. Those where shrubs or *Rubus* have taken over are considered collapsed. Climate changes may severely affect this system. Global warming can be expected to raise the lower elevational limit and greatly reduce the land area available to this system. A warming climate may lessen or eliminate precipitation from fog, which is the principal source of moisture available to this system.

CES201.564 Laurentian-Acadian Northern Hardwood Forest

CES201.564 CLASSIFICATION

Concept Summary: These northern hardwood forests range across New England and adjacent Canada, south to New York and possibly northern Pennsylvania and west to Minnesota. They occur in various dry-mesic to wet-mesic settings at low to moderate elevations, generally less than 610 m (2000 feet), throughout the Laurentian-Acadian Division. *Acer saccharum, Betula alleghaniensis*, and *Fagus grandifolia* are the dominant trees (the latter only east of northern Wisconsin). *Tsuga canadensis* or, in the Northeast, *Picea rubens* are common minor canopy associates. *Ostrya virginiana* is frequent but not dominant. Oak is a minor component and absent from northern regions. Successional stands may be dominated by *Populus tremuloides, Betula papyrifera, Acer rubrum, Fraxinus americana, Prunus serotina*, sometimes with scattered *Pinus strobus*. Soils range from moderately nutrient-poor to quite enriched, with associated shifts in the herb flora. This system can include large expanses of rich forest in areas of limestone or similar bedrock, as well as forests that are relatively poor floristically in areas of granitic (or similar) bedrock or acidic till. Blowdowns or snow and ice loading, with subsequent gap regeneration, are the most frequent form of natural disturbance.

CES201.563 Laurentian-Acadian Pine-Hemlock-Hardwood Forest

CES201.563 CLASSIFICATION

Concept Summary: This north-temperate forest system ranges from the northeastern U.S. and adjacent Canada west to the Great Lakes and upper Midwest. The mesic to dry-mesic forests usually occur on low-nutrient soils at low elevations, mostly less than 610 m (2000 feet). Canopy dominants include *Pinus strobus, Tsuga canadensis*, and *Quercus rubra* in varying percentages. *Acer rubrum* is also quite common; *Betula lenta* may be common at the southern periphery of this system's range. *Quercus velutina* and *Quercus alba* are essentially absent from this system, being more representative of systems in the Central Interior-Appalachian Division to the south. This is a widespread, matrix forest type for the more temperate portions of this division. Gap replacement and infrequent fire are the major natural regeneration modes.

CES103.020 Eastern Hemi-Boreal Aspen-Birch Forest

CES103.020 CLASSIFICATION

Concept Summary: These early-successional boreal hardwood forests and woodlands are widespread throughout the eastern subboreal region of Canada, extending into parts of the Laurentian-Acadian region, but more localized eastward. They originate naturally after fires and blowdowns, but more commonly originate after logging of conifer or mixed conifer-hardwood systems. *Populus tremuloides* and *Betula papyrifera* are the most important tree species. This system is maintained by repeated disturbance within 50-year return intervals and would otherwise succeed to conifer systems. Localized stands of mixed conifer-hardwoods (pines and spruces) can occur in this type, but are more typically part of conifer systems.

CES103.426 Laurentian-Acadian Sub-boreal Mesic Balsam Fir-Spruce Forest

CES103.426 CLASSIFICATION

Concept Summary: This ecological system represents the mesic southern or subboreal eastern boreal forest, ranging from northwestern Ontario to eastern Canada's Atlantic provinces and extending into the U.S. in northeastern Minnesota, Isle Royale, and near-coastal areas of Lake Superior shores in northern Wisconsin and Michigan. The low-elevation forests are dominated by *Picea glauca* and *Abies balsamea*. *Picea mariana* is often present, along with occasional *Pinus banksiana*. Codominant boreal hardwoods include *Populus tremuloides* and *Betula papyrifera*. Northern hardwoods, such as *Acer saccharum* and *Tilia americana* are relatively minor. The shrub and herb layers are variable, decreasing as the percent conifer cover increases. Common shrub species include *Acer spicatum, Alnus viridis, Corylus cornuta, Diervilla lonicera*, and *Lonicera canadensis*. The moss layer ranges from discontinuous to continuous. These upland forests typically occur on loamy soils over bedrock in scoured bedrock uplands and loamy, rocky, or sandy soils on glacial moraines, till plains and outwash plains, and moisture conditions range from well-drained to somewhat poorly drained. Wetter sites may contain *Alnus incana ssp. rugosa, Calamagrostis canadensis*, and *Equisetum* spp. This is the matrix forest type in many parts of its range. This group may include earlier-successional patches, in which *Populus* spp. and *Betula* spp. are dominant or mixed with *Picea* and *Abies*, that will develop into spruce-fir forests. Blowdown with subsequent gap regeneration is the most frequent form of natural disturbance, with large-scale fires important at longer return intervals. Insect infestations, in particular by *Choristoneura fumiferana* (spruce budworm), also can impact this group.

Distribution: This system ranges in Canada from northwestern Ontario (possibly eastern Manitoba) to eastern Canada's Atlantic provinces and extending into the U.S. in northeastern Minnesota, Isle Royale, and near-coastal areas of Lake Superior shores in northern Wisconsin and Michigan. Its range westward is marked by a shift towards greater *Picea glauca* dominance and lower *Abies balsamea* dominance.

Nations: CA, US

Concept Source: Faber-Langendoen, in Faber-Langendoen et al. (2012)

Description Author: D. Faber-Langendoen

CES103.426 CONCEPTUAL MODEL

Environment: These upland forests typically occur on loamy soils over bedrock in scoured bedrock uplands and loamy, rocky, or sandy soils on glacial moraines, till plains and outwash plains (Minnesota DNR 2003). Moisture conditions range from well-drained to somewhat poorly drained. Climate typically is characterized by cool, even temperatures, shorter growing season, and deep and sometimes severe winter snowfall. In the southern part of their range in the Great Lakes states, they occur along northern Great Lakes shorelines and on islands in Lake Superior. Cold temperate to boreal. Soils are typically neutral to acidic, shallow sandy, sandy-loam, or loamy-sand. Some examples occur on heavier, mesic silty or clay loams that are more alkaline in nature. Along Great Lakes shorelines, these soils overlay limestone or volcanic bedrock.

Key Processes and Interactions: These forests are affected by windthrow, insect defoliation, and infrequent fires. Forests closer to the Great Lakes shorelines occur on shallower soils and are more likely to experience more serious windthrow and snap-off of larger trees. Mammalian herbivory also can impact forest stands. Selective herbivory by white-tailed deer and moose (*Alces americanus*) can alter the composition and structure and favor browse-tolerant species such as *Picea glauca*. These forests typically regenerate from gap-phase dynamics.

CES202.704 Paleozoic Plateau Bluff and Talus

CES202.704 CLASSIFICATION

Concept Summary: This system is found in the driftless regions of southeastern Minnesota, southwestern Wisconsin, and northern Iowa and Illinois. This region was not glaciated like the surrounding areas and thus is predominated by rolling hills and bluff outcrops. This system is found primarily on blufftops and dry upper slopes along the Upper Mississippi River, although it can range into bordering regions such as the Baraboo Hills in Wisconsin. This system contains a mosaic of woodlands, savannas, prairies and sparsely vegetated limestone, dolomite, and/or sandstone outcrops, with occasional talus, especially algific talus. Soils range from thin to moderately deep and are moderately to excessively well-drained with a high mineral content. Woodlands consist of primarily a mixture of oak species such as *Quercus macrocarpa, Quercus rubra, Quercus muehlenbergii*, and *Quercus alba*. *Acer saccharum, Betula alleghaniensis*, and conifer species such as *Pinus* spp. and *Tsuga canadensis* may occur on more mesic and protected areas within this system. Prairie openings (also called "goat prairies") contain *Schizachyrium scoparium* and *Bouteloua curtipendula* with scattered *Juniperus virginiana*. Historically, fire was the most important dynamic maintaining these systems, however, fire suppression within the region has allowed more canopy cover and thus very few prairie openings remain. Algific talus harbors a number of unusual Pleistocene relict species, including plants and snails.

Distribution: This system is found within the Paleozoic Plateau (aka Driftless Region) of southeastern Minnesota, southwestern Wisconsin and northern Iowa and Illinois.

Nations: US

Concept Source: S. Menard

Description Author: S. Menard, mod. J. Drake

CES202.704 CONCEPTUAL MODEL

Environment: This system is found on an unglaciated landscape that is predominated by rolling hills and bluff outcrops. This system is found primarily on blufftops and dry upper slopes along the Upper Mississippi River, although it can range into bordering regions such as the Baraboo Hills in Wisconsin. This system contains limestone, dolomite, and/or sandstone outcrops, with occasional talus, especially algific talus. Soils are primarily loess and range from thin to moderately deep and are moderately to excessively well-drained with a high mineral content.

Key Processes and Interactions: This is a diverse system with different ecological processes necessary for different aspects. Fire is important for maintaining the prairie and dry oak aspects of the system, but the steep slope and thin soil reduce the suitability for many other species, so fire frequency does not need to be as high as in more fertile prairies and oak woodlands. The prolonged absence of fire will favor shrub and tree invasion of the prairie and an increase in mesophytic trees and shrubs in the oak forests and woodlands (Nowacki and Abrams 2008). The cooler, more mesic aspects of the system with significant conifers (*Pinus strobus, Pinus resinosa*, and *Tsuga canadensis*) occur in protected ravines or on steep slopes with little soil development, and fire is not important in establishing or maintaining these communities (McIntosh 1950, Kline and Cottam 1979). These communities occur where there are cooler summer soil and air temperatures and on this soiled sites over acidic bedrock (McIntosh 1950, Adams and Loucks 1971).

Threats/Stressors: Threats to this system include alteration of fire regime, nearby agricultural development and subsequent runoff, and erosion, whether natural or anthropogenic. Reduced fire frequency in the prairie and oak woodland will allow shrubs, particularly *Juniperus virginiana* but also others such as *Zanthoxylum americanum* and *Lonicera* spp., to proliferate. This system occurs on areas that are not well-suited to direct agricultural use due to the steep slopes and thin, rocky soil, but flat areas above this system can be used for crops or pasture. Erosion and runoff of sediment, fertilizers, and other agricultural chemicals can increase. This can deposit more soil, increase the site fertility (from fertilizer runoff) or harm plants or animals (from pesticide/herbicide runoff). Increased fertility of a site will favor invasion by species not typical of this low-fertility system. Increasing temperature from climate change will likely reduce the suitability of sites for conifer-dominated components of this system.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when fire regimes are disrupted in the warmer prairie and oak woodland communities of this system which results in invasion by shrubs and fire-sensitive exotic herbaceous species and allows tree canopies to become more closed.

High-severity environmental degradation occurs when fires become very infrequent (>35-year return interval) for the prairie and oak woodland components or when agricultural runoff (sediment, agricultural chemicals) severely disrupts the native plant component. Moderate-severity environmental degradation occurs when fires become infrequent (>20-year return interval) for the prairie and oak woodland components or when agricultural runoff (sediment, agricultural chemicals) moderately disrupts the native plant component.

High-severity disruption of biological processes occurs when shrubs become abundant (>60% cover) in the prairie or oak woodland communities or when the canopy becomes very dense (>90% cover) in the oak woodland or when exotic species comprise

>50% of the relative cover in the community. Moderate-severity disruption of biological processes occurs when shrubs are common (>25% cover) in the prairie community or when the tree canopy becomes dense (>60% cover) in the oak woodland or when exotic species comprise >30% of the relative cover in the community.

M159. Laurentian-Acadian Pine - Hardwood Forest & Woodland

CES201.562 Acadian Sub-boreal Spruce Flat

CES201.562 CLASSIFICATION

Concept Summary: These spruce-fir forests are found in the colder regions of the northern Appalachians-Acadian region, in areas of imperfectly drained soils where they often form extensive flats along valley bottoms. The nutrient-poor acidic soils are typically saturated at snowmelt but are moderately well-drained for much of the growing season and may be reasonably dry at the soil surface. The mostly closed-canopy forests have *Picea rubens, Picea mariana*, and *Abies balsamea* as the dominant trees; other conifers are often present. Bryophytes are abundant in the ground layer; other layers are typically rather sparse. Many occurrences may be jurisdictional wetlands due to seasonal saturation, but the vegetation is primarily made up of upland or facultative species. The distribution in the Laurentian-Acadian Division is mostly Canadian.

CES201.718 Laurentian Pine-Oak Barrens

CES201.718 CLASSIFICATION

Concept Summary: These pine-oak barrens occur in the northern and western Great Lakes region. They occur on sandplains/outwash habitats, with droughty, infertile sand or loamy sands and frequent fires (every 5-30 years). *Pinus banksiana, Pinus resinosa, Quercus ellipsoidalis*, and *Pinus strobus* are common overstory dominants. Prairie species are common throughout much of the range of the type. Common shrub and ground cover species include *Andropogon gerardii, Carex pensylvanica, Corylus americana, Schizachyrium scoparium*, and *Vaccinium angustifolium*. Oak grubs may be common under frequent burning. Catastrophic burns may create open bracken grasslands.
Related Concepts:
- Jack Pine: 1 (Eyre 1980) **<**
- Northern Pin Oak: 14 (Eyre 1980) **<**

Distribution: Occurs in the northern and western Great Lakes region.
Nations: CA, US
Concept Source: D. Faber-Langendoen
Description Author: D. Faber-Langendoen and J. Drake

CES201.718 CONCEPTUAL MODEL

Environment: These barrens occur on sandy outwash plains, glacial lakeplains, and broad riverine terraces. Soils are generally infertile, coarse-textured, and acidic sands and loamy sands. The landscape is flat to gently rolling.
Key Processes and Interactions: Fire and droughty soil conditions maintain the characteristic open tree/shrub canopy and prairie-like understory of this system. The dry, relatively infertile soil limits the rate of tree growth, while periodic fires remove most tree regeneration and, less commonly, canopy trees. Fires are also necessary for regeneration of *Pinus banksiana*. Sites with finer-textured and more fertile soils need greater fire frequency, while sites with coarser-textured, less fertile soils need less frequent fires to maintain this system. The historical fire-return interval is 5-20 years (Landfire 2007a). Fire-return intervals of 20-30 years result in abundant woody cover. Occasional frost during the growing season, sustained drought, and catastrophic winds can kill canopy trees (*Quercus* spp. would be more affected by frost) (Kost et al. 2007).
Threats/Stressors: The main threats to this system are fire suppression, high grazing and browsing rates, conversion to pine plantations, landscape fragmentation, and logging. In the absence of fire, *Quercus* spp. and other hardwoods and deciduous shrubs spread, creating a short, dense woody canopy. This shades out the shade-intolerant herbaceous species and pines and makes future fires less likely, though possibly more severe if they occur. Sustained high grazing and browsing pressure can eliminate native herbaceous species and will favor woody shrubs and other species not preferred by livestock or deer as well as provide more opportunities for invasive species. Landscape fragmentation due to agricultural and rural development disrupts the ecological processes under which this system developed, particularly fire, and can make managing stands through prescribed fire more difficult

due to fragmented ownership and perceived threat to private property (WNHI 2012). Fragmentation also creates greater edge-to-interior ratio and increases the opportunities for introduction of exotic species. Logging is currently uncommon but previously occurred on pine-oak barrens and removed all the large overstory *Pinus resinosa* and *Pinus strobus* (Vogl 1964). Recreational use (off-road vehicles, in particular) can affect limited areas but also can serve as a source for introduction of invasive species that can tolerate the dry conditions, among them *Centaurea biebersteinii (= Centaurea maculosa), Elaeagnus umbellata, Leucanthemum vulgare (= Chrysanthemum leucanthemum), Lonicera* spp., *Rhamnus cathartica*, and *Rosa multiflora*. Due to the relatively infertile soils, this system recovers fairly slowly from disturbance, so effects can accumulate over time.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from a lack of fire, high grazing and browsing pressure, severe landscape fragmentation, or when invasive or aggressive native species become abundant. Severe environmental degradation occurs when fire-return intervals are >50 years; when landscape fragmentation greatly reduces stand size. Moderate environmental degradation occurs when fire-return intervals are >20 years; when landscape fragmentation moderately reduces stand size. Severe disruption of biological processes results from greatly increased woody canopy (>60%), high grazing and browsing pressure, and a high degree of invasion by exotic or aggressive native species. Moderate disruption of biological processes results from increased woody canopy (25-60%), moderate, sustained grazing and browsing pressure, and moderate invasion by exotic or aggressive native species.

CES201.719 Laurentian-Acadian Northern Pine-(Oak) Forest

CES201.719 CLASSIFICATION

Concept Summary: This is a pine-dominated, or occasionally pine-oak, forest system that is typically found on nutrient-poor soils, or on moderately rich soils in the upper Midwest, northeastern U.S., and adjacent Canada, in a variety of topographic settings. Soils are loamy to sandy, varying from thin soil over bedrock to deeper soils, sometimes sandy. Sites are xeric to subxeric, but less strongly than barrens and sandplains. The dominant fire regime varies from 100-200 years for *Pinus strobus* and *Pinus resinosa*. Other boreal conifers, or in the East *Picea rubens*, may occasionally be present. Canopy structure is mostly closed but can be partially open. Conifers typically dominate the canopy, but codominates may include hardwoods, especially *Quercus rubra* or *Acer rubrum*, but also *Populus tremuloides* or *Betula papyrifera*. The shrub and field layers can be somewhat dense to sparse.

CES103.425 Eastern Hemi-Boreal Dry-Mesic Pine-Black Spruce-Hardwood Forest

CES103.425 CLASSIFICATION

Concept Summary: This subboreal forest ecological system is found on dry-mesic nutrient-poor soils in a variety of topographic settings. It ranges from northwestern Ontario to eastern Canada, and southward into Minnesota, the Great Lakes region, and very locally into northwestern Maine. Soils are loamy to sandy, varying from nutrient-poor, thin soils over bedrock to deeper soils, sometimes sandy. Sites are typically dry-mesic. The dominant fire regime varies from 50-100 years. *Pinus banksiana, Pinus resinosa*, and *Picea mariana* are characteristic overstory species, with *Pinus strobus* occasionally common, over much of the range, but east of the Great Lakes, *Picea mariana* becomes increasingly dominant with *Abies balsamea* as an important associate. Canopy structure is mostly closed but can be partially open. Conifers typically dominate the canopy, but boreal hardwoods (*Populus tremuloides, Betula papyrifera*) may codominate. As time since fire increases, *Picea mariana* may dominate. Tree regeneration includes *Abies balsamea, Betula papyrifera, Populus tremuloides*, and *Picea mariana*. The shrub and field layers can be very open to somewhat dense (5-75% cover). Characteristic low-shrub and herb species include *Amelanchier* spp., *Vaccinium angustifolium, Diervilla lonicera, Cornus canadensis, Linnaea borealis, Doellingeria umbellata*, and *Eurybia macrophylla*. Older *Picea mariana* stands may be strongly dominated by feathermosses.

CES103.424 Northern Dry Jack Pine-Red Pine-Hardwood Woodland

CES103.424 CLASSIFICATION

Concept Summary: This conifer woodland is found throughout the eastern southern or subboreal regions of eastern Canada, extending into the Upper Midwest and Northeast parts of the United States. It occurs on dry nutrient-poor sand plains and along rocky ridges, often adjacent to rivers and lakes, and along talus slopes. The canopy ranges from patchy to continuous and is dominated by a mix of primarily conifer and hardwood species. In some examples, canopy trees may be stunted. *Pinus banksiana* is the most frequent conifer species, although *Pinus resinosa, Pinus strobus, Picea mariana*, or *Picea glauca* can be common and may dominate some sites. Hardwood species vary in cover from 25-90% of the canopy. *Quercus ellipsoidalis* is a restricted dominant in the Midwest part of the range of this system, along with *Quercus macrocarpa* and *Quercus rubra*. More common are *Betula papyrifera* and *Populus* spp. In areas of open bedrock, species typical of bedrock outcrops and shallow soils can be found and include *Danthonia spicata, Poa alsodes, Elymus trachycaulus, Maianthemum canadense, Schizachne purpurascens*, and *Oryzopsis asperifolia*. The nonvascular layer can be absent or present with up to 30% cover. In the open bedrock areas, this layer consists mainly of the lichens and mosses. Infrequent fire is the primary dynamic, with catastrophic fires occurring approximately every 150-200 years with surface fires every 50-200 years.
Related Concepts:
Distribution: This system ranges in Canada from northwestern Ontario (possibly eastern Manitoba) to eastern Canada's Atlantic provinces and extending into the U.S. in northeastern Minnesota, Isle Royale, and near-coastal areas of Lake Superior shores in northern Wisconsin and Michigan.
Nations: CA, US
Concept Source: D. Faber-Langendoen, in Faber-Langendoen et al. (2012)
Description Author: S. Menard and D. Faber-Langendoen

CES103.424 CONCEPTUAL MODEL

Environment: Examples of this system occur on rocky ridgetops, high slopes, and terraces sometimes along rivers or lakeshores, including Great Lakes shorelines. These areas are dry, well-drained sites, often with exposed bedrock. Soils range from bare bedrock and talus slopes to rocky, shallow loams and deep sands. Those stands on bedrock may have occasional cracks in the underlying bedrock resulting in pockets of relatively deep (15-20 cm) soil. Bare rock (with crustose lichens) can cover up to 50% of the area.

Key Processes and Interactions:
Threats/Stressors:
Ecosystem Collapse Thresholds:

M016. Southern & South-Central Oak - Pine Forest & Woodland

CES205.896 Bastrop Lost Pines Forest and Woodland

CES205.896 CLASSIFICATION

Concept Summary: This system, dominated by *Pinus taeda*, is endemic to central Texas. Locally this is known as the "Bastrop Pines." Examples may share similarities, in terms of the vegetation, with Coastal Plain pine-hardwood systems to the east (in TNC Ecoregions 40 and 41) but differ in the fact that this system contains only loblolly pine which is generally considered successional in the more eastern systems. The vegetation includes a range of communities (that have yet to be defined) that range from very dry to xeric uplands to dry and even mesic areas with different suites of hardwood associates. The *Pinus taeda* of this region is genetically different than strains to the east; it has much greater drought tolerance. It is possible that this area was one of the epicenters of early southern pine colonization of the Coastal Plain based on fossil pollen evidence.

Related Concepts:

- Bastrop Lost Pines: Loblolly Pine Slope Forest (121) [CES205.896.11] (Elliott 2011) **<**

Distribution: This system is endemic to central Texas.
Nations: US
Concept Source: R. Evans and M. Pyne
Description Author: R. Evans, M. Pyne, L. Elliott

CES205.896 CONCEPTUAL MODEL

Environment: Stands of this system occur on dissected uplands. Sandy soils characterize this system with typical Ecological Sites being deep sand, sandy, and sandy loam. It may also occupy gravelly sites associated with more recent geologic strata. Sandy Eocene formations such as Carrizo, Sparta, and Queen City formations are most frequently associated with this system, though it may also occur on the Reklaw (another Eocene) Formation (Elliott 2010).
Key Processes and Interactions: Local accumulations of pine needles result in a patchy distribution of herbaceous cover. This system bears some resemblance to pine woodlands and forests farther to the east and may represent a western, more xeric outlier of these similar systems.
Threats/Stressors:
Ecosystem Collapse Thresholds:

CES205.682 Crosstimbers Oak Forest and Woodland

CES205.682 CLASSIFICATION

Concept Summary: This system is primarily found within central Texas and Oklahoma, ranging north to southeastern Kansas and east into eastern Oklahoma. It is distinct from the surrounding prairie by the higher density of tree species. The area consists of irregular plains with primarily sandy to loamy Ustalf soils that range from shallow to moderately deep. Rainfall can be moderate, but somewhat erratic, therefore moisture is often limiting during part of the growing season. Short, stunted *Quercus stellata* and *Quercus marilandica* characterize and dominate this system. Other species, such as *Carya texana, Carya cordiformis, Quercus prinoides, Ulmus crassifolia*, and other *Quercus* spp., can also be present within their respective ranges. The understory often contains species typical of the surrounding prairies, in particular *Schizachyrium scoparium*. Shrubs such as *Rhus* spp. may also be present. Drought, grazing, and fire are the primary natural processes that affect this system. Overgrazing and conversion to agriculture, along with fire suppression, have led to the invasion of some areas by problematic brush species such as *Juniperus virginiana* and *Juniperus ashei* and *Prosopis glandulosa* farther south in Texas and Oklahoma. It has also led to decreases in native grass cover allowing for annual grasses and forbs to invade.

- Eastern Redcedar: 46 (Eyre 1980) **<**
- Post Oak - Blackjack Oak: 40 (Eyre 1980) **><**

Distribution: This system is primarily found within central Texas and Oklahoma, with the northern extent reaching into southeastern Kansas in the Cross Timbers (EPA level III ecoregion 29). It also includes the "Lower Canadian Hills" and "Osage Cuestas" in eastern Oklahoma and the Edwards Plateau Woodland, Semiarid Edwards Plateau and Broken Red Plains of Texas (37e, 40b, 30a, 30d, 27i of EPA, respectively).

Nations: US

Concept Source: S. Menard and K. Kindscher

Description Author: S. Menard, K. Kindscher, J. Teague, M. Pyne and L. Elliott

CES205.682 CONCEPTUAL MODEL

Environment: This system is located on irregular plains composed of sandy to loamy Ustalf soils. These soils range from shallow to moderately deep. Rainfall can be moderate, but sporadic, leading to periods of limiting moisture. This system also includes smaller patch woodlands dominated by *Quercus stellata* occurring over Mollisols and scattered throughout the limestone uplands of the eastern Edwards Plateau and Lampasas Cutplain of Texas, locally referred to as "Redlands" (B. Carr pers. comm. 2005). The eastern occurrences of this system are associated with sandy members of the Cretaceous Woodbine Formation, while western occurrences occupy soils derived from the sands of the Cretaceous Trinity Group (such as Paluxy, Antler, and Twin Mountain-Travis Peak sands). Further west, in the fringe of the western Crosstimbers, the system occurs on more rugged, rocky and gravelly sites derived from Pennsylvanian formations. The landforms are gently rolling, moderately dissected uplands, and irregular plains becoming more rugged in the western fringe of the distribution of this system. Soils are sands or sandy loams, some with a claypan. Ecological Sites typical of the eastern expressions include Sandy Loam, Tight Sandy Loam, Claypan Prairie, Sandstone Hill, and Sandy. Those more typical of the western expressions include Sandy Loam, Loamy Sand, Tight Sandy Loam, Sandy, and Clay Loam (Elliott 2011).

Key Processes and Interactions: Drought, grazing, and fire primarily influence this system. Overgrazing and conversion to agriculture have allowed for the invasion of eastern red-cedar (*Juniperus virginiana*), Ashe's juniper (*Juniperus ashei*), and honey mesquite (*Prosopis glandulosa*) in some areas. Decreases in native grass cover associated with overgrazing can also lead to an increase in invasive annual grasses and forbs.

CES203.072 Crowley's Ridge Sand Forest

CES203.072 CLASSIFICATION

Concept Summary: This system of upland shortleaf pine - hardwood forests is confined to Crowley's Ridge on the western side of the Mississippi River. This vegetation is very distinctive from that of the adjacent alluvial plain, and the ridge itself also contrasts sharply with the adjacent alluvial plain. Crowley's Ridge is a remnant loess-capped feature rising from 30 m to over 60 m (100-200 feet) above the alluvial plain surface, to about 150 m (450 feet) above sea level. The base of the northern ridge is composed of Tertiary substrates overlain by alluvial deposits and capped with generally thin layers of Pleistocene loess. The Pleistocene alluvial deposits are often sandy, and in a very limited area, there are outcrops of sandstone of uncertain origin. Forests on the ridgetops are dominated by *Pinus echinata* with varying amounts of *Quercus alba, Quercus rubra, Quercus falcata, Quercus stellata, Carya texana*, and *Quercus velutina*. Loess slopes and ravines are dominated by mesic or dry-mesic hardwood forests such as those of the southern ridge, but are of relatively limited extent.

Related Concepts:

- Shortleaf Pine - Oak: 76 (Eyre 1980) **<**
- Shortleaf Pine: 75 (Eyre 1980) **<**

Distribution: This system is endemic to Crowley's Ridge in the Mississippi River Alluvial Plain of Arkansas and Missouri (Nelson 2010).

Nations: US

Concept Source: T. Foti, D. Zollner, M. Pyne

Description Author: T. Foti, D. Zollner, M. Pyne

CES203.072 CONCEPTUAL MODEL

Environment: These forests occur on sandy ridges and slopes in a dissected environment. The system is best expressed on northern Crowley's Ridge, but there are limited occurrences on the southern ridge as well, on sandy, exposed sites. They generally lie to the east of hydroxeric Pleistocene terrace flatwoods (now usually converted to cropland) that burned frequently. Those fires would have continued into these dry to dry-mesic forests, thereby increasing the fire frequency.

Key Processes and Interactions: These are fire-adapted forests. There is presumably some natural disturbance from the effects of windstorms and collapse of the fragile loess. This vegetation is classed as Fire Regime I, with frequent surface fire (mean fire-return interval is approximately five years) and less frequent mixed fire. In addition, straight-line winds or microbursts may cause blowdowns on a scale of 1 to 100 acres. Stand-replacement fires happen very infrequently (Landfire 2007a).

Threats/Stressors: Conversion of this type has primarily resulted from canopy removal and habitat fragmentation. Sites are typically impacted by sand and gravel mining, urbanization, and conversion to pastures. Degradation occurs from logging, as well as from lack of fire. Due to lack of fire for many years, the current forests are uncharacteristic (D. Zollner pers. comm. 2013).

Aside from actual site conversion, feral hogs represent one of the greatest threats to biodiversity in these forests (Engeman et al. 2007). In addition, invasive exotic species, including Ailanthus altissima, Macrothelypteris torresiana, Microstegium vimineum, Paulownia tomentosa, Phyllostachys aurea, and *Pueraria montana var. lobata*, can become dominant in the ground and shrub layers following canopy disturbance. For forests containing *Fraxinus* species, emerald ash borer (which as of October 2013 has been reported from southeastern Missouri) may also be (or become) a significant stressor.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from loss of the canopy, either from anthropogenic mechanical disturbance (land clearing for mining, development, forestry, or agriculture) or from severe alteration of the substrate from erosion. Ecological collapse can also result from such severe fragmentation (as in remnant patches left scattered among developments and roads) so that wildlife is driven out and natural processes are lacking. Fragmentation also breaks up the canopies of stands, making them more vulnerable to storms and damage from erosion of the substrate. Effects of forest fragmentation include the introduction of barriers to the movement of native animal and plant species, degradation of native habitats, degradation of water quality, and the introduction of non-native plant and animal species (Arkansas Forestry Commission 2010). In particular, feral hogs can significantly impact forest composition and structure (Engeman et al. 2007).

CES203.506 East Gulf Coastal Plain Interior Shortleaf Pine-Oak Forest

CES203.506 CLASSIFICATION

Concept Summary: This forested ecological system of the East Gulf Coastal Plain occurs most extensively on generally rolling uplands north of the range of *Pinus palustris*. It was the historical matrix in large areas of the region in Alabama and Mississippi, particularly from about 32°30'N latitude (the approximate local northern limit of the historic range of *Pinus palustris*), north to about 35°N latitude (the approximate limit where relatively extensive examples of *Pinus echinata* are replaced by predominantly hardwood-dominated systems). It is also understood that isolated examples of this system may occur both north and south of these boundaries in limited areas, including in the "Florida Parishes" of Louisiana. Stands tend to occur on generally well-drained sandy or clayey soils with dry to dry-mesic moisture regimes. *Pinus echinata* is the dominant pine species of the generalized "dry and dry-mesic oak-pine" forest type in the Gulf Coastal Plain and is the most characteristic floristic component of this system. The actual amount of *Pinus echinata* present varies based on a number of factors, but intact examples of this system often include stands that are dominated by *Pinus echinata* grading into stands with a mixture of upland hardwoods. Locally, on mid to lower slopes, *Pinus taeda* may be a component, extending further upslope in the absence of fire. Fire is possibly the most important natural process affecting the floristic composition and vegetation structure of this system, although fire-return intervals are lower than those associated with ~East Gulf Coastal Plain Interior Upland Longleaf Pine Woodland (CES203.496)$$. *Pinus echinata* may have difficulty replacing itself in the absence of fire, particularly on sites other than the driest ones. Local topographic conditions affecting natural fire compartment size generally lend themselves to this fire frequency, although some examples may have more frequent fires and some less than this generalized value. Where fire is most frequent the system may develop a relatively pure canopy of *Pinus echinata* typified by a very open woodland structure with scattered overstory trees and an herbaceous-dominated understory; such examples are rare on the modern landscape. More typical are areas in which *Quercus* spp., *Carya* spp., *Liquidambar styraciflua, Liriodendron tulipifera, Acer* spp., and *Nyssa sylvatica* have become prominent in the midstory and even overstory and in which herbaceous patches are rare. Although the general distributional boundaries described above indicate where this system formed an historical landscape matrix, smaller patches of the system may also be present in limited areas both north and south of these boundaries. Although some sources map the native range of shortleaf pine throughout a relatively large area of western Tennessee, the actual distribution of the species appears to be much more confined and almost absent from the Coastal Plain; when present, it occurs in only small stands on dry southwestern aspects.

Related Concepts:

- Shortleaf Pine - Oak: 76 (Eyre 1980) **<**
- Shortleaf Pine: 75 (Eyre 1980) **<**

Distribution: This system is restricted to the East Gulf Coastal Plain; it was the historical matrix in large areas of the region in Alabama and Mississippi, particularly between about 32°30'N latitude and about 35°N latitude. In southwestern Mississippi, this system is apparently dominant on the landscape west of 91°W longitude to the limits of the alluvial plain and northwest of a line running approximately from the intersection of 31°N latitude and 91°W longitude, northeastward to the city of Jackson, Mississippi, extending at least to about 34°N latitude. This is consistent with the ranges of Oak-Pine vegetation (generally equivalent to this system) versus Longleaf-Loblolly-Slash Pines in Shantz and Zon (1924). There are also limited and sporadic occurrences in the "Florida Parishes" of Louisiana (LNHP 2009).

Nations: US

Concept Source: R. Evans and A. Schotz

Description Author: R. Evans and A. Schotz

CES203.506 CONCEPTUAL MODEL

Environment: The core distribution of this system lies between about 32°30'N latitude and about 35°N latitude; more localized occurrences may be found as small patches both north and south of these boundaries embedded in other systems. The belted character of this region, in the form of inner lowlands and cuestas and other low-ridge landforms (Bowman 1911, Fenneman 1938), the associated diversity of soil types, and differences in settlement history appear to account for the importance of shortleaf pine in the Gulf Coast region when compared to the Atlantic Coastal Plain (White and Lloyd 1998). Cuestas and other hills create strong environmental gradients which, coupled with soil characteristics, promote a variety of mixed pine and pine-hardwood vegetation in this region; local differences in topography, parent material, and exposure influence site characteristics, resulting in numerous different plant communities. This system primarily occupies the dry and dry-mesic portion of regional moisture gradients. Wide variation in vegetation composition across this gradient is also strongly related to fire frequency and intensity (White and Lloyd 1998). Generally to the south and southeast it grades into longleaf pine-dominated system(s), and to the north into hardwood-dominated ones.

Key Processes and Interactions: The frequent presence of surface fire is important in order to support the reproduction of *Pinus echinata*, which is a critical species characteristic to the system. *Pinus echinata* is a shade-intolerant species and does not survive or grow well when fire-suppressed. Outbreaks of *Dendroctonus frontalis* (Southern Pine Beetle) also play an important role in shaping the dynamics of this system and the balance of pine versus hardwood dominance over time. Young shortleaf pines are generally slower growing and slower to dominate a site than *Pinus taeda* or many hardwood competitors, but they usually will endure competition longer than the common associate, *Pinus taeda*. *Pinus echinata* can maintain dominance on most sites after it overtops competing vegetation, but in general hardwoods cannot be eliminated from pine sites. On very good sites (i.e., with high site index), however, it may not outgrow competing species such as sweetgum and red maple (Lawson 1990).

CES203.483 East Gulf Coastal Plain Northern Dry Upland Hardwood Forest

CES203.483 CLASSIFICATION

Concept Summary: This system represents dry, upland, predominantly hardwood forests of limited portions of the East Gulf Coastal Plain of western Kentucky and Tennessee, northern Mississippi and Alabama. The core range of this type lies within the Northern Hilly Coastal Plain (EPA Level IV Ecoregion 65e), which includes the Northern Pontotoc Ridge (222Cf), Upper Loam Hills (222Cg), and Northern Loessal Hills (222Ce) Ecomap subsections. These areas occupy the eastern margin of the Upper East Gulf Coastal Plain where elevation is greatest and influence of loess is less than adjacent areas to the west. The vegetation has been broadly considered distinct from other coastal plain forests but has received almost no specific study. Although vastly forested when compared to the loess plains to the west, most of the vegetation is recovering from one or more forms of severe disturbance. *Quercus alba* dominates the upland forests which have been studied in a limited portion of this area, but communities have not been described to the same detail as in other ecological systems.

- White Oak - Black Oak - Northern Red Oak: 52 (Eyre 1980) **<**
- White Oak: 53 (Eyre 1980) **<**

Distribution: This system is found in the Coastal Plain of western Kentucky and Tennessee, ranging south to northern Mississippi and Alabama.

Nations: US

Concept Source: R. Evans and M. Pyne

Description Author: R. Evans and M. Pyne

CES203.483 CONCEPTUAL MODEL

Environment: The most northern examples (e.g., western Tennessee and Kentucky) occur along the eastern margin of the East Gulf Coastal Plain where elevation is greatest and influence of loess is minimal, and where they occur as predominantly slope forests in relatively deep, dissected stream valleys. The vegetation in this region has been broadly considered distinct from other coastal plain forests (Bryant et al. 1993, Fralish and Franklin 2002) but has received almost no specific study (Franklin and Kupfer 2004). Although vastly forested when compared to the loess plains to the west (USGS 1992), most of the vegetation is recovering from one or more forms of severe disturbance (Franklin and Kupfer 2004). *Quercus alba* dominates the upland forests which have been studied in a limited portion of this area (Franklin and Kupfer 2004), but communities have not been described to the same detail as in other ecological systems.

Key Processes and Interactions: Fire suppression and the resulting greater understory density and resulting cooler conditions on the forest floor affect this system.

Threats/Stressors:

Ecosystem Collapse Thresholds:

CES203.482 East Gulf Coastal Plain Northern Loess Plain Oak-Hickory Upland

CES203.482 CLASSIFICATION

Concept Summary: This is the former matrix hardwood system flanking the loess bluffs of the most northern portions of the Upper East Gulf Coastal Plain of western Tennessee, western Kentucky, possibly southern Illinois, and northern Mississippi. The core distribution of this system is mapped as the Loess Plains (EPA Ecoregion 74b). Extensive forests once covered this broad area of generally flat to rolling uplands. Most have been cleared for agriculture due to the rich, productive soils derived from relatively thick loess deposits. The areal extent of this forested system has been so heavily reduced that the component community types remain undocumented and speculative at best. Typical stands would contain oaks and other hardwoods. Some typical canopy dominants include *Quercus falcata, Quercus alba, Carya tomentosa, Quercus stellata, Quercus marilandica*, and *Quercus velutina*. Scattered successional stands would be dominated by *Juniperus virginiana var. virginiana*. In addition, *Liquidambar styraciflua* and *Liriodendron tulipifera* may be present.

Related Concepts:

- White Oak - Black Oak - Northern Red Oak: 52 (Eyre 1980) **<**

Distribution: This system would have occupied the most northern portions of the Upper East Gulf Coastal Plain of western Tennessee, western Kentucky, possibly southern Illinois, and northern Mississippi. Its core distribution is mapped by EPA (2004) as the Loess Plains (EPA Ecoregion 74b). Today it is reduced to remnant forest patches in a largely agricultural landscape.

Nations: US

Concept Source: R. Evans and M. Pyne

Description Author: R. Evans and M. Pyne

CES203.482 CONCEPTUAL MODEL

Environment: The habitat for this system is a broad area of generally flat to rolling uplands. Soils included in this system in western Tennessee are rich, productive, and silty, being derived from relatively thick loess deposits. Most of the soils have fragipans and some are poorly drained (Springer and Elder 1980).

Key Processes and Interactions: Most of the landscape in which this was the matrix system was cleared of forests for settlement and agriculture during the nineteenth and early twentieth century and very few sites remain in primary forest condition. Fire frequency and severity are classified as Fire Regime Group I, with frequent, low-intensity surface fires. The mean fire-return interval (MFRI) is about 15 years with wide year-to-year and within-type variation related to moisture cycles, degree of sheltering, and proximity to more fire-prone vegetation types. Anthropogenic fire may have contributed to presettlement fire frequency (Landfire 2007a). When sites are cleared for settlement or agriculture, *Liquidambar styraciflua* is a major component of the replacement successional forest, in addition to other wind-blown or bird-dispersed trees such as *Acer rubrum, Celtis* spp., *Fraxinus americana, Juglans nigra, Juniperus virginiana, Liquidambar styraciflua, Liriodendron tulipifera, Prunus serotina, Robinia pseudoacacia, Sassafras albidum, Ulmus americana*, and the exotic *Ailanthus altissima*. In addition, *Baccharis halimifolia* is a native increaser shrub that will colonize disturbed sites.

Threats/Stressors: Conversion of this type has primarily resulted from repeated canopy removal through logging, which is also the most critical anthropogenic threat. Most sites have long ago been cleared for agriculture due to the rich, productive soils derived from relatively thick loess deposits. The areal extent of this forested system has been so heavily reduced that the component community types remain undocumented and speculative at best.

The most critical anthropogenic threats to any remaining examples include removal of the characteristic dominant hardwoods and a lack of fire. Removal of the characteristic dominant hardwoods (primarily *Quercus* species and *Carya* species) through logging may result in a stand dominated by wind-blown or bird-dispersed tree species, including *Acer rubrum, Celtis* spp., *Fraxinus americana, Juglans nigra, Juniperus virginiana, Liquidambar styraciflua, Liriodendron tulipifera, Prunus serotina, Robinia pseudoacacia, Sassafras albidum, Ulmus americana*, and the exotic *Ailanthus altissima*. Sites may also be converted to *Pinus* species plantations. Lack of fire in the system leads to a closing of the subcanopy, and consequent loss of ground layer diversity. Feral hog (*Sus scrofa*) activity, combined with invasion of exotic species are also major threats. Another major threat is conversion to human-created land uses, including residential development, quarries, industrial development, and infrastructure development. The most significant potential climate change effects over the next 50 years include periods of drought, which will affect the health and survival of any remaining trees.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from sites having long ago been cleared for agriculture due to the rich, productive soils derived from relatively thick loess deposits. Ecological collapse of any remaining examples will result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (particularly *Quercus* and *Carya*) to regenerate. Periods of drought will also affect the health and survival of the canopy trees. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Feral hog (*Sus scrofa*) activity, combined with invasion of exotic species, can eradicate the native ground and shrub flora (Engeman et al. 2007, Edwards et al. 2013).

CES205.679 East-Central Texas Plains Post Oak Savanna and Woodland

CES205.679 CLASSIFICATION

Concept Summary: This ecological system is found in east-central Texas in a broad, northeast/southwest-trending band located west of the Upper West Gulf Coastal Plain, northwest of the Coastal Prairie, and east and south of the Blackland Prairie ecoregions. It exhibits some floristic and physiognomic variation across this northeast-southwest gradient, losing some eastern species and picking up some species with more western affinities. It is distinguished from the nearby prairie by the higher density of trees and diversity of woody species. The system differs from the floristically similar ~Crosstimbers Oak Forest and Woodland (CES205.682)$$ in that it generally occurs on Tertiary (primarily Eocene) geologic formations on the east-central Texas Plains, while the related Crosstimbers ecological system occupies Cretaceous and older formations of the interior plains. Floristically, Post Oak Savanna (at least north of the Colorado River) contains species of more eastern affinities such as *Callicarpa americana, Sassafras albidum, Cornus florida, Vaccinium arboreum, Ulmus alata*, and particularly *Ilex vomitoria*, the latter species being absent from ~Crosstimbers Oak Forest and

Woodland (CES205.682)$$. Post Oak Savanna generally occurs on sandy or loamy soils, often underlain by a claypan subsoil. Rainfall ranges from about 120 cm in the northeastern part of the range to about 70 cm in the southwest, where it becomes increasingly erratic. Therefore moisture is often limiting during part of the growing season. The system was historically characterized as having significant areas of graminoid cover with species composition resembling that of nearby prairie systems, punctuated by short, stunted woodlands and forests dominated by *Quercus stellata* and *Quercus marilandica*. Drought, grazing, and fire are the primary natural processes that affect this system. Much of this system has been impacted by conversion to improved pasture or crop production. Overgrazing and fire suppression have led to increased woody cover on most extant occurrences and the invasion of some areas by problematic brush species such as *Juniperus virginiana var. virginiana* and *Prosopis glandulosa* in the southern part of the system's range. These factors have also led to decreases in native grass cover allowing for annual grasses and forbs to invade.

Distribution: This ecological system is found in east-central Texas in a broad, northeast/southwest-trending band located west of the Upper West Gulf Coastal Plain, northwest of the Coastal Prairie, and east and south of the Blackland Prairie ecoregions. An arm extends along the Red River in north Texas.

Nations: US

Concept Source: L. Elliott and J. Teague

Description Author: L. Elliott, J. Teague, M. Pyne

CES205.679 CONCEPTUAL MODEL

Environment: This system is typically located on irregular plains in the East Central Texas Plains (Level III Ecoregion 33) of EPA (Griffith et al. 2004), composed of sedimentary formations of Tertiary age, including Eocene sands such the Queen City, Sparta, and Carrizo sands, as well as the Wilcox and Claiborne groups. The system also occupies other Tertiary formations such as the Goliad and Willis formations, as well as portions of the Quaternary Willis Formation. This system occupies gently rolling to hilly topography. It is moderately dissected by drainages. It usually occurs on sandy to sandy loam soils, often with a marked clay subsurface horizon. Soils of this system are generally Alfisols, are typically acidic to neutral, and range from shallow to moderately deep. Typical Ecological Sites include Claypan Savannah, Claypan Prairie, Sandy Loam, Sandy, and Deep Sand (Elliott 2011). Rainfall ranges from about 120 cm in the northeastern part of the range to about 70 cm in the southwest, where it becomes increasingly erratic.

Key Processes and Interactions: Drought, grazing, and fire are the primary natural processes that affect this system. This system is intricately tied with some occurrences of ~West Gulf Coastal Plain Herbaceous Seep and Bog (CES203.194)$$. The sandy soils and underlying geologic strata that support this system serve as recharge areas for groundwater that supports seeps and bogs along hillsides and at the heads of drainages supporting West Gulf Coastal Plain Herbaceous Seep and Bog.

Threats/Stressors: Though exact physiognomic condition of this ecological system during presettlement times is unknown, reconstruction of this history suggests that density of woody vegetation is higher today than historically (Campbell 1925, Tharp 1926, McBride 1933, Parmalee 1955, Midwood et al. 1998, Singhurst et al. 2004, Stambaugh et al. 2011b). Factors influencing the primary processes affecting this system, in particular, overgrazing and altered fire regimes, are likely responsible for this change in physiognomy, including invasion of some areas by problematic brush species such as *Juniperus virginiana var. virginiana* (to the north) and *Prosopis glandulosa* (to the south). These factors have also led to decreases in native grass cover allowing for annual grasses and forbs to invade. In addition, much of this system has been impacted by conversion to exotic pasture grasses *Cynodon dactylon* and *Paspalum notatum*. Other invasive species issues include *Ligustrum sinense, Melia azedarach, Triadica sebifera, Ailanthus altissima*, feral hogs, and red imported fire ants (TPWD 2012a). Early land uses, including grazing, then farming, and today urban and rural development, infrastructure development, and lignite coal mining, have resulted in the clearing of vast areas (Parmalee 1955, Bartlett 1995, Loucks 1999). Other threats include fragmentation and erosion (Bartlett 1995, Loucks 1999). Impacts of the altered composition and structure of vegetation regrowth since original land clearing are not well-studied and the vast majority of what remains is under private ownership. Less than 1% of the ecological system is under conservation management (Bezanson 2000).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from long-term lack of fire and the clearing and conversion of the ecological system to other land uses, e.g., pastures of exotic grasses, agriculture, and commercial, residential, and infrastructure development. Ecological collapse is characterized by fragmentation and complete conversion of the system to other land uses, or dense woody vegetation, the absence of native grasses that provide fine fuel to carry fires, and the presence of deep duff and litter.

CES203.531 Lower Mississippi River Dune Woodland and Forest

CES203.531 CLASSIFICATION

Concept Summary: This system represents the vegetation of sand dunes and related eolian features of the lower Mississippi River Alluvial Valley in Missouri and Arkansas. These Pleistocene dunes were overlooked or unrecognized until the late 1970s. This fact coupled with long periods of weathering and human disturbance, as well as proximity to a terrace mapped as "prairie" in General Land Office records, has led to considerable confusion regarding this type. These dunes are west of Crowley's Ridge and near the Black and White rivers, above the normal flood level of the Mississippi. Examples in Missouri occur amidst a series of low-lying, anastomosing channels that have helped to protect them from extensive alteration more typical in Arkansas where the uplands have been largely cleared. The uppermost portions of the dunes support a xeric community similar to sandhills of the West Gulf Coastal Plain (WGCP), but are outside the natural range of *Quercus incana*, a diagnostic species typical of the WGCP examples. Instead the dunes support very open *Quercus stellata* woodlands with *Schizachyrium scoparium* and abundant lichen cover (presumably *Cladonia* spp.), along with *Opuntia* sp. Less edaphically extreme slopes support more closed-canopied forests in which *Quercus stellata* is still important, along with *Quercus falcata* and possibly other species. In many instances, distinctive wetlands imbedded within this system are also present (~Lower Mississippi River Dune Pond (CES203.189)$$). Called "sand ponds" in Arkansas, these depressions have silty bottoms and perched water tables. The margins of these ponds are rimmed by *Quercus phellos* and have *Quercus lyrata*.

CES203.071 Mississippi River Alluvial Plain Dry-Mesic Loess Slope Forest

CES203.071 CLASSIFICATION

Concept Summary: This system of dry-mesic upland forests occurs most extensively on west-facing loess slopes on southern Crowley's Ridge, with more limited occurrences on northern Crowley's Ridge and in the erosional slopes and hills that bound the

Grand Prairie terrace of Arkansas and Macon Ridge in Louisiana and Arkansas. The vegetation is very distinctive from that of the adjacent alluvial plain, and the sites themselves, which occur on distinct slopes that rise above the alluvial plain surface, also contrast sharply with it. Occurrences of this system generally comprise dry-mesic forests that occupy west-facing slopes and narrow, "finger" ridgetops in a highly dissected landscape. In many cases, these slopes provide habitat for plant species that are uncommon in other parts of the alluvial plain. Forests on the ridgetops are dominated by *Quercus alba, Quercus rubra* (Crowley's Ridge only), *Quercus falcata, Quercus pagoda, Quercus stellata, Carya texana, Quercus shumardii*, and *Quercus velutina*.

- Shortleaf Pine: 75 (Eyre 1980) **<**
- White Oak - Black Oak - Northern Red Oak: 52 (Eyre 1980) **<**

Distribution: This system is endemic to well-drained sites on Crowley's Ridge (Arkansas, Missouri) and Macon Ridge (Louisiana/Arkansas), along the eastern slopes of the Grand Prairie terrace in Arkansas, and perhaps other such sites in the Mississippi River Alluvial Plain, including Missouri and extreme western Kentucky and Tennessee.

Nations: US

Concept Source: T. Foti and M. Pyne

Description Author: T. Foti, D. Zollner, M. Pyne

CES203.071 CONCEPTUAL MODEL

Environment: These forests occur on narrow ridgetops and slopes in a highly dissected environment. The system is best documented from southern Crowley's Ridge, Arkansas (Cross County south through Phillips County), with additional occurrences on the northern ridge, on the eastern border of the Grand Prairie terrace in Arkansas, on Macon Ridge (Louisiana/Arkansas) and probably on other upland sites within the alluvial plain, including Missouri and extreme western Kentucky and Tennessee. Loess soil is a characteristic and diagnostic component of the environment of this system.

Key Processes and Interactions: These are fire-maintained forests. In Arkansas, they generally lie to the east of hydroxeric Pleistocene terrace flatwoods or prairies (now usually converted to cropland) that burned frequently. Those fires would have continued into these dry to dry-mesic forests. There is presumably also some natural disturbance from the effects of windstorms and collapse of the fragile loess.

This loess forest type is Fire Regime Group III, surface fires with return intervals of 30 to 100 or more years. Mixed-severity fires will occur approximately every 100 years, opening the canopy with increased mortality. This effect may also be achieved by recurrent, severe insect defoliations or droughts. Straight-line winds or microbursts may cause blowdowns on a scale of 1 to 100 acres. Stand-replacement fires happen very infrequently (Landfire 2007a).

Threats/Stressors: Conversion of this type has primarily resulted from removal of the characteristic dominant hardwoods (primarily *Quercus* species and *Carya* species) through logging. This is also the most critical anthropogenic threat. This may result in a stand dominated by wind-blown or bird-dispersed tree species, including *Acer rubrum, Celtis* spp., *Fraxinus americana, Juglans nigra, Juniperus virginiana, Liquidambar styraciflua, Liriodendron tulipifera, Prunus serotina, Robinia pseudoacacia, Sassafras albidum, Ulmus americana*, and the exotic *Ailanthus altissima*. These and other fire-intolerant species persist and increase in the absence of fire (Edwards et al. 2013).

Aside from actual site conversion, feral hogs (*Sus scrofa*) represent one of the greatest threats to biodiversity in these forests (Engeman et al. 2007). In addition, invasive exotic species, including *Ailanthus altissima, Macrothelypteris torresiana, Microstegium vimineum, Paulownia tomentosa, Phyllostachys aurea*, and *Pueraria montana var. lobata*, can become dominant in the ground and shrub layers following canopy disturbance. For forests containing *Fraxinus* species, emerald ash borer (which as of October 2013 has been reported from southeastern Missouri) may also be (or become) a significant stressor.

The most significant potential climate change effects over the next 50 years include an increase in storms, which would contribute to severe erosion of the fragile loess substrate. Climate change may also bring increased periods of drought, which will affect the health and survival of the trees, as well as increase the probability of damaging wildfire.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (particularly *Quercus* and *Carya*) to regenerate. Periods of drought will also affect the health and survival of the canopy trees. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Feral hog activity, combined with invasion of exotic species, can eradicate the native ground and shrub flora (Engeman et al. 2007, Edwards et al. 2013).

CES202.306 Ouachita Montane Oak Forest

CES202.306 CLASSIFICATION

Concept Summary: This system represents hardwood forests of the highest elevations of the Ouachita, Rich, and Black Fork mountains of Arkansas and Oklahoma (about 790-850 m [2600-2800 feet]). Vegetation consists of either forests or open woodlands dominated by *Quercus alba* or *Quercus stellata*. Canopy trees are often stunted due to the effects of ice, wind and cold conditions, in combination with fog, shallow soils over rock, and periodic severe drought. Some stands form almost impenetrable thickets.

CES202.707 Ozark-Ouachita Dry Oak Woodland

CES202.707 CLASSIFICATION

Concept Summary: This system occurs in the Ozark and Ouachita Highlands and far western portions of the Interior Low Plateau regions along gentle to steep slopes and over bluff escarpments with southerly to westerly aspects. Parent material can range from calcareous to acidic with very shallow, well- to excessively well-drained soils, sometimes with a fragipan that causes "xero-hydric" moisture conditions. Historically, this system primarily exhibited a woodland structure with related composition and processes, but now most stands have a more closed canopy. Oak species such as *Quercus stellata, Quercus marilandica*, and *Quercus coccinea* dominate this system with an understory of grassland species such as *Schizachyrium scoparium* and shrub species such as *Vaccinium arboreum*. Drought stress is the major dynamic influencing and maintaining this system. Some examples are flatwoods with fragipans; in these examples *Quercus stellata* is the major dominant. In addition, *Quercus alba, Quercus falcata*, and/or *Carya texana* may be present in some stands.

CES202.708 Ozark-Ouachita Dry-Mesic Oak Forest

CES202.708 CLASSIFICATION

Concept Summary: This system is found throughout the Ozark and Ouachita Highlands ranging to the western edge of the Interior Low Plateau. It is the matrix system of this region and occurs on dry-mesic to mesic, gentle to moderately steep slopes. Soils are typically moderately to well-drained and more fertile than those associated with oak woodlands. A closed canopy of oak species (*Quercus rubra* and *Quercus alba*) often associated with hickory species (*Carya* spp.) typifies this system. *Acer saccharum* (or *Acer floridanum* to the south) may occur on more mesic examples of this system. Wind, drought, lightning, and occasional fires can influence this system.

CES202.325 Ozark-Ouachita Shortleaf Pine-Bluestem Woodland

CES202.325 CLASSIFICATION

Concept Summary: This system represents woodlands of the Ouachita and Ozark mountains region of Arkansas, adjacent Oklahoma, and southern Missouri in which *Pinus echinata* is the canopy dominant, and the understory is characterized by *Andropogon gerardii, Schizachyrium scoparium*, and other prairie plants. Although examples of this system occur throughout this region, there is local variation in the extent to which they were present. The center of distribution is the northern and western Ouachita Mountains, and it is best developed in large, dry, and flat to gently undulating portions of the landscape which carry fire well, creating extensive natural fire compartments. In the Ouachitas, the system occurs on the northern Hogback Ridges excluding the Novaculite areas to the south. These are large, gently sloping, east/west-trending ridges of sandstone and shale, the south-facing slopes of which constitute large fire compartments. In nearly all examples, *Pinus echinata* occurs with a variable mixture of hardwood species. The exact composition of the hardwoods is much more closely related to aspect and topographic factors than is the pine component. In the Ozark Highlands this system is less extensive but was historically prominent where sandstone-derived soils are common. In Missouri and Oklahoma, this system occurs on gently dissected upland cherty plains (in addition to sandstone ridges).

CES202.325 CONCEPTUAL MODEL

Environment: This system occurs throughout the Ouachita and Ozark mountains region, and there is some local variation in the extent to which it is present. The system is best developed in large portions of the landscape which are flat to gently undulating and which would carry fire well, creating extensive natural fire compartments. In the Ouachitas, the system occurs on the northern Hogback Ridges, which are large, gently sloping, east/west-trending ridges of sandstone and shale, the south-facing slopes of which constitute large fire compartments. In nearly all examples, *Pinus echinata* occurs with a variable mixture of hardwood species. The exact composition of the hardwoods is much more closely related to aspect and topographic factors than is the pine component. In the Ozark Highlands this system is less extensive but was historically prominent where sandstone-derived soils are common. In Missouri and Oklahoma, this system occurs on gently dissected upland cherty plains (in addition to sandstone ridges). This system is primarily confined to gently to moderately sloping, upland plains (larger fire compartments) and is thereby distinguished from shortleaf pine-oak woodland, which occurs on more steeply dissected ridges and steep southwest-facing slopes (smaller fire compartments). In the Ouachitas, the primary pine-bluestem landscape lies to the north of the two tallest ridges, Blackfork Mountain and Rich Mountain, which form a rainshadow by orographic lifting of the moisture-laden winds from the Gulf of Mexico that strongly influence the climate of this region; precipitation on those ridges can be as high as 147 cm (58 inches) annually, while just to the north, it may fall to 117 cm (46 inches) (T. Foti pers. comm. 2013).

Key Processes and Interactions: This system is Fire Regime Group I (Landfire 2007a), with frequent surface fires. Area fire frequency is 3 to 4 years, and the mean fire-return interval ranges from 1 to 12 years (Masters et al. 1995). Annual fire was common historically, such as in the 1800s. Replacement and mixed-severity fires are infrequent, every 100 to 1000 years. Stand-replacement fires occurred mostly under extreme drought conditions during the growing season. The impact of native ungulate grazing (buffalo and elk) was negligible, but fire generally maintained these open woodlands. Drought and moist cycles play a strong role interacting with both fire and native grazing. Other disturbance types include ice storms, wind events, and insect infestations. These disturbances can add significantly to downed woody debris, which can add fuel and increase fire intensity when that downed material is dry and burns. *Pinus echinata* has shorter needles and is not as susceptible to ice as *Pinus taeda*, which is more common further south in Arkansas.

Fire is an important dynamic process, which maintains open woodland conditions and can promote oak and pine regeneration. Today the region consists largely of closed-canopy forests, though relatively frequent fires prior to Euro-American settlement created and maintained forests, woodlands, savannas and glades (Stambaugh and Guyette 2006). Prior to 1820, fires were most frequent in areas with low topographic roughness, such as flat or gently sloping lands away from ravines and creeks (Stambaugh and Guyette 2008). For the next hundred years, fires increased as population increased (Stambaugh and Guyette 2006, 2008), until about 1930 when very effective fire-suppression practices began (Guldin et al. 2005). During the 1800s, these fires helped maintain *Pinus echinata* woodlands with floristically rich understory vegetation of prairie grasses and forbs (Hedrick et al. 2007). There is a very low rate of fire ignitions from lightning strikes in the area, nearly all ignitions are caused by people (Stambaugh and Guyette 2006).

Threats/Stressors: Lack of fire is a big threat. Without fire, the development of a closed forest canopy can lead to declines in the native herbaceous ground cover vegetation, especially the grasses which are more typical of open prairies. Clearcut logging of *Pinus echinata*, and forest succession by hardwood trees, or planting of *Pinus taeda* are threats to *Pinus echinata* woodlands. *Pinus echinata* woodlands have declined due to conversion to intensively managed pine plantations. Often sites have been replanted with *Pinus taeda*, and are then no longer burned for forest management. Some stands do not have adequate reproduction with restoration thinnings and prescribed fire, and will need to have *Pinus echinata* seedlings planted to regenerate stands (Guldin et al. 2005).

Ecosystem Collapse Thresholds: Ecological collapse results from the long-term lack of fire, which leads to failure of *Pinus echinata* recruitment and the decline of the herbaceous ground cover of native grasses and forbs, including legumes. Lack of fire is one of many factors which can contribute to the increase of invasive exotic plants; high cover of invasive exotic plants is a characteristic of ecological collapse. The cutting of *Pinus echinata* without managing for its regeneration on the site can contribute to ecological collapse. Ecological collapse is characterized by the transition of the stand to a hardwood forest stand, without *Pinus echinata*. Under these conditions, it would begin to transition to another ecological system, such as ~Ozark-Ouachita Dry-Mesic Oak Forest (CES202.708)$$ or ~Ozark-Ouachita Shortleaf Pine-Oak Forest and Woodland (CES202.313)$$.

CES202.313 Ozark-Ouachita Shortleaf Pine-Oak Forest and Woodland

CES202.313 CLASSIFICATION

Concept Summary: This system represents forests and woodlands of the Ouachita and Ozark mountains region of Arkansas, adjacent Oklahoma, and southern Missouri in which *Pinus echinata* is an important or dominant component. Although examples of this system occur throughout this region, there is local variation in the extent to which they were present. For example, in the Ozark Highlands, this system was historically prominent only in the southeastern part where sandstone-derived soils were common, and in the southern part on soils derived from chert, being excluded from or diminished in other areas by non-conducive soils. In contrast, pine was virtually ubiquitous in the historical forests of the Ouachitas. In nearly all cases (at least in the Ouachitas), *Pinus echinata* occurs with a variable mixture of hardwood species. The exact composition of the hardwoods is much more closely related to aspect and topographic factors than is the pine component. In some examples of this system, the aggregate importance of hardwoods may be greater than pine, especially on subxeric and mesic sites.

Description Author: T. Foti, R. Evans, M. Pyne and C. Nordman

CES202.313 CONCEPTUAL MODEL

Environment: In the Ozark Highlands, this system was historically prominent only in the southeastern part, where sandstone derived soils were common (USFS 1999) and in the southern part on soils derived from chert; being limited in other areas by non-conducive soils. In contrast, pine was "virtually ubiquitous in the historical forests of the Ouachitas" (USFS 1999). In nearly all cases (at least in the Ouachitas), Pinus echinata occurs with a variable mixture of hardwood species. The exact composition of the hardwoods is much more closely related to aspect and topographic factors than is the pine component (Dale and Ware 1999).

Key Processes and Interactions: Fire is an important dynamic process, which maintains open woodland conditions and can promote oak and pine regeneration. Fires have historically occurred more frequently than once every 10 years (Hedrick et al. 2007). Today the region consists largely of closed-canopy forests, though relatively frequent fires prior to Euro-American settlement created and maintained forests, woodlands, savannas and glades (Stambaugh and Guyette 2006). Prior to 1820, fires were most frequent in areas with relatively low topographic roughness, such as flat or gently sloping lands away from ravines and creeks (Stambaugh and Guyette 2008). For the next hundred years, fires increased as population increased (Stambaugh and Guyette 2006, 2008), until about 1930 when very effective fire-suppression practices began (Guldin et al. 2005). During the 1800s, these fires helped maintain *Pinus echinata* and hardwood forests with floristically rich understory vegetation of grasses and forbs (Hedrick et al. 2007). There is a very low rate of fire ignitions from lightning strikes in the Ozark Highlands area, nearly all ignitions are caused by people (Stambaugh and Guyette 2006). However, fires started by lightning could become very large, since ignitions may occur associated with drought, high winds, drying fuels, and decreasing humidity. The number of lightning strike-initiated wildfires is higher in the Ouachita Mountains and Boston Mountains. In these areas, presettlement wildland fires were ignited by Native Americans and by lightning (Foti and Glenn 1990). Other disturbances include wind, tornados, drought, and ice storms. These disturbances can open forest canopies and add significantly to downed woody debris, which can add fuel and lead to increased fire intensity when that downed material is dry and burns. *Pinus echinata* has shorter needles and is not as susceptible to ice as *Pinus taeda*, which is more common further south in Arkansas.

Threats/Stressors: Lack of fire is a big threat. Without fire, the development of a closed forest canopy can lead to declines in the native herbaceous ground cover vegetation. Some forestry practices used with *Pinus echinata*, and forest succession by hardwood trees, or planting of *Pinus taeda* are threats to *Pinus echinata*-dominated or -codominated forests and woodlands. *Pinus echinata* woodlands have declined due to conversion to intensively managed *Pinus* spp. plantations. Usually sites have been replanted with *Pinus taeda*, and are then no longer burned for forest management. Some natural stands do not have adequate reproduction after restoration thinnings and prescribed fire, and will need to have *Pinus echinata* seedlings planted to regenerate stands (Guldin et al. 2005).

Ecosystem Collapse Thresholds: Ecological collapse results from the long-term lack of fire, which leads to failure of *Pinus echinata* recruitment and the decline of the herbaceous ground cover of native grasses and forbs, including legumes. Lack of fire is one of many factors which can contribute to the increase of invasive exotic plants; high cover of invasive exotic plants is a characteristic of ecological collapse. The cutting of *Pinus echinata* without managing for its regeneration on the site can contribute to ecological collapse. Ecological collapse is characterized by the transition of the stand to a hardwood forest stand, without *Pinus echinata*. It could transition and become a stand of another ecological system, such as ~Ozark-Ouachita Dry-Mesic Oak Forest (CES202.708)$$.

CES202.268 Piedmont Hardpan Woodland and Forest

CES202.268 CLASSIFICATION

Concept Summary: This system of the southern Piedmont occurs in places where a particularly dense clay hardpan has developed over a range of typically mafic rocks, sometimes with more limited areas of shallow glade-like vegetation. In the deeper soil portions of this system, the density of the clay, in combination with its shrink-swell properties, limits water and root penetration into the soil and creates xeric conditions for plants despite the presence of deep soil. Possibly the most typical expression of this system in North and South Carolina is an open forest or woodland of *Quercus stellata*, with *Quercus marilandica* as a characteristic associate. The open canopy leads to a better developed herb layer than in most Piedmont forests, one that is usually grassy. In Virginia, typical canopy trees include *Quercus alba, Carya glabra*, and *Fraxinus americana*. Some of these sites may have once supported open prairies or prairie savannas when they burned more frequently. Fire was probably once the most important natural dynamic process, but the universal elimination of fire in the Piedmont makes this difficult to observe on most of the modern landscape.

Distribution: As currently known, this system is found in the Piedmont of Maryland, Virginia, North Carolina, South Carolina and Georgia. Its status in Alabama is not known. Its occurrence may be more frequent in the Triassic basins, but it is not restricted to them.

Nations: US

Concept Source: M. Schafale, R. Evans, G. Fleming, M. Pyne

Description Author: M. Schafale, R. Evans, G. Fleming, M. Pyne, J. Teague

CES202.268 CONCEPTUAL MODEL

Environment: This system occurs in places in the southern Piedmont where a particularly dense clay hardpan, typically composed of Montmorillonite, has developed. The substrate is typically mafic igneous or metamorphic rock (gabbro, basalt, diabase, or amphibolite) but occasionally is slate. The density of the clay, or its shrink-swell properties, limits penetration of water into the soil and limits penetration of roots, creating xeric conditions for plants despite the presence of deep soil. These areas generally occur on unusually flat uplands but may occur on tops of narrower ridges. Only a minority of these substrates form the distinctive soil conditions of this system. Local topography that promotes runoff is important to forming this system. Areas with these soil conditions but with concave topography perch water and support Piedmont depressional wetlands. Soils in most examples are basic or circumneutral, but those formed from slate are somewhat acidic. In Virginia and adjacent Maryland, this system occupies one of the largest Triassic basins in eastern North America. It includes a mix of sedimentary rocks, especially siltstone, mixed with igneous intrusions. The igneous rocks weather to form more mafic soils, while the sedimentary rocks are more acidic. The local landscape may best be thought of as a lowland, in comparison with the surrounding and prevailing topography.

Key Processes and Interactions: Fire was probably once the most important natural dynamic process, but the universal elimination of fire in the Piedmont makes this difficult to determine. Both the drier character of the sites and the distinctive soil conditions interact with one another to retard woody succession. These factors would presumably have interacted with the fire regime to promote more open vegetation on these sites. This would presumably lead to a greater probability that these open woodland conditions would prevail for a longer period than they would on more typical soils. Fire would have kept canopies open and would have promoted a more diverse, grass-dominated herb layer. Bison may have once been a significant grazing influence on this system. These sites are now of limited extent and it is harder to determine how these past disturbance factors operated in the larger landscape.

Threats/Stressors: Conversion of this type has primarily resulted from removal of the characteristic dominant hardwoods (primarily *Quercus* species and *Carya* species) through logging, and the subsequent development of the sites to human uses. This is also the most critical anthropogenic threat. This may result in a stand dominated by wind-blown or bird-dispersed tree species, including *Acer rubrum, Celtis* spp., *Fraxinus americana, Juglans nigra, Juniperus virginiana, Liquidambar styraciflua, Liriodendron tulipifera, Prunus serotina, Robinia pseudoacacia, Sassafras albidum, Ulmus americana*, and the exotic *Ailanthus altissima*. These and other fire-intolerant species persist and increase in the absence of fire (Edwards et al. 2013). Logging which is not carefully done can lead to soil erosion, and then conversion to *Pinus taeda* plantations or succession to *Acer rubrum, Liquidambar styraciflua, Pinus taeda* ruderal forest (Nordman 2013). Patches dominated by *Pinus taeda* are artifacts of past disturbance and succession in the absence of fire. These are likely to eventually succumb to drought, fire or insect damage. Another major threat is conversion to human-created land uses, including residential development, industrial development, and infrastructure development. Feral hog (*Sus scrofa*) activity can eradicate the native ground and shrub flora (Engeman et al. 2007). In addition, invasive exotic species, including *Ligustrum sinense, Lonicera japonica, Microstegium vimineum, Pueraria montana var. lobata, Rosa multiflora*, and others can become dominant in the ground and shrub layers following canopy disturbance and are threats to the natural species diversity of these habitats (Edwards et al. 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from canopy closure and succession in the absence of fire and mechanical disturbance, which over time renders the vegetation of these distinctive sites basically indistinguishable from the more typical oak-pine forests of the Piedmont region. Conversion to *Pinus taeda* plantations or to other human-oriented land uses would also represent ecological collapse. Feral hog activity, combined with invasion of exotic species, can eradicate the native ground and shrub flora (Engeman et al. 2007, Edwards et al. 2013).

CES202.319 Southeastern Interior Longleaf Pine Woodland

CES202.319 CLASSIFICATION

Concept Summary: This system encompasses the fire-maintained non-Coastal Plain woodlands and forests where *Pinus palustris* is a dominant or codominant canopy species. Its current range includes the outer Piedmont of Georgia and the Carolinas and various parts of Alabama, including the Talladega upland region (quartzite-slate transition) and the Cumberland Plateau, as well as, at least historically, the intervening Ridge and Valley. Examples occur on rolling to somewhat mountainous upland slopes in North Carolina, South Carolina, Georgia, and Alabama. They are believed to naturally be open woodlands with grassy ground cover, but many are now closed forests with dense shrubs or with little ground cover. *Pinus palustris* is either dominant, codominant, or present in circumstances that indicate former dominance or codominance. *Pinus echinata, Quercus coccinea, Quercus falcata, Quercus marilandica, Quercus montana, Quercus stellata*, and *Quercus velutina* are frequent associates, often codominating. *Carya pallida* and *Sassafras albidum* are also frequent trees. Some of the most frequently encountered grasses include *Andropogon* spp., *Chasmanthium laxum, Danthonia spicata, Dichanthelium commutatum, Panicum virgatum, Piptochaetium avenaceum, Schizachyrium scoparium*, and *Sorghastrum nutans*. Important forbs include *Coreopsis major, Euphorbia corollata, Helianthus microcephalus, Pityopsis graminifolia, Solidago odora, Tephrosia virginiana*, and the fern *Pteridium aquilinum*.

Distribution: This system once occurred in parts of the mostly outer Piedmont, from central North Carolina to Alabama, where it extends into the adjacent Ridge and Valley in northeastern Alabama and northwest Georgia. More extensive areas are now largely, if not exclusively, restricted to south-central North Carolina (outer Piedmont) and eastern Alabama (Talladega upland), as well as the Cumberland Plateau and at least historically, the Ridge and Valley of Alabama. Smaller remnants are found in very limited areas of South Carolina and Georgia (such as Pine Mountain).

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, M. Pyne and C. Nordman

CES202.319 CONCEPTUAL MODEL

Environment: This system occurs in upland settings, which may range from gently rolling to rugged and mountainous. Geologic substrates vary. Most portions are dry, but occasional moist areas and seepage wetlands occur. The primary influence on the system is frequent fire, associated with a location near a fire-prone portion of the Coastal Plain or with other factors. Apparently once widespread along the Fall-line, remnants are now largely limited to two clusters, in eastern Alabama and adjacent Georgia and in south-central North Carolina. There are also examples on the Piedmont portion of the Sumter National Forest, on the Long Cane Ranger District and possibly on the Enoree Ranger District. The former occurs on rugged terrain associated with the extension of geologic belts of the Blue Ridge. The latter is on gently to moderately rolling topography of metasedimentary and volcanic rocks. Most common on the poorest soils in the Piedmont of eastern Alabama, *Pinus palustris* was "a prominent constituent of the upland forests of nearly every county" but, by the first half of the twentieth century, "grew too scattered to be logged economically" (Harper 1943). About 35% of the original forest there was estimated to have been evergreen; the most common pines were *Pinus taeda, Pinus palustris*, and *Pinus echinata* (Harper 1943). However, this estimate is likely to have been low, since much *Pinus palustris* logging, turpentining and regeneration failure had already occurred prior to Harper's time (J.M. Varner pers. comm.). Today, montane *Pinus palustris* occurs mainly on ridgelines and south to southwesterly slopes (USFWS 2005), but was previously found on nearly all upland sites surveyed in Coosa County, Alabama (Reed 1905). In northwest Georgia, *Pinus palustris* occurs above 300 m (1000 feet) elevation, and it occurs up to nearly 600 m (2000 feet) in Talladega County, Alabama (Harper 1905).

Key Processes and Interactions: The dynamics of this system are strongly dominated by fire. The needles of *Pinus palustris* are an important fuel source for low-intensity fires. Fires probably once occurred at frequencies similar to those in the Coastal Plain but more frequently than in any other Piedmont ecological system. Evidence suggests fire frequencies of once every two to four years, with some annual fires (Bale 2009). Modern fire suppression has allowed *Pinus taeda* and *Quercus* spp. to increase in density, along with shrubs, and has resulted in the decrease in cover and diversity of the herb layer. Reproduction of *Pinus palustris* has been largely eliminated by the lack of fire, and the rooting of feral hogs (*Sus scrofa*). Where the canopy was also logged, *Pinus palustris* has often been completely eliminated, leaving the system indistinguishable from logged examples of ~Southern Piedmont Dry Oak-(Pine) Forest (CES202.339)$$. Because *Pinus palustris* and some of the canopy species naturally associated with it are fairly resilient to fire, and many have the ability to sprout, reintroduction of fire can return this system to its natural composition and structure, but this must be done gradually. Despite frequent fire, canopy dynamics were probably naturally dominated by gap-phase regeneration, with trees reproducing in small to medium-sized gaps created by wind storms and hot spots in fires. *Pinus palustris* is a long-lived tree, which continues to produce greater numbers of cones after age 100.

Threats/Stressors: Lack of fire is probably the biggest threat. Without fire, the development of a closed forest canopy can lead to declines in the native herbaceous ground cover vegetation, reducing their contribution to the surface fuels which are needed for frequent fires. Feral hogs (*Sus scrofa*) have been known as a threat to *Pinus palustris* seedlings for over a century (Reed 1905). Conversion of *Pinus palustris* sites via harvesting is another clear threat. Clearcut logging of *Pinus palustris* and subsequent succession to mesophytic hardwood forest and conversion to intensively managed *Pinus taeda* plantations are common at extant sites. Often when sites have been replanted with *Pinus taeda*, the sites are no longer burned for forest management.

Ecosystem Collapse Thresholds: These longleaf pine woodlands need to be burned often enough that herbaceous plant diversity is maintained and *Pinus palustris* regeneration occurs. This may be just as frequently as other *Pinus palustris* woodlands (Bale 2009), at least once every decade. Historic fire regimes of Alabama and Georgia montane *Pinus palustris* communities were estimated to be dominated by frequent surface fires, every one to five years, and on average, every three years (Klaus 2006, Bale 2009). Ecological collapse tends to result from long-term lack of fire, which leads to failure of *Pinus palustris* recruitment and the decline of the herbaceous ground cover of native grasses and forbs (especially composites and legumes). Ecological collapse can also result from the cutting of *Pinus palustris* without managing for its regeneration, or the increase of exotic plants such as *Imperata cylindrica, Lespedeza bicolor, Lespedeza cuneata*, or *Lonicera japonica* (Harper 1943).

Ecological collapse is characterized by the canopy dominated by trees other than *Pinus palustris*. Mesophytic hardwoods are dominant, with few *Pinus palustris* remaining, but site is suitable for *Pinus palustris*. *Pinus palustris* basal area <10 ft2/acre or hardwood. None of these old-growth characteristics are present: medium-sized canopy gaps, flat-topped *Pinus palustris* tree crowns, or snags. In stands with *Pinus echinata*, it is very sparse (<2% cover), but *Pinus echinata* trees may be even or uneven aged. A stand with both tall and dense midstory. Shrubs average >75% cover and average >2.1 m tall. Cover of invasive exotic plant species >10%, lichen or moss cover >5%. No *Andropogon ternarius, Danthonia spicata, Panicum virgatum, Piptochaetium avenaceum, Schizachyrium scoparium*, or *Sorghastrum nutans* is present. Site may be an old field or where intensive forestry site preparation was used in the past. There may be a significant amount of weedy plants, especially on more open sites. Depth of duff (Oe and Oa horizons) beneath canopy *Pinus palustris* trees is more than 10 cm (>4") deep. (NatureServe 2011).

CES202.332 Southern Appalachian Low-Elevation Pine Forest

CES202.332 CLASSIFICATION

Concept Summary: This ecological system consists of *Pinus echinata*- and *Pinus virginiana*-dominated forests in the lower elevation Southern Appalachians and adjacent Piedmont and Cumberland Plateau, extending into the Interior Low Plateau of Indiana, Kentucky and Tennessee. Examples can occur on a variety of topographic and landscape positions, including ridgetops, upper and midslopes, as well as lower elevations (generally below 700 m [2300 feet]) in the Southern Appalachians such as mountain valleys. Examples occur on a variety of acidic bedrock types. Frequent, low-intensity fires coupled with severe fires may have been the sole factor favoring the occurrence of this system instead of hardwood forests in the absence of fire. Under current conditions, stands are dominated by *Pinus echinata* or *Pinus virginiana*. *Pinus rigida* may sometimes be present. Hardwoods are sometimes abundant, especially dry-site oaks such as *Quercus falcata, Quercus montana*, and *Quercus coccinea*, but also *Carya glabra, Acer rubrum*, and others. The shrub layer may be well-developed, with *Gaylussacia baccata, Kalmia latifolia, Rhododendron minus, Vaccinium pallidum*, or other acid-tolerant species most characteristic. Herbs are usually sparse but may include *Pityopsis graminifolia* and *Tephrosia virginiana*.

- White Pine Forest (Schafale and Weakley 1990) **<**
- White Pine-Mixed Deciduous (DuMond 1970) **<**

Distribution: This system is found primarily in the Appalachian regions of Kentucky and the Southern Blue Ridge in northern Georgia, western North Carolina, southeastern Tennessee, the Cumberlands of Alabama, parts of the Interior Low Plateau (e.g., the Knobs Region of Kentucky and southern Indiana and the western Highland Rim of Tennessee), and southwestern Virginia. Any possible stands in the Piedmont would be found in the western foothills portions adjacent to the mountains.

CES202.332 CONCEPTUAL MODEL

Environment: This system occurs on ridgetops, upper and midslopes, in mountain valleys and the lower ranges. It is found on south- and southwest-facing slopes (Whittaker 1956). Bedrock may be a variety of types, but the system may be limited to acidic substrates. Fire is undoubtedly a very important and necessary influence.

Key Processes and Interactions: Fire is clearly an important influence on the dynamics of this ecological system, and frequent, low-intensity fires coupled with occasional severe fires (Harrod and White 1999, Fesenmyer and Christenson 2010) are thought to have been the primary factor leading to the occurrence of this system rather than hardwood forests on dry sites in the absence of fire. Fires probably were frequent and of low intensity, or a mix of low and higher intensity. Over many decades, accumulation of dead biomass can predispose these forests to catastrophic fire. However, even in the absence of fire, successional changes are normally restricted (possibly ending with oak domination) because most sites are infertile and dry (Murphy and Nowacki 1997). Fire probably is important for determining the dominance of pine species, the component of hardwoods, and the overall vegetation structure. *Pinus echinata* is fairly resilient to fire once mature, while *Pinus virginiana* individuals are fairly susceptible to fire but well-adapted to establishing in areas opened by intense fire.

Southern pine beetles (*Dendroctonus frontalis*) are an important disturbance and threat in this system, at least under present conditions and severe outbreaks can kill all the pines without creating the conditions for the pines to regenerate. Effects of logging and past clearing as well as lack of fire make understanding of this system's natural character and dynamics difficult. An extensive hardwood component may partly be the result of lack of fire. Some pine-dominated areas appear to be successional stands established in former hardwood forests after logging or cultivation, and would not be expected to have the same dynamics or ecosystem characteristics as natural pine forests maintained by fire. In natural pine forests, with adequate seed and seedlings, logging may allow pines to regenerate or, without adequate seedlings and with lack of fire may lead to a change in composition to hardwoods. This might also alter canopy composition as well as structure. In many cases, several prescribed fires or a combination of fire and thinning treatments will be necessary to restore these ecosystems (Elliott and Vose 2005).

Threats/Stressors: Southern pine beetles (*Dendroctonus frontalis*) are an important disturbance and threat in this system, especially to the *Pinus echinata* trees, at least under present conditions. Lack of fire has contributed to the loss of this ecological system. Without fire, the development of a closed forest canopy can lead to declines in the native herbaceous ground cover vegetation. Clearcut logging of *Pinus echinata* and forest succession by hardwood trees, *Pinus virginiana* and/or *Pinus taeda* are threats to the very limited extent of *Pinus echinata* forests. *Pinus echinata* woodlands have declined due to conversion to intensively managed pine plantations, especially on the Cumberland Plateau. Often sites have been replanted with *Pinus taeda*, and are then no longer burned for forest management.

Ecosystem Collapse Thresholds: Ecological collapse results from the long-term lack of fire, which leads to failure of *Pinus echinata* recruitment and the decline of the herbaceous ground cover of native grasses and forbs, including legumes (Elliott and Vose 2005, Elliott et al. 2011). Lack of fire can also contribute to the increase of invasive exotic plants, such as *Lonicera japonica* (Harper 1943). Southern pine beetles (*Dendroctonus frontalis*) can lead to ecological collapse, in situations where there is very high *Pinus echinata* mortality and low *Pinus echinata* regeneration, and the stand is replaced with hardwoods or *Pinus taeda*. The cutting of *Pinus echinata* without managing for its regeneration on the site can contribute to ecological collapse. The increase of *Kalmia latifolia* or encroachment by *Pinus strobus* also can contribute to ecological collapse.

CES203.241 Southern Atlantic Coastal Plain Dry and Dry-Mesic Oak Forest

CES203.241 CLASSIFICATION

Concept Summary: This system encompasses oak-dominated forests of somewhat fire-sheltered dry to dry-mesic sites in the Mid-Atlantic and South Atlantic coastal plains from southeastern Virginia to Georgia. Sites where this system occurs are somewhat protected from most natural fires by some combination of steeper topography, isolation from the spread of fire, and limited flammability of the vegetation. If fires were more frequent, the vegetation would likely be replaced by more fire-tolerant southern pines, especially *Pinus palustris*.

Distribution: This system ranges from southeastern Virginia (south of the James River) south to southeastern Georgia in the Atlantic Coastal Plain.
Nations: US
Concept Source: R. Evans and M. Schafale
Description Author: R. Evans, M. Schafale, M. Pyne

CES203.241 CONCEPTUAL MODEL

Environment: This system occurs in dry-mesic to dry but not xeric sites, generally on upper to midslopes in bluff systems, but occasionally it occurs on broader uplands or on the highest parts of non-flooded river terraces. Soils are generally acidic, though calcareous soils occur occasionally (as in ~Carya glabra - Tilia americana var. caroliniana - Acer barbatum / Trillium maculatum Forest (CEGL004747)$$). Soils are loamy to clayey and well-drained but not excessively drained. Similar sites with coarse sandy soils tend to support other ecological systems, in part due to the influence of more frequent fire. Sites are somewhat protected from most natural fires by steep topography and by limited flammability of the vegetation. Fires that penetrate them are generally low in intensity and have fairly limited ecological effect.

Key Processes and Interactions: Fire is intermediate in frequency in this system, being less frequent than in adjacent *Pinus palustris*-dominated stands, and more frequent than in mesic hardwood stands below. This fire regime is an important factor separating it from adjacent *Pinus palustris*-dominated systems. If fire does penetrate, it is likely to be low in intensity and have somewhat limited ecological effects. However, there is some evidence that this system has expanded into areas once occupied by *Pinus palustris* as fire has been suppressed (Ware et al. 1993). There may have been a shifting boundary between these systems, driven by variation in fire frequency. These forests probably generally naturally existed as old-growth forests, with canopy dynamics dominated by gap-phase regeneration. However, exposure to occasional fires and hurricanes may create more frequent and larger canopy disturbances than analogous systems inland.

Frequent surface fires occurred on a 5- to 10-year return interval from both lightning and Native American ignitions. These frequent light surface fires would have maintained a grassy understory and kept more fire-tolerant hardwoods and shrubs from capturing the understory and forming a midstory layer. Lightning fires occurred primarily during the spring dry season (April and May) with a secondary peak of Native American and settler burning during the fall (October and November) (Landfire 2007a). Occasionally, during extensive droughts, mixed-severity or stand-replacement fires did occur, especially in drier stand dominated of codominated by *Pinus echinata*.

Local blowdown winds associated with thunderstorms created gaps on a small but continual basis. More extensive regional disturbances included tropical storms during the growing season and ice storms during winter (in the northern part of the range). Dense stands of middle to older aged pines (where present) were susceptible to periodic mortality from bark beetle epidemics (Landfire 2007a).

Threats/Stressors: Conversion of this type has primarily resulted from removal of the characteristic dominant hardwoods (primarily *Quercus* species and *Carya* species) through logging, and the subsequent development of the sites to human uses. This is also the most critical anthropogenic threat. This may result in a stand dominated by wind-blown or bird-dispersed tree species, including Acer rubrum, Celtis spp., *Fraxinus americana, Juglans nigra, Juniperus virginiana, Liquidambar styraciflua, Liriodendron tulipifera, Prunus serotina, Robinia pseudoacacia, Sassafras albidum, Ulmus americana*, and the exotic *Ailanthus altissima*. These and other fire-intolerant species persist and increase in the absence of fire (Edwards et al. 2013). Logging which is not carefully done can lead to soil erosion, and then conversion to pine plantation or succession to *Pinus taeda, Liquidambar styraciflua, Acer rubrum* ruderal forest (Nordman 2013). Patches dominated by *Pinus taeda* and/or *Pinus echinata* are artifacts of past disturbance and succession in the absence of fire. These are likely to eventually succumb to drought, fire or insect damage. Another major threat is conversion to human-created land uses, including residential development, industrial development, and infrastructure development. Feral hog (*Sus scrofa*) activity can eradicate the native ground and shrub flora (Engeman et al. 2007). In addition, invasive exotic species, including *Ligustrum sinense, Lonicera japonica, Microstegium vimineum, Pueraria montana var. lobata, Rosa multiflora*, and others can become dominant in the ground and shrub layers following canopy disturbance and are threats to the natural species diversity of these habitats (Edwards et al. 2013). The most significant potential climate change effects over the next 50 years include periods of drought, which will affect the health and survival of the canopy trees.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species (particularly *Quercus* and *Carya*) to regenerate. Periods of drought will also affect the health and survival of the canopy trees. Tree health (and soil fertility) will suffer from the effects of ozone and acidic atmospheric deposition, leading to decline and death of the characteristic canopy species. Feral hog activity, combined with invasion of exotic species, can eradicate the native ground and shrub flora (Engeman et al. 2007, Edwards et al. 2013).

CES202.898 Southern Interior Low Plateau Dry-Mesic Oak Forest

CES202.898 CLASSIFICATION

Concept Summary: This system of upland hardwood-dominated forests occurs in the Interior Low Plateau region of the southeastern United States along ridgetops and slopes of various aspects. The system includes essentially all upland hardwood stands of the region except for mesic hardwood forests (which are accommodated by ~South-Central Interior Mesophytic Forest (CES202.887)$$). The floristic expression of different stands included in this system varies considerably with aspect and soil type. Included here are a variety of associations ranging along a moisture gradient from submesic to drier ones. The submesic to dry-mesic expressions tend to be found on midslopes with northerly to easterly aspects, and the drier ones on southerly to westerly aspects and on broad ridges. Parent material can range from calcareous to acidic with very shallow, well- to excessively well-drained soils in the drier expressions and moderately well-drained soils in the submesic to dry-mesic ones. The canopy closure of this system ranges from closed to somewhat open in the drier examples. Historically, these examples may have been more open under conditions of more frequent fire.

A number of different *Quercus* species may dominate stands of this system, with *Carya* species also prominent. In some drier examples on more acidic substrates, *Quercus montana* is typical over most of the range, reflecting relations with other Appalachian systems to the east. In addition, *Quercus stellata, Quercus marilandica*, and *Quercus coccinea* will also share dominance or be prominent in many of the drier examples. *Quercus muehlenbergii* and/or *Quercus shumardii* may appear in drier examples with high base status. *Quercus alba* may also be present but not typically dominant. In the submesic to dry-mesic examples, *Quercus alba* will typically exhibit dominance, possibly with *Quercus velutina* or *Quercus falcata*. The understories are typically shrub- and small tree-dominated, with the typical species varying with aspect, soil, and moisture relations.

CES202.339 Southern Piedmont Dry Oak-(Pine) Forest

CES202.339 CLASSIFICATION

Concept Summary: This system encompasses the prevailing upland forests of the southern Piedmont from Alabama north to central and southern Virginia. High-quality and historic examples are typically dominated by combinations of upland oaks, sometimes with pines as a significant component, especially in the southern portions of the region. These forests occur in a variety of habitats and, under natural conditions, were the matrix vegetation type covering most of the landscape. Much of this system is currently composed of successional forests that have arisen after repeated cutting, clearing, and cultivation of original oak-hickory and oak-hickory-pine forests. Stands of these forests are dominated by combinations of upland oaks, particularly *Quercus alba, Quercus rubra, Quercus velutina, Quercus stellata, Quercus coccinea*, and *Quercus falcata*, along with *Carya glabra, Carya tomentosa*, and other *Carya* spp. Other common tree species include *Pinus taeda, Pinus echinata, Pinus virginiana, Acer rubrum, Liquidambar styraciflua*, and *Liriodendron tulipifera*. There is considerable variation in this widespread matrix system. In particular, there are "dry-mesic" as well as "dry" components, as well as stands with codominance by *Pinus echinata*, and distinctive stands dominated by *Quercus montana* with other dry-site species on the summits of hills called monadnocks. There are particular associations that represent this variation.

Distribution: This system ranges throughout the Piedmont from Alabama to Virginia. In Virginia, it is primarily central and southern, but extends into a narrow portion of northern Virginia in the Piedmont ecoregion.
Nations: US
Concept Source: M. Schafale, R. Evans, M. Pyne
Description Author: M. Schafale, R. Evans, M. Pyne, S.C. Gawler

CES202.339 CONCEPTUAL MODEL

Environment: This system occurs on upland ridges and upper to midslopes, occupying most of the uplands. Moisture conditions, determined by topography, are dry to dry-mesic. This system may occur on soils derived from any kind of rock type, with rock chemistry being an important determinant of variation. Soils include almost the full range of upland soils, with only the shallowest rocky soils and those with extreme clay hardpans excluded.

The Piedmont has mostly gently rolling topography ranging from 90 to 365 m (300-1200 feet) elevation. Several erosion-resistant metamorphic and igneous rock types have been left as monadnocks that stand 60 to 305 m (200-1000 feet) above the surrounding landscape. Average annual precipitation is 110-122 cm (44-48 inches). The presettlement vegetation as described by early explorers and the first settlers was a mosaic of forest and open woodland, with interspersed savannas or prairies (Lederer 1672, Logan 1859). The prairie component was located on the flat to convex and gently rolling uplands of the larger fire compartments. The largest of these in the southern part of the range was up to five miles wide without a tree or only a few blackjack oaks (Logan 1859).

This ecological system encompasses the prevailing upland forests of the southern Piedmont. High-quality and historic examples are typically dominated by combinations of upland oaks, sometimes with pines as a significant component, especially in the southern portions of the region. These forests occur in a variety of habitats and, under natural conditions, were the matrix upland vegetation type covering most of the landscape.

The Piedmont Monadnock Forest (Schafale and Weakley 1990) is included within this broad type. Stands are dominated by *Quercus montana*, and occur mainly on resistant ridges (monadnocks) over felsic rocks of the Piedmont, including quartzite, rhyolite, and pyrophyllite. Soils are well-drained, acidic and nutrient-poor. Lightning strikes and high winds are common in these exposed locations (Schafale and Weakley 1990).

Key Processes and Interactions: In successional forests recovering from clearcutting or cultivation, *Pinus taeda, Pinus echinata*, and/or *Pinus virginiana* typically dominate for a number of decades, with *Quercus* spp., *Carya* spp., and other hardwoods gradually invading the understory.

Fire was probably an important natural disturbance in this system, affecting vegetation structure and composition of the lower strata. It may have been important in favoring oaks and pines over other trees. Fires were likely almost always low-intensity surface fires. Native American burning was also important in the Piedmont (Cowell 1998). These forests appear to occur naturally as predominantly old-growth, with canopy dynamics dominated by gap-phase regeneration. Small to medium-sized canopy gaps created by wind are the primary natural disturbance at present, and probably were in the past as well. Fire likely created some small to medium-sized gaps in the past also, and likely caused all canopy gaps to persist longer. The dominant tree species are capable of living for several centuries.

Fire and grazing are possibly the most important natural processes affecting the floristic composition and vegetation structure of this system (Landfire 2007a). The presence of frequent (2-5 years) surface fire is important in order to support the reproduction of *Pinus echinata* and the development of diverse herbaceous understories. *Pinus echinata* is a shade-intolerant species and does not compete and regenerate well when fire is absent. Where fire occurs at an appropriate frequency, the stand may develop a relatively pure canopy of *Pinus echinata*, typified by a very open woodland structure with scattered overstory trees and an herbaceous-dominated understory (Landfire 2007a).

The frequency of fire is variable across the landscape to create a mosaic of vegetation. However, most agree that the fire-return interval was relatively short. Fire may have been as frequent as every two to three years. Brewer (2001) compared the current tree species composition to bearing tree records in the upper coastal plain of northern Mississippi and found that *Pinus echinata* and more fire-tolerant species such as *Quercus velutina* and *Quercus stellata* were prevalent on the landscape, indicating a greater fire frequency. Without a short fire-return interval, community succession tends to favor upland mixed pine-xeric hardwood forests or hardwood-dominated forests. Landers (1989) inferred a fire-return interval of 10 times per century for pure stands of *Pinus echinata*.

Lightning fires occurred primarily during the spring dry season (April and May) with a second peak of Native American burning during the fall (October and November). Occasionally, during extensive droughts, mixed-severity or stand-replacement fires did occur, especially on drier pine-dominated sites. Local thunderstorms and outbreaks of southern pine beetle (*Dendroctonus frontalis*) created gaps on a small but continual basis. More extensive regional disturbances included tropical storms during the growing season, ice storms during winter, and tornadoes throughout the year (Landfire 2007a).

Threats/Stressors: Land clearing is a threat. This is mainly for development or conversion to plantation forestry, but in the past was primarily for farming. Successional forests (which include novel ecosystems) occur on formerly farmed sites. Many have lost significant topsoil when farmed, mostly prior to the 1930s. Most of the characteristic dominant hardwoods (primarily *Quercus* species and *Carya* species) are only moderately tolerant of shade. In recent years, more shade-tolerant species appear to be increasing in many of these forests, particularly *Acer rubrum* (McDonald et al. 2002). This may be a result of loss of regular fire in the system. Invasive exotic plant species such *Ligustrum sinense, Lonicera japonica*, and *Microstegium vimineum* will also increase under these conditions, and represent a threat. Loss of predators (bobcat, mountain lions, wolves) has led to increases in deer and rabbits, herbivores which have caused overbrowsing of herbaceous flora and decline of many plant species (Taverna et al. 2005). Fragmentation is also a threat, as it leads to an increase in white-tailed deer, an important browser on herbaceous plants.

Ecosystem Collapse Thresholds: Ecological collapse of this ecological system results from plowing, erosion, land clearing, lack of fire, extirpation of predators, fragmentation, and the introduction of intensive plantation forestry (on unplowed sites). After land clearing and soil disturbance (such as plowing), successional forests dominated by *Acer rubrum, Liquidambar styraciflua, Liriodendron tulipifera, Pinus echinata, Pinus taeda*, and *Pinus virginiana* may regenerate and prevent the regeneration of the characteristic *Quercus* and *Carya* spp.

CES203.378 West Gulf Coastal Plain Pine-Hardwood Forest

CES203.378 CLASSIFICATION

Concept Summary: This West Gulf Coastal Plain ecological system consists of forests and woodlands dominated by *Pinus taeda* and/or *Pinus echinata* in combination with a variety of dry to dry-mesic site hardwood species. This type was the historical matrix vegetation (dominant vegetation type) for large portions of the West Gulf Coastal Plain landward of the range of *Pinus palustris*, where it replaced *Pinus palustris*-dominated vegetation. In this region of southern Arkansas, northwestern Louisiana, and parts of eastern Texas, this type was historically present on nearly all uplands in the region except on the most edaphically limited sites (droughty sands, calcareous clays, and shallow soil barrens/rock outcrops). Such sites are underlain by loamy to fine-textured soils of variable depths. These are upland sites on ridgetops and adjacent sideslopes, with moderate fertility and moisture retention. This type was also present in more limited areas within the range of *Pinus palustris* (in the West Gulf Coastal Plain), where it was confined more typically to sideslopes and other locations not dominated by *Pinus palustris*. There are no known "fidel" herbaceous species or any local endemic or globally rare plant species, and overall this system may have supported relatively low levels of vascular plant species diversity. This system has undergone major transformations since European settlement of the region.

Concept Source: R. Evans and T. Foti

Description Author: R. Evans, T. Foti, M. Pyne and L. Elliott

CES203.378 CONCEPTUAL MODEL

Environment: In southern Arkansas, northwestern Louisiana, and parts of eastern Texas, this type was historically present on nearly all uplands in the region except on the most edaphically limited sites (droughty sands, calcareous clays, and shallow soil barrens/rock outcrops). Such sites are underlain by loamy to fine-textured soils of variable depths and generally are Alfisols or Ultisols. These are upland sites on ridgetops and adjacent sideslopes, with moderate fertility and moisture retention. In Texas, this system occurs over a wide variety of landforms, with drier expressions occurring on hilltops and ridges. It occupies slopes and lower landscape positions, where conditions are more mesic, and composition of the system varies across these gradients. It is found on numerous Cenozoic sedimentary formations and some Cretaceous formations of the Mesozoic era. These formations range from sandstone, shale, alluvium, and conglomerate, to marl, with glauconitic formations (Weches) and tuffaceous formations (Catahoula) present (Elliott 2011).

Key Processes and Interactions: Forests with dense tree cover (especially evergreen cover) have reduced shrub and herbaceous cover. Herbaceous cover may be additionally limited by dense litter accumulation. Few occurrences of this system can be considered old-growth.

Threats/Stressors:

Ecosystem Collapse Thresholds:

CES203.056 West Gulf Coastal Plain Sandhill Oak and Shortleaf Pine Forest and Woodland

CES203.056 CLASSIFICATION

Concept Summary: This ecological system occurs west of the Mississippi River primarily outside the natural range of longleaf pine (*Pinus palustris*) and less commonly within this range. Like other sandhill systems of the Gulf and Atlantic coastal plains, this type is found on uplands underlain with deep, coarse sandy soils. These sites are typified by low fertility and moisture retention, which contribute to open tree canopies with usually less than 60% canopy closure. Sparse understory vegetation and abundant patches of bare soil are indicative of this system. Vegetation indicators are species tolerant of droughty sites, especially *Quercus incana* and *Quercus arkansana*, but also *Quercus marilandica* and *Quercus stellata*. *Pinus echinata* is usually present, and *Pinus palustris* is absent (or perhaps at low frequency within its range). This system supports a large concentration of vascular plant endemics, near endemics, and a number of plant species with high fidelity to sandhills in the region. Elsewhere in the Atlantic and Gulf coastal plains, including most of the adjacent outer West Gulf Coastal Plain ecoregion, these site conditions are closely associated with longleaf pine.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne, L. Elliott and J. Teague

CES203.056 CONCEPTUAL MODEL

Environment: This system type is found on droughty uplands underlain with deep, coarse sandy soils. It is generally associated with Eocene sand formations such as Carrizo, Sparta, and Queen City sands, including the Betis, Darco, Letney, Tehran, Tonkawa, and other Grossarenic or Psammentic soil series. It is also found on sands derived from the Pliocene Willis formation (Elliott 2011). These sites are typified by low fertility and moisture retention. In particular, these are found on deep sands on generally high, convex landforms, and often display a relatively open overstory canopy.

Key Processes and Interactions: The primary natural processes controlling this system are droughty, deep sandy soils, and a natural fire regime. Fire is believed to have been a critical natural disturbance process which affected the vegetation structure and likely the species composition of communities in this system. There are several indirect pieces of evidence which suggest this: (1) *Pinus echinata* is intolerant of competition, and young stems are generally slower growing and slower to dominate sites than either *Pinus taeda* or many hardwood species (Lawson 1990); (2) *Pinus echinata* regeneration decreases dramatically with time since fire (Ferguson 1958); and (3) *Pinus echinata* has the ability to resprout. Watson (1986) postulates that most seedlings of *Pinus echinata* are killed during the periodic fires, and the mature trees are spared. This prevents the formation of thickets. This paper implies that low fuel levels accompany the sparse vegetation of these sandy areas, leading to a somewhat longer fire-return interval, which suits *Pinus echinata*. A variety of fire-return intervals have been estimated for *Pinus echinata* vegetation. Garren (1943) proposed an 8- to 10 -year return interval, Landers (1989) inferred a regime of 10 per century, and Martin and Smith (1993) estimated a 5- to 15 -year interval, however, none of these estimates were specific to *Pinus echinata* on sandhills. Many such sites in the region lack well - developed and continuous fine fuels necessary to ignite and spread fires, possibly due to site infertility and droughtiness (R. Evans pers. obs., L. Smith pers. comm.).

Threats/Stressors: The primary threat to this system is conversion to pine plantations or other agriculture (e.g., watermelon farms), increase in canopy closure due to alterations of the natural fire regime, and conversion developed land uses.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from fragmentation and long-term alteration of the natural fire regime, logging, conversion to forest plantations, and other land-use conversion. Collapse of the ecological system is characterized lack of *Pinus echinata* regeneration, decline of herbaceous ground cover of native grasses and forbs, a closed tree or shrub canopy, high cover of exotic plants, conversion to other land uses. Collapse is also characterized by the absence of the many animal and plant species of conservation concern that inhabit this system.

1.B.2.Nb. Rocky Mountain Forest & Woodland

M501. Central Rocky Mountain Dry Lower Montane-Foothill Forest

CES306.959 Middle Rocky Mountain Montane Douglas-fir Forest and Woodland

CES306.959 CLASSIFICATION

Concept Summary: This ecological system occurs throughout the middle Rocky Mountains of central and southern Idaho (Lemhi, Beaverhead and Lost River ranges), south and east into the greater Yellowstone region, and south and east into the Wind River, Gros Ventre and Bighorn ranges of Wyoming. It extends north into Montana on the east side of the Continental Divide, north to about the McDonald Pass area, and into the Rocky Mountain Front region of Montana. This is a *Pseudotsuga menziesii*-dominated system without the maritime floristic composition; these are forests and woodlands occurring in the Central Rockies where the southern monsoon influence is lessened and maritime climate regime is not important. This system includes extensive *Pseudotsuga menziesii* forests, occasionally with *Pinus flexilis* on calcareous substrates, and *Pinus contorta* at higher elevations. True firs, such as *Abies concolor, Abies grandis*, and *Abies lasiocarpa*, are absent in these occurrences, but *Picea engelmannii* can occur in some stands. Understory components include shrubs such as *Physocarpus malvaceus, Juniperus communis, Symphoricarpos oreophilus*, and *Mahonia repens*, and graminoids such as *Calamagrostis rubescens, Carex rossii*, and *Leucopoa kingii*. The fire regime is of mixed severity with moderate frequency. This system often occurs at the lower treeline immediately above valley grasslands, or sagebrush steppe and shrublands. Sometimes there may be a "bath-tub ring" of *Pinus ponderosa* at lower elevations or *Pinus flexilis* between the valley non-forested and the solid *Pseudotsuga menziesii* forest. In the Wyoming Basins, this system occurs as isolated stands of *Pseudotsuga menziesii*, with *Artemisia tridentata, Pseudoroegneria spicata, Leucopoa kingii*, and *Carex rossii*.

Description Author: M.S. Reid and K.A. Schulz

CES306.959 CONCEPTUAL MODEL

Environment: These are forests and woodlands occurring in the Central Rockies where the southern monsoon influence is lessened and maritime climate regime is not important. These *Pseudotsuga menziesii* forests occur under a comparatively drier and more continental climate regime, and at higher elevations than in the Pacific Northwest. Elevations range from less than 1000 m in the central Rocky Mountains to over 2400 m in the Wyoming Rockies. Lower-elevation stands typically occupy protected northern exposures or mesic ravines and canyons, often on steep slopes. At higher elevations, these forests occur primarily on southerly aspects or ridgetops and plateaus.

Annual precipitation ranges from 50-100 cm with moderate snowfall and a greater proportion falling during the growing season. Monsoonal summer rains can contribute a significant proportion of the annual precipitation in the southern portion of the range.

Soils are highly variable and derived from diverse parent materials. *Pseudotsuga menziesii* forests are reported by most studies (Pfister et al. 1977, Steele et al. 1983, Mauk and Henderson 1984) to show no particular affinities to geologic substrates. Rock types can include extrusive volcanics in the Yellowstone region, and sedimentary rocks elsewhere in the Rockies. The soils are typically slightly acidic (pH 5.0-6.0), well-drained, and well-aerated. They can be derived from moderately deep colluvium or shallow-jointed bedrock and are usually gravelly or rocky.

Key Processes and Interactions: Successional relationships in this group are complex. *Pseudotsuga menziesii* is less shade-tolerant than some montane trees such as *Abies concolor* or *Picea engelmannii*, and seedlings compete poorly in deep shade. At drier locales, seedlings may be favored by moderate shading, such as by a canopy of *Pinus flexilis*, which helps to minimize drought stress. In some locations, much of these forests have been logged or burned during European settlement, and present-day stands are second-growth forests dating from fire, logging, or other stand-replacing disturbances (Mauk and Henderson 1984). *Pseudotsuga menziesii* forests were probably subject to a moderate-severity fire regime in presettlement times, with fire-return intervals of 30-100 years. Many of the important tree species in these forests are fire-adapted (*Populus tremuloides, Pinus contorta*) (Pfister et al. 1977). Some stands may have higher tree-stem density than historically, due largely to fire suppression (Steele et al. 1983).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2111660). These are summarized as:

A) (10% of type in this stage) Tree cover is 0-100%. Dominated by graminoids and seedling/sapling Douglas-fir and possibly lodgepole pine. Understory may be dominated by *Calamagrostis rubescens* and/or *Carex* spp. Shrub species such as *Symphoricarpos* spp. may be present. Succession occurs in approximately 40 years, and the class moves to a mid-open state. Replacement fire occurs every 500 years, and mixed fire occurs every 200 years. If this class experiences no fire in 20 years, it will move to class B, a mid-closed state. Wind/weather events occur infrequently (probability of 0.001), but the class is maintained in this state.

B) Mid Development 1 Closed (tree-dominated - 10% of type in this stage): Tree cover is 41-100%. Relatively dense pole and some medium Douglas-fir and possibly lodgepole pine. The understory is open and relatively depauperate. Understory may be dominated by *Calamagrostis rubescens* and/or *Carex* spp. This class persists for 80 years, then moves to a late-closed stage. Replacement fire occurs every 200 years, and mixed fire every 50 years, causing a transition to a mid-open stage. Insect/disease outbreaks occur with a probability of 0.005 and can move the class to a mid-open state. Also, wind/weather stress causes a change to a mid-open state with a probability of 0.001. Although reviewers recommended removing insects/disease from this class, it was decided by Region 1 insect experts that some insect damage is likely for the class B forest types. The insects to be concerned about at low levels are Douglas-fir pole beetle and western spruce budworm.

C) Mid Development 1 Open (tree-dominated - 10% of type in this stage): Tree cover is 21-40%. Open pole and medium Douglas-fir that may have lodgepole pine with patchy graminoid cover and dispersed shrubs such as *Symphoricarpos* spp. Understory may be dominated by *Calamagrostis rubescens* and/or *Carex* spp. Conifer heights range between 5-20 m but adjusted to eliminate class overlap. This class can persist for 60 years, then moves to a late-open stage. Replacement fire occurs every 200 years, and mixed fire every 40 years. Without fire for 58 years, this class can move to a mid-closed state. Insect/disease outbreaks and wind/weather events occur with a probability of .005, and maintain this class in a mid-open state.

D) Late Development 1 Open (conifer-dominated - 50% of type in this stage): Tree cover is 21-40%. Open canopy of medium to large Douglas-fir with a graminoid and shrub understory with highly variable understory cover. Lodgepole pine may be present. Understory may be dominated by *Symphoricarpos* spp., *Calamagrostis rubescens*, and/or *Carex* spp. Heights can exceed 25 m up to approximately 30 m. Replacement fire occurs every 500 years, and mixed fire every 50 years. Without fire for 45 years, this class can move to a late-closed state. Insect disturbance occurs every 10 years but does not move this class to another class. Wind/weather stress also occurs, with a probability of 0.008, but does not cause a transition to another class.

E) Late Development 1 Closed (conifer-dominated - 20% of type in this stage): Tree cover is 41-100%. Multi-storied Douglas-fir, sometimes with lodgepole pine present. Understory with variable cover often dominated by *Calamagrostis rubescens, Carex* spp., *Symphoricarpos* spp., and/or *Physocarpus malvaceus*. Heights can exceed 25 m up to approximately 30 m. Replacement fire occurs every 200 years, and mixed fire every 30 years, causing a transition back to a late-open state. Insect outbreaks occur frequently, probability of 0.01, and cause a transition to an open state. Wind/weather stress occurs with a probability of 0.005 and causes a transition to a late-open state.

Fire regime is predominantly mixed-severity (Fire Regime III) with a MFI of approximately 20-50 years (Houston 1973, Arno and Gruell 1983, Fischer and Clayton 1983, Littell 2002, Korb et al. in prep.). Mixed-severity fires are generally characterized as spatially heterogeneous (LANDFIRE 2007a, BpS 2111660). Fire regime in more northern stands is predominantly mixed with a MFI of approximately 35-50 years (Crane and Fischer 1986, Bradley et al. 1992) (LANDFIRE 2007a, BpS 1911660).

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. Biological decomposition in ponderosa pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994, Graham and Jain 2005).

Threats/Stressors: Threats and stressors to this forest and woodland system include altered fire regime, altered stand structure from fragmentation due to roads, logging, mining, or other human disturbances. These disturbances can cause significant soil loss/erosion and negatively impact the water quality within the immediate watershed. Invasive exotic species can become abundant in disturbed areas and alter floristic composition. Direct and indirect effects of climate change may alter dynamics of indigenous insects such as Douglas-fir beetle (*Dendroctonus pseudotsugae*) causing a buildup in population size (with less extreme winters) leading to large outbreaks that can cause high mortality in mature trees.

CES306.805 Northern Rocky Mountain Dry-Mesic Montane Mixed Conifer Forest

CES306.805 CLASSIFICATION

Concept Summary: This ecological system is composed of highly variable montane coniferous forests found in the interior Pacific Northwest, from southernmost interior British Columbia, eastern Washington, eastern Oregon, northern Idaho, western and north-central Montana, and south along the east slope of the Cascades in Washington and Oregon. In central Montana it occurs on mountain islands (the Snowy Mountains). This system is associated with a submesic climate regime with annual precipitation ranging from 50 to 100 cm, with a maximum in winter or late spring. Winter snowpacks typically melt off in early spring at lower elevations. Elevations range from 460 to 1920 m. Most occurrences of this system are dominated by a mix of *Pseudotsuga menziesii* and *Pinus ponderosa* (but there can be one without the other) and other typically seral species, including *Pinus contorta, Pinus monticola* (not in central Montana), and *Larix occidentalis* (not in central Montana). *Picea engelmannii* (or *Picea glauca* or their hybrid) becomes increasingly common towards the eastern edge of the range. The nature of this forest system is a matrix of large patches dominated or codominated by one or combinations of the above species; *Abies grandis* (a fire-sensitive, shade-tolerant species not occurring in central Montana) has increased on many sites once dominated by *Pseudotsuga menziesii* and *Pinus ponderosa*, which were formerly maintained by low-severity wildfire. Presettlement fire regimes may have been characterized by frequent, low-intensity surface fires that maintained relatively open stands of a mix of fire-resistant species. Under present conditions the fire regime is mixed severity and more variable, with stand-replacing fires more common, and the forests are more homogeneous. With vigorous fire suppression, longer fire-return intervals are now the rule, and multi-layered stands of *Pseudotsuga menziesii, Pinus ponderosa*, and/or *Abies grandis* provide fuel "ladders," making these forests more susceptible to high-intensity, stand-replacing fires. They are very productive forests which have been priorities for timber production. They rarely form either upper or lower timberline forests. Understories are dominated by graminoids, such as *Pseudoroegneria spicata, Calamagrostis rubescens, Carex geyeri*, and *Carex rossii*, that may be associated with a variety of shrubs, such as *Acer glabrum, Juniperus communis, Physocarpus malvaceus, Symphoricarpos albus, Spiraea betulifolia*, or *Vaccinium membranaceum* on mesic sites. *Abies concolor* and *Abies grandis x concolor* hybrids in central Idaho (the Salmon Mountains) are included here but have very restricted range in this area. *Abies concolor* and *Abies grandis* in the Blue Mountains of Oregon are probably hybrids of the two and mostly *Abies grandis*.

CES306.805 CONCEPTUAL MODEL

Environment: This interior Pacific Northwest montane coniferous forest ecological system ranges from southernmost interior British Columbia, eastern Washington, and eastern Oregon across northern Idaho, western and north-central Montana extending east out on mountain islands (the Snowy Mountains) in the northwestern Great Plains and south along the east slope of the Cascades in Washington and Oregon. It has a submesic climate regime with annual precipitation ranging from 50 to 100 cm, with a maximum in winter or late spring. Winter snowpacks typically melt off in early spring at lower elevations. Stands are often dry in late summer when fire season begins. Elevations range from 460 to 1920 m. Substrates are variable, but it often occurs on shallow rocky soils.

Key Processes and Interactions: LANDFIRE developed several state-and-transition vegetation dynamics VDDT models for this system. Some mapzone teams created multiple models for different dominant trees. Below is a model with five classes from mountains of eastern Oregon (LANDFIRE 2007a, BpS 0910450). These are summarized as:

A) Early Development 1 All Structures (10% of type in this stage): Tree cover is 0-20%. Open stand of ponderosa pine and other tree seedlings mixed with grasses and shrubs. Early-seral dominant species include ceanothus, scouler willow, *Bromus*, some sedges and grasses. We use Comp/Maintenance to hold a portion of this class back in an extended shrub-dominated stage. Also, we use AltSucc. without TSD to allow a portion of this type to succeed to class B - mid-closed.

B) Mid Development 1 Closed (tree-dominated - 5% of type in this stage): Tree cover is 41-100%. Closed stands of 5-20 inches dbh early-seral tree species. Forests in this type rarely if ever exceed 80% canopy closure even in closed, dense conditions.

C) Mid Development 1 Open (tree-dominated - 30% of type in this stage): Tree cover is 11-40%. Open stands of 5-20 inches dbh early-seral tree species. Dominant understory plants include elk sedge, pinegrass, common snowberry, rose, mountain-mahogany (wetter), heartleaf arnica and lupines. This class has low probability of replacement fire due to discontinuous fuel in these open stands. A small portion of the class succeeds to class E - late-closed.

D) Late Development 1 Open (conifer-dominated - 45% of type in this stage): Tree cover is 11-40%. Open stands of 20+ inches dbh early-seral tree species. Dominant understory plants include elk sedge, pinegrass, common snowberry, rose, mountain-mahogany (wetter), heartleaf arnica and lupines.

E) Late Development 1 Closed (conifer-dominated - 10% of type in this stage): Tree cover is 41-100%. Closed stands of 20+ inches dbh early-seral tree tree species. Forests in this PNVG rarely if ever exceed 80% canopy closure even in closed, dense conditions. This class has relatively high probability of replacement fires, due to the dense understory, though it is less than the probability of replacement fire in the mid-closed.

Typical disturbance regimes under natural conditions include frequent, low-intensity underburns that maintain open stands of fire-resistant trees. Much more infrequent mixed-severity and stand-replacement wildfire occurred and tended to generate mosaics of older, larger trees and younger regeneration. Endemic bark beetles produced patch mortality. Rarer epidemic bark beetle outbreaks caused larger-scale overstory mortality and released understory trees. Defoliator outbreaks also caused fir mortality in some areas. Defoliation by spruce budworm is now more widespread than historically. Root diseases may play a significant role in later-seral forests in this environment (LANDFIRE 2007a, BpS 0910450).

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. Biological decomposition in ponderosa pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994, Graham and Jain 2005).

Threats/Stressors: Threats and stressors to this forest and woodland system include altered fire regime, altered stand structure from fragmentation due to roads, logging, mining, or other human disturbances. These disturbances can cause significant soil loss/erosion and negatively impact the water quality within the immediate watershed. Invasive exotic species can become abundant in disturbed areas and alter floristic composition. Direct and indirect effects of climate change may alter dynamics of indigenous insects such as Douglas-fir beetle (*Dendroctonus pseudotsugae*) or mountain pine beetle (*Dendroctonus ponderosae*) causing a buildup in population size (with less extreme winters) leading to large outbreaks that can cause high mortality in mature trees.

CES306.958 Northern Rocky Mountain Foothill Conifer Wooded Steppe

CES306.958 CLASSIFICATION

Concept Summary: This inland Pacific Northwest ecological system occurs in the foothills of the northern Rocky Mountains in the Columbia Plateau region and west along the foothills of the Modoc Plateau and eastern Cascades into southern interior British Columbia. It also occurs east across Idaho into the eastern foothills of the Montana Rockies. The system may also occur on the lower treeline slopes of the Wyoming Rockies. These wooded steppes occur at the lower treeline/ecotone between grasslands or shrublands and forests and woodlands, typically on warm, dry, exposed sites too droughty to support a closed tree canopy. This is not a fire-maintained system. The "savanna" character results from a climate-edaphic interaction that results in widely scattered trees over shrubs or grasses, and even in the absence of fire, a "woodland" or "forest" structure will not be obtained. Elevations range from less than 500 m in British Columbia to 1600 m in the central Idaho mountains. Occurrences are found on all slopes and aspects; however, moderately steep to very steep slopes or ridgetops are most common. This system can occur in association with cliff and canyon systems. It generally occurs on glacial till, glacio-fluvial sand and gravel, dune, basaltic rubble, colluvium, to deep loess or volcanic ash-derived soils, with characteristic features of good aeration and drainage, coarse textures, circumneutral to slightly acidic pH, an abundance of mineral material, rockiness, and periods of drought during the growing season. These can also occur on areas of sand dunes, scablands, and pumice where the edaphic conditions limit tree abundance. *Pinus ponderosa* (*var. ponderosa* and *var. scopulorum*) and *Pseudotsuga menziesii* are the predominant conifers (not always together); *Pinus flexilis* may be present or common in the tree canopy. In interior British Columbia, *Pseudotsuga menziesii* is the characteristic canopy dominant. In transition areas with big sagebrush steppe systems, *Purshia tridentata, Artemisia tridentata ssp. wyomingensis, Artemisia tridentata ssp. tridentata*, and *Artemisia tripartita* may be common in fire-protected sites such as rocky areas. Deciduous shrubs, such as *Physocarpus malvaceus, Symphoricarpos albus*, or *Spiraea betulifolia*, can be abundant in more northerly sites or more moist climates. Important grass species include *Pseudoroegneria spicata, Poa secunda, Hesperostipa* spp., *Achnatherum* spp., and *Elymus elymoides*.

- Ponderosa Pine - Grassland (110) (Shiflet 1994) **><**
- Ponderosa Pine - Shrubland (109) (Shiflet 1994) **><**

Distribution: This system is found in the Fraser River drainage of southern British Columbia south along the Cascades into the Modoc Plateau of California, and the northern Rocky Mountains of Washington and Oregon. In the northeastern part of its range, it extends across the northern Rocky Mountains west of the Continental Divide into northwestern Montana and south to the Snake River Plain in Idaho. In Oregon, it is most common in south-central Oregon, in lands managed by the Lakeview District of the BLM, and by the adjacent Fremont and Deschutes national forests. It also occurs on the marginal lands coming south out of the Blue Mountains, on the edge of the northern Basin and Range.

Nations: CA, US

Description Author: M.S. Reid, R. Crawford and K.A. Schulz

CES306.958 CONCEPTUAL MODEL

Environment: These wooded steppes occur at the lower treeline/ecotone between grasslands or shrublands and forests and woodlands, typically on warm, dry, exposed sites too droughty to support a closed tree canopy. The "savanna" character results from a climate-edaphic interaction that results in widely scattered trees over shrubs or grasses, and even in the absence of fire, a "woodland" or "forest" structure will not be obtained. Elevations range from less than 500 m in British Columbia to 1600 m in the central Idaho mountains. Occurrences are found on all slopes and aspects; however, moderately steep to very steep slopes or ridgetops are most common. This system can occur in association with cliff and canyon systems. It generally occurs on glacial till, glacio-fluvial sand and gravel, dune, basaltic rubble, colluvium, to deep loess or volcanic ash-derived soils, with characteristic features of good aeration and drainage, coarse textures, circumneutral to slightly acidic pH, an abundance of mineral material, rockiness, and periods of drought during the growing season. These can also occur on areas of sand dunes, scablands, and pumice where the edaphic conditions limit tree abundance.

Key Processes and Interactions: This is not a fire-maintained system. Periodic drought that limits tree establishment is the driving factor in this system. The concept is that of the climate-edaphic interaction that results in widely scattered trees over "shrub-steppe" of sage, bitterbrush, or sparsely distributed grasses. Tree growth is likely episodic, with regeneration episodes in years with available moisture. Tree density is limited in some areas by available growing space due to rocky conditions of the site. The tree canopy in this system will never reach woodland density or close due to the interaction of climate and edaphic factors, even in the absence of fire. This system burns occasionally, but the vegetation is sparse enough that fires are typically not carried through the stand. Fire frequency is speculated to be 30-50 years. This type usually has little surface fuel and replacement fires would be a function of extreme conditions, such as very high winds (LANDFIRE 2007a). Western pine beetle is a significant disturbance and especially affects larger trees, while parasitic mistletoe can cause tree mortality in young and small trees.

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has four classes in total (LANDFIRE 2007a, BpS 0911650). These are summarized with some modifications below:

A) Early Development 1 All Structures (10% of type in this stage): Dominated by bunchgrasses, mountain sagebrush and seed/sapling-sized Douglas-fir. Limber pine and ponderosa pine may be present in varying amounts.

B) Mid Development 1 Closed (tree-dominated - 2% of type in this stage): Tree cover is 31-100%. Relatively dense pole- and/or large-sized Douglas-fir. Limber pine and ponderosa pine may be present in varying amounts. Sagebrush has largely dropped out of the stand. Mixed-severity fire may open up the canopy; however, vegetation is generally too sparse to carry fire through stand and is more affected by drought.

C) Mid Development 1 Open (tree-dominated - 8% of type in this stage): Tree cover is 0-30%. Open poles of Douglas-fir with bunchgrass and sagebrush understory. Limber pine and ponderosa pine may be present in varying amounts. Surface fires may help maintain the open condition; however, vegetation is generally too sparse to carry fire through stand and is more affected by drought.

D) Late Development 1 Open (conifer-dominated - 80% of type in this stage): Tree cover is 0-30%. Widely spaced, open canopy of medium- to large-diameter Douglas-fir with bunchgrass and sagebrush understory. Canopy fuels are discontinuous. Limber pine and ponderosa pine may be present in varying amounts. Surface fires may help maintain the open condition; however, vegetation is generally too sparse to carry fire through stand except under extreme conditions.

LANDFIRE modeled fire regime as predominantly (70%) frequent, low-severity fires with an MFI of approximately 30 years. Mixed-severity fires occur with a typical frequency of 30-50 years primarily in dense stands (classes B and E). Native American burning may have occurred in many of these low-elevation forests. Limber pine may be affected by blister rust (LANDFIRE 2007a, BpS 0911650). However, this system generally has low surface fuels and is too sparse to carry fire through stand except under extreme conditions so fires are patchy.

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. Biological decomposition in ponderosa pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994, Graham and Jain 2005).

Threats/Stressors: This is not a heavily converted system, although some stands have been converted by various development activities, including suburban or rural expansion and road building. From WNHP (2011): The primary land uses that alter the natural processes of this system are associated with livestock practices, tree removal, exotic species, fire regime alteration, direct soil surface disturbance, and fragmentation. Excessive grazing disturbs the soil, opening the perennial herbaceous layers to the establishment of native disturbance-increasers and exotic annual grasses. Persistent grazing will further diminish perennial cover, expose bare ground, and increase exotic annuals. Any soil and bunchgrass layer disturbances, such as vehicle tracks or chaining of shrubs, will increase the probability of alteration of vegetation structure and composition and response to fire. Harvesting of tree species alters the structural characteristics of this system and, given the harsh environment, reestablishment of the trees typically occurs very slowly. Fire suppression has resulted in increased tree regeneration and thus a denser understory with young trees. Road development has fragmented many occurrences creating firebreaks.

In the Pacific Northwest, regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation, averaged over all models, are small (+1 to +2%), and some models project wetter autumns and winters and drier summers. Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. This change will result in: less winter snow accumulation, higher winter streamflows, earlier spring snowmelt, earlier peak spring streamflow and lower summer streamflows in rivers that depend on snowmelt (as do most rivers in the Pacific Northwest) (Littell et al. 2009). Potential climate change effects could include: reduction in freshwater inflows through the further reduction in summer flows (Littell et al. 2009); but models also predict increases in extreme high precipitation over the next half-century, particularly around Puget Sound (Littell et al. 2009), which may provide freshwater pulses that are intermittent, less predictable; drop in groundwater table; increased fire frequency due to warmer temperatures resulting in drier fuels, the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009); and additionally, likely climatic warming may stress host trees so mountain pine beetle outbreaks are projected to increase in frequency and cause increased tree mortality.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from a severe departure from historic fire regime, fire suppression is evident, fuel laddering is severe and throughout much of stand; the occurrence is embedded in <10% natural habitat; occurrences are small in size (less than 50 ha) and surrounded by non-natural land uses; exotic plant species have >10% absolute cover, and native plants have <50% cover, with native bunchgrasses <25%; indicator or diagnostic species are absent, remaining native species are weedy; many, if not all, old (>150 years) *Pinus ponderosa* have been harvested and remaining trees are of a single age class and younger than 100 years; connectivity between stands has been eliminated or reduced due to intervening areas of human land uses (WNHP 2011).

Environmental Degradation (from WNHP 2011): High-severity environmental degradation appears where occurrence is less than 10 ha in size; the occurrence is no longer in a native land cover landscape, <10% natural or semi-natural habitat in surroundings; there is severe departure from the historic fire regime (FRCC = 3); fire suppression is evident; fuel laddering is severe and throughout much of stand. Moderate-severity appears where occurrence is 10-100 ha in size; embedded in 10-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2); evidence of at least one low- to moderate-severity fire since 1900 (Euro-American settlement period); fuel laddering may be present in these areas.

Disruption of Biotic Processes (from WNHP 2011): High-severity disruption of biotic processes appears where greater than 10% absolute cover of exotic invasives; non-native species dominate understory with minor native component (native species relative cover in shrub and herb layers <50%); native increasers (indicative of grazing or soil disturbance) have >20% relative cover; most (over 75%) old trees (>150 years) have been harvested; <25% of area with widely-spaced, large, old trees with herbaceous or shrub understory. OR >50% of stands with old trees have a continuous cohort of regenerating pine in the understory; most or all indicator/diagnostic species are absent; native species consist mostly of weedy species; occurrences are fragmented, connectivity is essentially gone; exotic and native pathogens are significantly effecting forest structure, beyond natural range of variation. Moderate-severity appears where exotic invasives prevalent with 3-10% absolute cover; native species have 50 to <85% relative cover; native increasers (indicative of grazing or soil disturbance) have 10-20% relative cover; non-natives can be codominant; many (over 50%) of the old trees (>150 years), may have been harvested; 25-50% of area with widely-spaced, large, old trees with herbaceous or shrub understory. OR 25-50% of stands with old trees have a continuous cohort of regenerating pine in the understory; native species characteristic of the type remain present but weedy (pioneer, early-successional) native species that develop after clearcutting or clearing are dominant; many indicator/diagnostic species may be absent; exotic and native pathogens are significantly effecting forest structure, beyond natural range of variation.

CES306.030 Northern Rocky Mountain Ponderosa Pine Woodland and Savanna

CES306.030 CLASSIFICATION

Concept Summary: This inland Pacific Northwest ecological system occurs in the foothills of the northern Rocky Mountains in the Columbia Plateau region and west along the foothills of the Modoc Plateau and eastern Cascades into southern interior British Columbia. These woodlands and savannas occur at the lower treeline/ecotone between grasslands or shrublands and more mesic coniferous forests typically in warm, dry, exposed sites. Elevations range from less than 500 m in British Columbia to 1600 m in the central Idaho mountains. Occurrences are found on all slopes and aspects; however, moderately steep to very steep slopes or ridgetops are most common. This ecological system generally occurs on glacial till, glacio-fluvial sand and gravel, dune, basaltic rubble, colluvium, to deep loess or volcanic ash-derived soils, with characteristic features of good aeration and drainage, coarse textures, circumneutral to slightly acidic pH, an abundance of mineral material, rockiness, and periods of drought during the growing season. In the Oregon "pumice zone" this system occurs as matrix-forming, extensive woodlands on rolling pumice plateaus and other volcanic deposits. These woodlands in the eastern Cascades, Okanagan and northern Rockies regions receive winter and spring rains, and thus have a greater spring "green-up" than the drier woodlands in the central Rockies. *Pinus ponderosa* (primarily *var. ponderosa*) is the predominant conifer; *Pseudotsuga menziesii* may be present in the tree canopy but is usually absent. In southern interior British Columbia, *Pseudotsuga menziesii* or *Pinus flexilis* may form woodlands or fire-maintained savannas with and without *Pinus ponderosa var. ponderosa* at the lower treeline transition into grassland or shrub-steppe. The understory can be shrubby, with *Artemisia tridentata, Arctostaphylos patula, Arctostaphylos uva-ursi, Cercocarpus ledifolius, Physocarpus malvaceus, Purshia tridentata, Symphoricarpos oreophilus* or *Symphoricarpos albus, Prunus virginiana, Amelanchier alnifolia*, and *Rosa* spp. common species. Understory vegetation in the true savanna occurrences is predominantly fire-resistant grasses and forbs that resprout following surface fires; shrubs, understory trees and downed logs are uncommon. These more open stands support grasses such as *Pseudoroegneria spicata, Hesperostipa* spp., *Achnatherum* spp., dry *Carex* species (*Carex inops*), *Festuca idahoensis*, or *Festuca campestris*. The more mesic portions of this system may include *Calamagrostis rubescens* or *Carex geyeri*, species more typical of ~Northern Rocky Mountain Dry-Mesic Montane Mixed Conifer Forest (CES306.805)$$. Mixed fire regimes and surface fires of variable return intervals maintain these woodlands typically with a shrub-dominated or patchy shrub layer, depending on climate, degree of soil development, and understory density. This includes the northern race of Interior Ponderosa Pine old-growth (USFS Region 6, USFS Region 1). Historically, many of these woodlands and savannas lacked the shrub component resulting from 3- to 7-year fire-return intervals.

Related Concepts:
- Interior Ponderosa Pine: 237 (Eyre 1980) **>**
- Ponderosa Pine - Grassland (110) (Shiflet 1994) **><**
- Ponderosa Pine - Shrubland (109) (Shiflet 1994) **><**

Distribution: This system is found in the Fraser River drainage of southern British Columbia south along the Cascades and northern Rocky Mountains of Washington, Oregon and California. In the northeastern part of its range, it extends across the northern Rocky Mountains west of the Continental Divide into northwestern Montana, south to the Snake River Plain in Idaho, and east into the foothills of western Montana.

Nations: CA, US

Concept Source: NatureServe Western Ecology Team

Description Author: M.S. Reid, C. Chappell, R. Crawford, K.A. Schulz

CES306.030 CONCEPTUAL MODEL

Environment: This ecological system within the region occurs at the lower treeline/ecotone between grasslands or shrublands and more mesic coniferous forests typically in warm, dry, exposed sites at elevations ranging from 500-1600 m (1600-5248 feet). These woodlands receive winter and spring rains, and thus have a greater spring "green-up" than the drier ponderosa woodlands in the Colorado and New Mexico Rockies. In eastern Washington, precipitation varies from 36-76 cm (~14-30 inches) with most occurring as snowfall (WNHP 2011). It can occur on all slopes and aspects; however, it commonly occurs on moderately steep to very steep slopes or ridgetops. This ecological system generally occurs on most geological substrates from weathered rock to glacial deposits to eolian deposits (e.g., glacial till, glacio-fluvial sand and gravel, dunes, basaltic rubble, colluvium, to deep loess or volcanic ash-derived soils) (WNHP 2011). Characteristic soil features include good aeration and drainage, coarse textures, circumneutral to slightly acidic pH, an abundance of mineral material, and periods of drought during the growing season. Some occurrences may occur as edaphic climax communities on very skeletal, infertile and/or excessively drained soils, such as pumice, cinder or lava fields, and scree slopes. In the Oregon "pumice zone" this system occurs as matrix-forming, extensive woodlands on rolling pumice plateaus and other volcanic deposits. Surface textures are highly variable in this ecological system ranging from sand to loam and silt loam. Exposed rock and bare soil consistently occur to some degree in all the associations.

Key Processes and Interactions: Summer drought and frequent, low-severity fires create woodlands composed of widely spaced, large trees with small scattered clumps of dense, even-aged stands which regenerated in forest gaps or were protected from fire due to higher soil moisture or topographic protection. Closed-canopy or dense stands were also part of the historical range of stand variability but under natural disturbance regimes are a minor component of that landscape. Mixed fire regimes and surface fires of variable return intervals maintain these woodlands typically with a shrub-dominated or patchy shrub layer, depending on climate, degree of soil development, and understory density. Historically, many of these woodlands and savannas lacked the shrub component resulting from low-severity but high-frequency fires (2 - to 10-year fire-return intervals). Some sites, because of low productivity, naturally lacked a dense shrub understory. Mixed-severity fires had a return interval of 25-75 years while stand-replacing fire occurred at an interval of >100 years (Arno 1980, Fischer and Bradley 1987). The latter two intervals only occurred on 20-25% of stands within the landscape while surface fires were the dominant fire regime on over 75% of stands (Landfire 2007a). Presettlement fires were triggered by lightning strikes or deliberately set fires by Native Americans.

Pinus ponderosa is a drought-resistant, shade-intolerant conifer which usually occurs at lower treeline in the major ranges of the western United States. Establishment of ponderosa pine is erratic and believed to be linked to periods of adequate soil moisture and good seed crops as well as fire frequencies, which allow seedlings to reach sapling size.

Western pine beetle is another significant disturbance and especially affects larger trees. Bark beetle outbreaks are highly related to stand density. Denser stands in relation to site capacity will favor outbreaks, which will decrease as trees are thinned (Landfire 2007a). Mistletoe can cause tree mortality in young and small trees. Fires and insect outbreaks resulted in a landscape consisting of a mosaic of open forests of large trees (most abundant patch), small denser patches of trees, and openings (Franklin et al. 2008). White-headed woodpecker, pygmy nuthatch, and flammulated owl are indicators of healthy ponderosa pine woodlands. All these birds prefer mature trees in an open woodland setting (Jones 1998, Levad 1998 Winn 1998, as cited in Rondeau 2001).

LANDFIRE developed several state-and-transition vegetation dynamics VDDT models for this system across its range and dry or mesic conditions. This model is typical of much of the range and has five classes in total (LANDFIRE 2007a, BpS 1910530). These are summarized as:

A) Early Development 1 Open (5% of type in this stage): Fire-maintained grass/forb and/or seedlings and saplings. Seedling/sapling size class would be less than 5 inches in diameter. There would be no large patches (10-100 acres) of large or old-growth trees due to poor site conditions and abundance of rock outcroppings. However, dispersed large-diameter fire-remnant ponderosa pines and snag trees could be present. These large-diameter trees would have a density of less than one tree per acre. Grass species are the dominant lifeform in this class attaining maximum heights of 3 feet and patchy in distribution (25-75% cover).

B) Mid Development 1 Closed (tree-dominated - 10% of type in this stage): Tree cover is 41-60%. Closed ponderosa pine pole and medium-diameter stand; may have Douglas-fir as incidentals. Larger, old-growth trees may be present in this class, though the pole and medium-diameter class (5-21 inches) occurring between these large trees is most abundant and characteristic of this class. May see large-diameter snags, dead and downed trees present. High-density stunted pole stands are counted here; may see insect/disease here.

C) Mid Development 1 Open (tree-dominated - 20% of type in this stage): Tree cover is 0-40%. Open ponderosa pine pole and medium-diameter stand that may have Douglas-fir as incidentals. Larger, old-growth trees may be present in this class, the pole and medium-diameter (5-21 inches) trees are characteristic for this class. These patches have probably had recent fire or are drier so they retain a more open condition.

D) Late Development 1 Open (conifer-dominated - 55% of type in this stage): Tree cover is 0-40%. Fire-maintained open, park-like ponderosa pine; nearly any fire maintains; Douglas-fir may be seen as incidentals or in patches, but not a major component of the overstory. The overstory is characterized by large and very large ponderosa pine and isolated Douglas-fir. Understory is dominated by grasses and is relatively open. Seedlings are very infrequent, with <10% cover and usually occurring in patches.

E) Late Development 1 Close (conifer-dominated - 5% of type in this stage): Tree cover is 41-60%. High-density, multi-storied ponderosa pine stand; Douglas-fir regeneration on some sites. Thickets of various size classes distributed within the class and may be interspersed with large snags.

Frequent, non-lethal surface fires were the dominant disturbance factor, occurring every 3-30 years (Arno 1980, Arno and Petersen 1983, Fischer and Bradley 1987). Three-year fire-return intervals are likely very localized and associated with Native American burning. However, there is some disagreement as to the extent of Native burning. More median fire-return intervals were likely about 15 years. Mixed-severity fires likely occurred about every 50 years, again, depending on the vegetative state. Stand-replacement fires likely occurred in stands and small patches on the order of a few hundred acres every 300-700 years depending on the vegetative state. Some authors note that little information is available regarding the exact nature of stand-replacement fire severity in this BpS (LANDFIRE 2007a, BpS 1910530). Western pine beetle can attack large ponderosa pine in any canopy density (LANDFIRE 2007a, BpS 1910530).

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. However, biological decomposition in ponderosa pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994, Graham and Jain 2005).

Threats/Stressors: Conversion of this type has commonly come from rural and urban development. Since European settlement, fire suppression, timber harvest, livestock grazing, introduced diseases, road building, development, and plantation establishments have all impacted natural disturbance regimes, forest structure, composition, landscape patch diversity, and tree regeneration (Franklin et al. 2008). Timber harvesting has focused on the large, older trees in mid- and late-seral forests thereby eliminating many old forest attributes from stands (Franklin et al. 2008). Overgrazing may have contributed to the contemporary dense stands by eliminating grasses in some areas thereby creating suitable spots for tree regeneration as well as reducing the abundance and distribution of flashy fuels that are important for carrying surface fires (Hessburg et al. 2005, Franklin et al. 2008). Road development has fragmented many forests creating firebreaks. With settlement and subsequent fire suppression, occurrences have become denser. Presently, many occurrences contain understories of more shade-tolerant species, such as *Pseudotsuga menziesii* and/or *Abies* spp., as well as younger cohorts of *Pinus ponderosa*. These altered occurrence structures have affected fuel loads and alter fire regimes. With fire suppression and increased fuel loads, fire regimes are now less frequent and often become intense crown fires, which can kill mature *Pinus ponderosa* (Reid et al. 1999). Longer fire-return intervals have resulted in many occurrences having dense subcanopies of overstocked and unhealthy young *Pinus ponderosa* (Reid et al. 1999). With vigorous fire suppression, longer fire-return intervals are now the rule, and multi-layered stands of *Pinus ponderosa* and/or *Pseudotsuga menziesii* provide fuel "ladders," making these forests more susceptible to high-intensity, stand-replacing fires. The resultant stands at all seral stages tend to lack snags, have high tree density, and are composed of smaller and more shade-tolerant trees (WNHP 2011). Mid-seral forest structure is currently 70% more abundant than in historical, native systems, and late-seral forests of shade-intolerant species are now essentially absent (WNHP 2011). Early-seral forest abundance is similar to that found historically but lacks snags and other legacy features.

In the Pacific Northwest, regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation, averaged over all models, are small (+1 to +2%), and some models project wetter autumns and winters and drier summers. Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. This change will result in: less winter snow accumulation, higher winter streamflows, earlier spring snowmelt, earlier peak spring streamflow and lower summer streamflows in rivers that depend on snowmelt (as do most rivers in the Pacific Northwest) (Littell et al. 2009). Potential climate change effects could include: reduction in freshwater inflows through the further reduction in summer flows (Littell et al. 2009); drop in groundwater table; increased fire frequency due to warmer temperatures resulting in drier fuels, the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009); and additionally, likely warming may stress host trees so mountain pine beetle outbreaks are projected to increase in frequency and cause increased tree mortality.

The ways in which the climate in the region where this system reaches its eastern limit is likely to change, and the effects of those changes on the structure and function of this system are all hard to predict, and only broad generalizations can be made (Rice et al. 2012). Average annual temperature likely will increase by 1.7°C by 2050 and by 1.1° to 5.5°C by the end of this century. Annual precipitation may increase by 10%, with wetter winters and drier summers, but less certainty can be assigned to possible precipitation changes than temperature changes. Climate changes will also affect the ecological system indirectly, through bark beetle populations and other ecological agents. Changes in the extremes of temperature and precipitation likely will have a stronger effect than will changes in annual averages, and the patterns of these extremes are especially hard to predict. Climate changes almost certainly will disrupt the composition, structure, and function of this ecological system, in ways that can only be very generally anticipated.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from a severe departure from historic fire regime, fire suppression is evident, fuel laddering is severe and throughout much of stand; the occurrence is embedded in <10% natural habitat; occurrences are small in size (less than 50 ha) and surrounded by non-natural land uses; exotic plant species have >10% absolute cover, and native plants have <50% cover, with native bunchgrasses <25%; indicator or diagnostic species are absent, remaining native species are weedy; many, if not all, old (>150 years) *Pinus ponderosa* have been harvested and remaining trees are of a single age class and younger than 100 years; connectivity between stands has been eliminated or reduced due to intervening areas of human land uses (WNHP 2011).

Environmental Degradation (from WNHP 2011): High-severity environmental degradation appears where occurrence is less than 50 ha in size; the occurrence is no longer in a native land cover landscape, <10% natural or semi-natural habitat in surroundings; fire is no longer occurring, there is severe departure from the historic regime (FRCC = 3); fire suppression is evident; fuel laddering is severe and throughout much of stand. Moderate-severity appears where occurrence is 50-500 ha in size; embedded in 10-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape;

there is moderate departure from the historic fire regime (FRCC = 2); evidence of at least one low- to moderate-severity fire since 1900 (Euro-American settlement period); fuel laddering may be present in these areas.

Disruption of Biotic Processes (from WNHP 2011): High-severity disruption of biotic processes appears where greater than 10% absolute cover of exotic invasives; non-native species dominate understory with minor native component (native species relative cover in shrub and herb layers <50%); native bunchgrasses have only 10-25% relative cover; native increasers (indicative of grazing or soil disturbance) have >20% relative cover; many, if not all, old (>150 years) *Pinus ponderosa* have been harvested; most or all indicator/diagnostic species are absent; native species consist mostly of weedy species; occurrences are fragmented, connectivity is essentially gone. Moderate-severity appears where exotic invasives prevalent with 3-10% absolute cover; native species have 50 to <85% cover, native bunchgrasses have 25-50% cover; native increasers (indicative of grazing or soil disturbance) have 10-20% cover; non-natives can be codominant; many (over 50%) old (>150 years) *Pinus ponderosa* have been harvested; native species characteristic of the type remain present but weedy (pioneer, early-successional) native species that develop after clearcutting or clearing are dominant; many indicator/diagnostic species may be absent.

CES303.650 Northwestern Great Plains-Black Hills Ponderosa Pine Woodland and Savanna

CES303.650 CLASSIFICATION

Concept Summary: This system occurs throughout the northwestern Great Plains along areas that border the Rocky Mountains. The expansion of this system within the central Great Plains may be due to fire suppression. These can be physiognomically variable, ranging from very sparse patches of trees on drier sites, to nearly closed-canopy forest stands on north slopes or in draws where available soil moisture is higher. This system occurs primarily on gentle to steep slopes along escarpments, buttes, canyons, rock outcrops or ravines and can grade into one of the surrounding prairie systems or the Great Plains canyon system. Soils typically range from well-drained loamy sands to sandy loams formed in colluvium, weathered sandstone, limestone, scoria or eolian sand. This system is primarily dominated by *Pinus ponderosa* but may include a sparse to relatively dense understory of *Juniperus scopulorum, Thuja*, or *Cercocarpus* with just a few scattered trees. Deciduous trees are an important component in some areas (western Dakotas, Black Hills) and are sometimes codominant with the pines, including *Fraxinus pennsylvanica, Betula papyrifera, Quercus macrocarpa, Ulmus americana, Acer negundo*, and *Populus tremuloides*. Along the Missouri Breaks in north-central Montana, woodlands dominated by *Pseudotsuga menziesii* are in similar ecological settings as *Pinus ponderosa* in the Great Plains and are included in this system. In the breaks where it occurs, *Pseudotsuga menziesii* has a very open canopy over grassy undergrowth, predominantly composed of *Pseudoroegneria spicata*, with little to no shrubs present. Important or common shrub species with ponderosa pine can include *Arctostaphylos uva-ursi, Mahonia repens, Yucca glauca, Symphoricarpos* spp., *Prunus virginiana, Juniperus communis, Juniperus horizontalis, Amelanchier alnifolia, Rhus trilobata*, and *Physocarpus monogynus*. The herbaceous understory can range from sparse to a dense layer with species typifying the surrounding prairie system, with mixedgrass species common, such as *Andropogon gerardii, Bouteloua curtipendula, Carex inops ssp. heliophila, Carex filifolia, Danthonia intermedia, Koeleria macrantha, Nassella viridula, Oryzopsis asperifolia, Pascopyrum smithii, Piptatheropsis micrantha*, and *Schizachyrium scoparium*. Timber cutting and other disturbances have degraded many examples of this system within the Great Plains. However, some good examples may occur along the Pine Ridge escarpment and Pine Ridge district of the Nebraska National Forest in Nebraska.

Related Concepts:
- Interior Ponderosa Pine: 237 (Eyre 1980) **><**
- Northwestern Great Plains Pine Woodland (Rolfsmeier and Steinauer 2010) =

Distribution: This system is found in central and eastern Montana, the western Dakotas, eastern Wyoming (east of the Bighorns), the Black Hills, and south into the Sand Hills of Nebraska and northeastern Colorado (north of Pawnee National Grasslands to Cedar Point near Limon and south). In Montana, it occurs along the Missouri River breaks, around the Little Belts and Snowy mountains, in south-central Montana between the Bighorns and the Black Hills (along the Tongue and Powder rivers), and other areas of eastern Montana. In Wyoming, it is found around the Black Hills and Bear Lodge Mountains, and in isolated areas of eastern Wyoming on bluffs and rock outcrops, and along "breaks." Whether this system occurs in Kansas is uncertain.
Nations: US
Concept Source: M.S. Reid
Description Author: M.S. Reid and K.A. Schulz

CES303.650 CONCEPTUAL MODEL

Environment: The ponderosa pine system is found in a matrix of northwestern Great Plains grassland systems along escarpments and in foothills and mountains in the Black Hills. It is often surrounded by mixedgrass or tallgrass prairie, in places where available soil moisture is higher, or soils are more coarse and rocky. Some stands are found adjacent to major creek bottoms and the lower toeslope and footslope positions. In some cases, these woodlands or savannas may occur where fire suppression has allowed trees to become established (in areas where deciduous trees are more abundant) (Girard et al. 1987). These are typically not in the same setting as Rocky Mountain ponderosa pine, where ponderosa pine forms woodlands at lower treeline and grades into mixed montane conifer systems at higher elevations. These are physiognomically variable woodlands, ranging from very sparse patches of trees on drier, often rocky sites, to nearly closed-canopy forest stands on north slopes or in draws where available soil moisture is higher. This system occurs primarily on gentle to steep slopes along escarpments, buttes, canyons, rock outcrops or ravines and can grade into the Great Plains canyons the surrounding mixedgrass prairie systems (Hoffman and Alexander 1987). Soils typically range from well-drained loamy sands to loams formed in colluvium, weathered sandstone, limestone, calcareous shales, scoria or eolian sand (Hoffman and Alexander 1987, Hansen and Hoffman 1988).
Key Processes and Interactions: Marriot and Faber-Langendoen (2000) report different fire regimes for ponderosa pine communities in the Black Hills, with their "Dry Group" more typically having frequent surface fires and the "Mesic Group" having infrequent catastrophic fires (every 100-200 years). The Dry Group of associations includes lower elevation foothill savanna associations, and the mesic group somewhat higher elevation, north-slope, swale associations. K. Kindscher (pers. comm. 2007) believes that almost all the stands in Nebraska were there at the time of settlement and are not a result of pine expansion due to fire suppression; in addition, at least some have disappeared, such as the one in southern Nebraska (Franklin County). It is possible, however, that some areas of this system have expanded in size due to fire suppression, but this needs substantiation.

LANDFIRE developed several a state-and-transition vegetation dynamics VDDT models for this system for different map zones and savanna vs low elevation woodland stands. Shone in the grassland model for Map Zone 29 which has five classes in total (LANDFIRE 2007a, BpS 2911792). These are summarized as:

A) Early Development 1 All Structures (5% of type in this stage): This community is dominated by herbaceous and woody species, including the graminoids needlegrasses, western wheatgrass, bluebunch wheatgrass, sedges, Idaho fescue and little bluestem in moister areas, and various shrubs including skunkbush and snowberry. Ponderosa pine seedlings are scattered and found in small clumps. Little bluestem will also be an indicator species. Number of years in this class is variable depending on climatic patterns and fire disturbances. This class typically ends at 30 years in this model. Without fire for 25 years, this class can move to a mid-closed stage.

B) Mid Development 1 Closed (2% of type in this stage): Tree cover is 0-50%. Multi-story stand of small and medium trees with saplings and seedlings coming in as clumps. Understory is sparse. Some juniper might be present - could be an outlier. Grasses and shrubs are shaded out. This class lasts approximately 70 years, then moves to a late-closed stage. Low-severity surface fires occur every 15 years and move this stage to a mid-open stage. Replacement fires occur infrequently, approximately every 300 years. Insect/disease was modeled at approximately occurring every 50 years, not causing a transition.

C) Mid Development 1 Open (8% of type in this stage): Tree cover is 0-50%. Predominantly single-story stands with a few pockets of regeneration. Low shrubs such as snowberry and skunkbush and poison ivy are dominant as well as grasses and forbs. Graminoids could have up to 70-80% cover. Rocky Mountain juniper present in patches (Rocky Mountain juniper is not common on the Pine Ridge in Nebraska). *Carex* spp. and little bluestem will also be indicator species. This class lasts approximately 50 years then goes to a late-open stage. Without fire for 40 years, this could transition back to a mid-closed stage. Low-severity surface fires occur every 15 years, maintaining this class. Replacement fires occur very infrequently (modeled at 0.0015 probability).

D) Late Development 1 Open (80% of type in this stage): Tree cover is 0-50%. Predominantly single-story stands of large ponderosa pine with pockets of smaller size classes (replacement). Snowberry, skunkbush and patches of Rocky Mountain juniper. Understory is dominated by shrub species and grasses and poison ivy. Graminoids could have up to 70-80% cover. *Carex* spp. and little bluestem will also be indicator species. It is thought that class D, the late-open stage, should occupy approximately 80% of the historical landscape. Low-severity fires occur every 15 years and maintain this stage. Replacement fires occur very infrequently (0.0015 probability). If no fire occurs after 40 years, this class could transition to the late-closed stage. Insect/disease occurs every 50 years and maintains this stage.

E) Late Development 1 Closed (5% of type in this stage): Tree cover is 51-100%. This is a somewhat uniform late-development stage, multi-story stands of large, medium, small and seedling ponderosa pine. Shrubs and grasses are sparse. This type generally exceeds 70% canopy cover. dbh is less in this class than late-open. Low-severity surface fires occur every 15 years and cause a transition back to the late-open stage. Replacement fires occur every 300 years. Insect/disease occurs every 250 years, causing a transition back to the late-open stage. Drought can also occur - every 500 years, causing a transition to the late-open stage.

Generally, the fire regime is characterized by frequent fire-return interval of low-severity surface fire. The presence of abundant fire-scarred trees in multi-aged stands supports a prevailing historical model for ponderosa pine forests in which recurrent surface fires affected heterogeneous forest structure (Brown 2006). Mixed-severity fire occurs in closed-canopy conditions and stand-replacement fire is very infrequent (300+ years) (LANDFIRE 2007a, BpS 2911792). Low-severity fires are frequent and range from <10 years to more than 20 years (Fischer and Clayton 1983, Brown and Sieg 1999), but probably not more than 40 years at the high end (3-70 years range). The MFRI is approximately 12-15 years for low-severity fires (LANDFIRE 2007a, BpS 2911792).

There is considerable debate over the role of mixed-severity and surface fires in the historical range of variability in this and other ponderosa pine forests in the northern and central Rockies (Veblen et al. 2000, Baker and Ehle 2001, 2003, Barrett 2004a, b). However, Brown (2006) argues that surface fire was the dominant mode of fire disturbance and that the role of mixed-severity fires is overstated. For MZs 29 and 30, it was suggested that mixed fire be removed from this savanna model; reviewers agreed, and therefore mixed fire is not in this model (LANDFIRE 2007a, BpS 2911792).

Variation in precipitation and temperature interacting with fire, tip moths and ungulate grazing affects pine regeneration. Windthrow, storm damage and mountain pine beetles were minor disturbances in this type unless stands reach high densities. The interactions among drought, insects and disease are not well understood (LANDFIRE 2007a, BpS 2911792). *Pinus ponderosa - Juniperus scopulorum* savanna in the southern Black Hills has lots of rock exposure or sparsely grassed soils, which probably protected some of the juniper seed trees from being wiped out by fire (LANDFIRE 2007a, BpS 2911792).

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. However, biological decomposition in ponderosa pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994, Graham and Jain 2005).

Threats/Stressors: With settlement and a century of anthropogenic disturbance and fire suppression, stands now have a higher density of *Pinus ponderosa* trees, altering the fire regime and species composition. Presently, many stands contain understories of more shade-tolerant species, such as *Pseudotsuga menziesii* and/or *Abies* spp., as well as younger cohorts of *Pinus ponderosa*. These altered structures have affected fuel loads and fire regimes. Presettlement fire regimes were primarily frequent (5- to 15-year return intervals), low-intensity ground fires triggered by lightning strikes or deliberately set by Native Americans, which maintained a savanna or open woodland structure. With fire suppression and increased fuel loads, fire regimes are now less frequent and often become intense crown fires, which can kill mature *Pinus ponderosa* (Reid et al. 1999).

Conversion of this type has commonly come from urban and exurban development. Restoration to open woodland or savanna is difficult or impossible when adjacent to housing development. Common stressors and threats include fragmentation from housing and water developments, altered fire regime from fire suppression and indirectly from livestock grazing and fragmentation, and introduction of invasive non-native species.

CES306.955 Rocky Mountain Foothill Limber Pine-Juniper Woodland

CES306.955 CLASSIFICATION

Concept Summary: This ecological system occurs in foothill and lower montane zones in the Rocky Mountains from northern Montana south to central Colorado and on escarpments across Wyoming extending out into the western Great Plains. Elevation ranges from 1000-2440 m. It occurs generally below continuous forests of *Pseudotsuga menziesii* or *Pinus ponderosa* and can occur in large stands well within the zone of continuous forests in the northeastern Rocky Mountains. It is restricted to shallow soils and fractured bedrock derived from a variety of parent material, including limestone, sandstone, dolomite, granite and colluvium. Soils have a high rock component (typically over 50% cover) and are coarse- to fine-textured, often gravelly and calcareous. Slopes are typically moderately steep to steep. At lower montane elevations, it is limited to the most xeric aspects on rock outcrops, and at lower elevations to the relatively mesic north aspects. Fire is infrequent and spotty because rocky substrates prevent a continuous vegetation canopy needed to spread. Vegetation is characterized by an open-tree canopy or patchy woodland that is dominated by *Pinus flexilis, Juniperus osteosperma*, or *Juniperus scopulorum*. *Pinus edulis* is not present. A sparse to moderately dense short-shrub layer, if present, may include a variety of shrubs, such as *Arctostaphylos uva-ursi, Artemisia nova, Artemisia tridentata, Cercocarpus ledifolius, Cercocarpus montanus, Dasiphora fruticosa ssp. floribunda, Ericameria nauseosa, Juniperus horizontalis, Purshia tridentata, Rhus trilobata, Rosa woodsii, Shepherdia canadensis* (important in Montana stands), *Symphoricarpos albus*, or *Symphoricarpos oreophilus*. Herbaceous layers are generally sparse, but range to moderately dense, and are typically dominated by perennial graminoids such as *Bouteloua gracilis, Festuca idahoensis, Festuca campestris, Danthonia intermedia, Leucopoa kingii, Hesperostipa comata, Koeleria macrantha, Piptatheropsis micrantha, Poa secunda*, or *Pseudoroegneria spicata*. Within this ecological system, there may be small patches of grassland or shrubland composed of some of the above species.

Distribution: This system occurs in foothill and lower montane zones in the Rocky Mountains from northern Montana south to central Colorado and on escarpments across Wyoming, extending out into the western Great Plains. Elevation ranges from 1000-2400 m. This system may also occur in southeastern Idaho, though it would not be common there. It is also very likely to occur north into Canada along the Front Range of Alberta, in similar ecological settings.

CES306.955 CONCEPTUAL MODEL

Environment: This ecological system occurs in foothill and lower montane zones in the Rocky Mountains from northern Montana south to central Colorado and on exposed, windswept escarpments and other geographic breaks across Wyoming extending out into the northwestern Great Plains. Elevation typically ranges from 1000-2400 m. It occurs generally below continuous forests of *Pseudotsuga menziesii* or *Pinus ponderosa* but can occur in large stands well within the zone of continuous forests in the northeastern Rocky Mountains. In Wyoming, some limber pine stands are found up to 2440 m (8000 feet) elevation and are still included in this system.

Climate: This woodland system occurs in a semi-arid, cool-temperate climate. Annual precipitation patterns and amounts are variable but are typically below 500 mm annual precipitation with much occurring in winter as snow or spring rain.

Physiography/landform: Stands occur on moderately steep to steep slopes on all aspects but are most common on dry south- and west-facing slopes. At higher elevations, it is limited to the most xeric aspects on rock outcrops, and at lower elevations to the relatively mesic north aspects.

Soil/substrate/hydrology: It is restricted to shallow soils and fractured bedrock derived from a variety of parent material, including limestone and calcareous sandstone, but also dolomite, granite, gneiss, quartzite, rhyolite, schist, shale and colluvium. Some stands are on eroded substrates and resemble "badlands" while others may occur on lava flows. Soils are typically shallow and have a high rock component (skeletal) with typically over 50% cover of surface rock. They are often coarse-textured, such as gravelly, sandy loams or loams, but may include alkaline clays. Exposed soil is common, and many stands have over 50% cover of bare soil. Soil pH is typically neutral or slightly alkaline, but ranges from acidic to alkaline.

Key Processes and Interactions: The processes shaping the distribution and persistence of scarp woodlands is not well understood (CNHP 2010). The interaction of wind, fire, and topography is thought to have played a major role in the current pattern of occurrences. These woodlands are not physiologically limited to a particular substrate, but are generally found on larger, relatively high escarpments, and not on smaller or more gently sloping breaks. The abrupt topographic changes may act as natural firebreaks. In addition, the typically sparse vegetation of the breaks in comparison with the adjacent deeper soils does not allow grassland fires to carry into the woodland understory (CNHP 2010).

Although some of the conifers that are typically codominant in *Pinus flexilis* stands are late-successional species, they are not likely to displace *Pinus flexilis*. This is because most of these stands occur on harsh sites where *Pinus flexilis* is more competitive than most other conifer species. These stands are generally considered to be topographic or edaphic "climax" stands (Cooper 1975, Eyre 1980). Even in stands at lower elevations, such as prairie breaks, it is unlikely that other coniferous species will become dominant (Eyre 1980). Because *Pinus flexilis* occurs over a broad range of elevations, it can also be important as a post-fire seral species on drier sites in the Rocky Mountains (Cooper 1975, Peet 1988). Peet (1978a) reported apparent competitive displacement with *Pinus flexilis* in Colorado. He noted that *Pinus flexilis* may dominate xeric sites from low to high elevations, except where *Pinus aristata* or *Pinus albicaulis* occur. There, *Pinus flexilis* is largely restricted to lower elevation, rocky sites. Peet (1978a) also reported that *Pinus flexilis* occurs in the less xeric *Pinus contorta* and *Pinus ponderosa* habitats. However, the higher elevation *Pinus flexilis* stands would be included in ~Rocky Mountain Subalpine-Montane Limber-Bristlecone Pine Woodland (CES306.819)$$.

Birds and small mammals often eat and cache the large, wingless pine seeds. Most important is the Clark's nutcracker, which can transport the seeds long distances and cache them on exposed windswept sites (Lanner and Vander Wall 1980, Lanner 1985, 1996). This results in the regeneration of pines in clumps from forgotten caches (Woodmansee 1977, Eyre 1980, Steele et al. 1983).

Fire history information is lacking and has a wide range, making modeling difficult. As a whole, fire has occurred in this community in relation to fuel types adjacent to and within the woodland site. On shallow, rocky sites fire may have occurred less frequently. On deeper-soiled sites, the associated vegetation is more robust and would support a more frequent fire-return interval.

Given the uncertainty about the fire frequencies of this ecological system, it is predicted to vary from 30 to 80 years for mixed-severity fire and over 200 years for replacement fires (LANDFIRE 2007a). Fire is likely infrequent and spotty because rocky substrates prevent a continuous vegetation canopy that is needed for fire to spread.

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has three classes in total (LANDFIRE 2007a, BpS 2010490). These classes are summarized as:

A) Early Development 1 All Structures (30% of type in this stage): Grass/forb/shrub/seedling - usually post-fire. Cover is 0-30%. Shrub height 0-1.0 m. The first 25 years dominated by shrub/herbaceous. Toward end of class increasing pine/juniper. When pine/juniper becomes dominant it has 10-20% cover. Height of pine/juniper reaching 15 m (48 feet). On shallow, rocky sites, seedlings tend to establish in protected areas, such as sheltered spaces in rocky outcrops. On these sites there is little grass or herb competition. On deeper-soiled sites, there is a significant herbaceous component and seedlings are established from bird seed caches and seed from limber pine and juniper that were not killed. This class lasts for 50 years or less. Replacement fire occurs every 250 years.

B) Mid Development 1 Open (30% of type in this stage): Tree cover is 21-40%. Tree height <10 m. Trees are established, but typically short and widely spaced. Grasses and herbs are sparse in shallow, rocky soils. On deeper-soil sites grasses and shrubs are prevalent. This class lasts until trees are approximately 100 years old, and then succeeds to Class C. Other indicator species might be *Cercocarpus montanus*. Replacement fire occurs every 200 years.

C) Late Development 1 Closed (40% of type in this stage). Tree cover is 41-60%. Tree height <10 m. Mature trees greater than 100 years old. On shallow, rocky sites trees dominate the site with sparse shrub-grass understory. On deeper-soil sites mature trees are codominant with shrub-grass understory with an increasing component of younger age class limber pine and juniper that will shade out shrubs and eventually leave a woodland site dominated by pine or pine-juniper overstory and grass understory. It is possible that limber pine might not occur in this stage in some areas. Replacement fire occurs every 200 years. Insect/disease occur with a probability of 0.0016 (every 625 years, or 0.16% of this class each year), returning the class to class A.

Threats/Stressors: Disturbance from firewood cutting, drought, and agricultural use may also influence the distribution and persistence of these woodlands (CNHP 2010).

Pinus flexilis is very susceptible to the non-native white pine blister rust (*Cronartium ribicola*) that infects and kills this tree (Hoff et al. 1980). There is long-term concern with the persistence of this species/system. Although the isolation of many stands on rocky outcrops and ranges has reduced that rate of spread, the only long-term solutions is propagating individuals that have high genetic resistance to blister rust (Steele et al. 1983, Burns and Honkala 1990a, Schmidt and McDonald 1990).

Other insect threats include epidemics of native mountain pine beetle (*Dendroctonus ponderosae*), which can attack and kill limber pine trees. The limber pine dwarf mistletoe (*Arceuthobium cyanocarpum*) is a common parasite of this tree, which can weaken but rarely kills it (Burns and Honkala 1990a).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from loss of limber pine due to non-native white pine blister rust (*Cronartium ribicola*). Ecological collapse can also result from stand-replacing fires occurring under more extreme fire conditions and cause mortality of pines and junipers, leaving soil bare and exposed to erosion and invasions by exotic species. Non-native species such as *Bromus tectorum* provide fine fuels that increase fire frequency and the probability of stand-replacing fires that cause mortality of pine and juniper trees. Frequent fires will reduce or eliminate tree regeneration, resulting in the conversion to invasive annual grassland or shrublands adapted to frequent fire. With loss of ecosystem structure many of the animals that depend on juniper berries and pine seeds will also be gone.

High-severity environmental degradation appears where occurrences tend to be relatively small (<10 acres) and may include intervening draws without trees (CNHP 2010). Occurrence is surrounded primarily by urban or agricultural landscape, with <25% landscape cover of natural or semi-natural vegetation (CNHP 2010). Disturbances is extensive and occurs on more than 50% of the area. Soil erosion may be severe in places.

Moderate-severity environmental degradation appears where occurrences are moderate (10-50 acres) and the significant disturbance is easily restorable (CNHP 2010). Landscape is a mosaic of agricultural or semi-developed areas with >50% natural or semi-natural vegetation (CNHP 2010). There are more than a few roads found within the occurrence (CNHP 2010). Microbiotic crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence. Soil erosion and gullying may be observed in patches (up to 30%) within the stand (CNHP 2010).

High-severity biotic disruption appears where occurrences have non-native invasive species (e.g., leafy spurge, knapweeds, non-native thistle, *Bromus inermis, Poa pratensis*, and *Bromus tectorum*) present and possibly abundant (CNHP 2010). Limber pine and juniper populations are declining. Alteration of vegetation is extensive and restoration potential is low (CNHP 2010). Connectivity is severely hampered by fragmentation from roads and other unnatural barriers that restrict or prevent natural ecological processes from occurring, and create barriers to natural movement of animal and plant populations (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have non-native species codominant with native species (CNHP 2010). Limber pine population may be declining. Alteration of vegetation is extensive but potentially restorable over several decades. Limber pine and juniper populations may be declining (CNHP 2010). Connectivity is moderately hampered by fragmentation from roads and other unnatural barriers that restrict natural ecological processes from occurring, and create barriers to natural movement of animal and plant populations (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

M500. Central Rocky Mountain Mesic Lower Montane Forest

CES204.086 East Cascades Mesic Montane Mixed-Conifer Forest and Woodland

CES204.086 CLASSIFICATION

Concept Summary: This ecological system occurs on the upper east slopes of the Cascades in Washington, south of Lake Chelan and south to Mount Hood in Oregon. Elevations range from 610 to 1220 m (2000-4000 feet) in a very restricted range occupying less than 5% of the forested landscape in the east Cascades. This system is associated with a submesic climate regime with annual precipitation ranging from 100 to 200 cm (40-80 inches) and maximum winter snowpacks that typically melt off in spring at lower elevations. This ecological system is composed of variable montane coniferous forests typically below Pacific silver fir forests along the crest east of the Cascades. This system also includes montane forests along rivers and slopes, and in mesic "coves" which were historically protected from wildfires. Most occurrences of this system are dominated by a mix of *Pseudotsuga menziesii* with *Abies* *grandis* and/or *Tsuga heterophylla*. Several other conifers can dominate or codominate, including *Thuja plicata, Pinus contorta, Pinus monticola*, and *Larix occidentalis*. *Abies grandis* and other fire-sensitive, shade-tolerant species dominate forests on many sites once dominated by *Pseudotsuga menziesii* and *Pinus ponderosa*, which were formerly maintained by wildfire. They are very productive forests in the eastern Cascades which have been priority stands for timber production. *Mahonia nervosa, Linnaea borealis, Paxistima myrsinites, Acer circinatum, Spiraea betulifolia, Symphoricarpos hesperius, Cornus nuttallii, Rubus parviflorus*, and *Vaccinium membranaceum* are common shrub species. The composition of the herbaceous layer reflects local climate and degree of canopy closure and contains species more restricted to the Cascades, for example, *Achlys triphylla, Anemone deltoidea*, and *Vancouveria hexandra*. Typically, stand-replacement fire-return intervals are 150-500 years with moderate-severity fire-return intervals of 50-100 years.

CES306.802 Northern Rocky Mountain Mesic Montane Mixed Conifer Forest

CES306.802 CLASSIFICATION

Concept Summary: This ecological system occurs in the Northern Rockies of western Montana west into northeastern Washington and southern British Columbia. These are vegetation types dominated by *Tsuga heterophylla* and *Thuja plicata* in most cases, found in areas influenced by incursions of mild, wet, Pacific maritime air masses. Much of the annual precipitation occurs as rain, but where snow does occur, it can generally be melted by rain during warm winter storms. Occurrences generally are found on all slopes and aspects but grow best on sites with high soil moisture, such as toeslopes and bottomlands. At the periphery of its distribution, this system is confined to moist canyons and cooler, moister aspects. Generally these are moist, non-flooded or upland sites that are not saturated yearlong. Along with *Tsuga heterophylla* and *Thuja plicata, Pseudotsuga menziesii* commonly shares the canopy, and *Pinus monticola, Pinus contorta, Abies grandis, Taxus brevifolia*, and *Larix occidentalis* are major associates. Mesic *Abies grandis* associations are included in this system, and *Abies grandis* is often the dominant in these situations; *Tsuga heterophylla* and *Thuja plicata* can both be absent. *Cornus nuttallii* may be present in some situations. *Picea engelmannii, Abies lasiocarpa*, and *Pinus ponderosa* may be present but only on the coldest or warmest and driest sites. *Linnaea borealis, Paxistima myrsinites, Alnus incana, Acer glabrum, Spiraea betulifolia, Symphoricarpos hesperius, Cornus canadensis, Rubus parviflorus, Menziesia ferruginea*, and *Vaccinium membranaceum* are common shrub species. The composition of the herbaceous layer reflects local climate and degree of canopy closure; it is typically highly diverse in all but closed-canopy conditions. Important forbs and ferns include *Actaea rubra, Anemone piperi, Aralia nudicaulis, Asarum caudatum, Clintonia uniflora, Coptis occidentalis, Thalictrum occidentale, Tiarella trifoliata, Trientalis borealis, Trillium ovatum, Viola glabella, Gymnocarpium dryopteris, Polystichum munitum*, and *Adiantum pedatum*. Typically, stand-replacement, fire-return intervals are 150-500 years, with moderate-severity fire intervals of 50-100 years.

CES306.837 Northern Rocky Mountain Western Larch Savanna

CES306.837 CLASSIFICATION

Concept Summary: This ecological system is restricted to the interior montane zone of the Pacific Northwest in northern Idaho and adjacent Montana, Washington, Oregon, and in southeastern interior British Columbia. It also appears in the east Cascades of Washington. Winter snowpacks typically melt off in early spring at lower elevations. Elevations range from 680 to 2195 m (2230-7200 feet), and sites include drier, lower montane settings of toeslopes and ash deposits. This system is composed of open-canopied "savannas" of the deciduous conifer *Larix occidentalis*, which may have been initiated following stand-replacing crownfires of other conifer systems, but are maintained by a higher frequency, surface-fire regime. These savannas are found in settings where low-intensity, high-frequency fires create open larch woodlands, often with the undergrowth dominated by low-growing *Arctostaphylos uva-ursi, Calamagrostis rubescens, Linnaea borealis, Spiraea betulifolia, Vaccinium cespitosum*, or *Xerophyllum tenax*. Less frequent or absence of fire creates mixed-dominance stands with often shrubby undergrowth; *Vaccinium cespitosum* is common, and taller shrubs can include *Acer glabrum, Ceanothus velutinus, Shepherdia canadensis, Physocarpus malvaceus, Rubus parviflorus*, or *Vaccinium membranaceum*. Fire suppression has led to invasion of the more shade-tolerant tree species *Abies grandis, Abies lasiocarpa, Picea engelmannii*, or *Tsuga* spp. and loss of much of the single-story canopy woodlands.

Distribution: This ecological system is restricted to the interior montane zone of the Pacific Northwest in northern Idaho and adjacent Montana, Washington, Oregon, and in southeastern interior British Columbia. It also appears in the east Cascades of Washington.

Nations: CA?, US

Concept Source: R.C. Crawford and M.S. Reid

Description Author: R.C. Crawford and M.S. Reid

CES306.837 CONCEPTUAL MODEL

Environment:

Key Processes and Interactions: *Larix occidentalis* is a long-lived species (in excess of 700 years in the northern Rocky Mountains), and thus stands fitting this concept are themselves long-persisting; the life of *Larix*-dominated stands probably does not much exceed 250 years due to various mortality sources and the ingrowth of shade-tolerant species. Occurrences of this ecological system are generated by stand-replacing fire, the fire-return interval for which is speculated to be on the order of 80 to 200 years. These sites may be maintained in a seral status for hundreds of years due to the fact that *Larix occidentalis* is a long-lived species and the understory is often dominated by *Pseudotsuga*, which will grow into the upper canopy. The potential dominants *Abies lasiocarpa, Picea engelmannii*, or *Abies grandis* are slow to establish on these sites and grow slowly presenting the distinct probability, given the fire-return intervals for this type, that the "climax" (long-term stable) condition is never realized.

It has been noted in northern Idaho that, following disturbance (particularly logging) in some mesic-site occurrences, *Larix occidentalis* does not necessarily succeed itself, the first tree-dominated successional stages being dominated by *Pseudotsuga menziesii, Pinus contorta*, or less frequently by more shade-tolerant species (Cooper et al. 1987); this response is a consequence of the episodic nature of favorable cone crop years in *Larix occidentalis*.

M020. Rocky Mountain Subalpine-High Montane Conifer Forest

CES304.776 Inter-Mountain Basins Aspen-Mixed Conifer Forest and Woodland

CES304.776 CLASSIFICATION

Concept Summary: This ecological system occurs on montane slopes and plateaus in Utah, western Colorado, northern Arizona, eastern Nevada, southern Idaho, western Wyoming, and in north-central Montana in the Big Snowy Mountains. It also occurs in localized settings in the Klamath Mountains of California, as well as in the Sierra Nevada and adjacent Great Basin mountains (Inyo, White, Warner, and Modoc Plateau). Elevations range from 1700 to 2800 m. Occurrences are typically on gentle to steep slopes on any aspect but are often found on clay-rich soils in intermontane valleys. Soils are derived from alluvium, colluvium and residuum from a variety of parent materials but most typically occur on sedimentary rocks. The tree canopy is composed of a mix of deciduous and coniferous species, codominated by *Populus tremuloides* and conifers, including *Pseudotsuga menziesii, Abies concolor, Abies lasiocarpa, Abies magnifica, Picea engelmannii, Picea x albertiana, Picea pungens, Pinus contorta, Pinus flexilis, Pinus jeffreyi, Pinus contorta var. murrayana*, and *Pinus ponderosa*. As the stands age, cover of *Populus tremuloides* may be slowly reduced until the conifer species become dominant. Common shrubs include *Amelanchier alnifolia, Prunus virginiana, Acer grandidentatum, Symphoricarpos oreophilus, Juniperus communis, Paxistima myrsinites, Rosa woodsii, Spiraea betulifolia, Symphoricarpos albus*, or *Mahonia repens*. Herbaceous species include *Bromus carinatus, Calamagrostis rubescens, Carex geyeri, Elymus glaucus, Poa* spp., and *Achnatherum, Hesperostipa, Nassella*, and/or *Piptochaetium* spp. *Achillea millefolium, Arnica cordifolia*, Asteraceae spp., *Erigeron* spp., *Galium boreale, Geranium viscosissimum, Lathyrus* spp., *Lupinus argenteus, Mertensia arizonica, Mertensia lanceolata, Maianthemum stellatum, Osmorhiza berteroi*, and *Thalictrum fendleri*. Most occurrences at present represent a late-seral stage of aspen changing to a pure conifer occurrence. Nearly a hundred years of fire suppression and livestock grazing have converted much of the pure aspen occurrences to the present-day aspen-conifer forest and woodland ecological system. This is the typical meadow edge aspen-conifer setting in the Sierra Nevada where frequently, due to fire suppression, the conifers are replacing aspens.

Related Concepts:
- Aspen Woodland (411) (Shiflet 1994) **><**
- Aspen: 217 (Eyre 1980) **><**

Distribution: This system occurs on montane slopes and plateaus in Utah, eastern Nevada, southern Idaho, western and central Wyoming (in the Bighorn Mountains), and in north-central Montana in the Big Snowy Mountains. Elevations range from 1700 to 2800 m.

Nations: US

Description Author: K.A. Schulz, M.S. Reid and G. Kittel

CES304.776 CONCEPTUAL MODEL

Environment: This ecological system is found on montane slopes and high plateaus in Utah, western Colorado, northern Arizona, eastern Nevada, southern Idaho, and western Wyoming from 1700 to 2800 m elevation. Climate is temperate with cold winters. Mean annual precipitation is greater than 38 cm and typically greater than 50 cm. Although often drier, sites are similar to ~Rocky Mountain Aspen Forest and Woodland (CES306.813)$$ with regards to environmental characteristics. Topography is variable, with sites ranging from level to steep slopes. Aspect varies according to the limiting factors. Occurrences at high elevations are restricted by cold temperatures and are found on warmer southern aspects. At lower elevations aspen is restricted by lack of moisture and is found on cooler north aspects and mesic microsites such as seeps and drainages. Soils are derived from alluvium, colluvium and residuum from a variety of parent materials and may include sedimentary, metamorphic or igneous rocks, but it appears to grow best on sedimentary rocks such as limestone and calcareous or neutral shales, or basalt (Mueggler 1988). Soil texture ranges from sandy loam to clay loam. This system represents a stable mixed aspen - conifer woodlands typically found on broad plateaus where periodic disturbance such as die-back from drought is thought to maintain the mixed deciduous-conifer composition. It is sometimes confused with the relatively short-lived, mid-seral stages of conifer-dominated forest and woodland systems such as ~Rocky Mountain Subalpine Dry-Mesic Spruce-Fir Forest and Woodland (CES306.828)$$, ~Rocky Mountain Subalpine Mesic-Wet Spruce-Fir Forest and Woodland (CES306.830)$$, or ~Southern Rocky Mountain Mesic Montane Mixed Conifer Forest and Woodland (CES306.825)$$. Distribution of this ecological system is primarily limited by adequate soil moisture required to meet its high evapotranspiration demand (Mueggler 1988). Secondarily, its range is limited by the length of the growing season or low temperatures (Mueggler 1988). The environmental description is based on several other references, including DeByle and Winokur (1985), Mueggler (1988), Howard (1996), Reid et al. (1999), Bartos (2001), Comer et al. (2002), Tuhy et al. (2002), and Sawyer et al. (2009).

Key Processes and Interactions: *Populus tremuloides* is a fast-growing deciduous tree that reaches 20 m in height and forms clones that can be ancient, although the stems are relatively short-lived (up to 150 years in the western U.S.) (Howard 1996, Sawyer et al. 2009). It is thin-barked and stems are readily killed by fire, although the clone will usually resprout after burning or other disturbance (Howard 1996). It is a fire-adapted species that generally needs a large disturbance to establish and maintain dominance in a forest stand. Mixed aspen - conifer forests are generally seral and, in the absence of stand-replacing disturbance such as fire, will slowly convert to a conifer-dominated forest (Mueggler 1988). Although the young conifer trees in these occurrences are susceptible to fire, older individuals develop self-pruned lower branches and develop a thick corky bark that makes them resistant to surface fires. The natural fire-return interval is approximately 20 to 50 years for seral occurrences (Hardy and Arno 1996). Intervals that approach 100 years are typical of late-seral occurrences (Hardy and Arno 1996).

However, this system represents stable mixed aspen - conifer woodlands typically found on broad plateaus in the interior western U.S. where periodic disturbance such as die-back from drought or other disturbance is thought to maintain the mixed deciduous-conifer composition and not allow conifers to dominate and shade out the aspen (Tuhy et al. 2002). Sudden aspen decline (SAD) results in root mortality with subsequent effects on tree canopy and clone persistence. It appears to be triggered by severe drought (Worrall et al. 2010). This may have increasing impact on these forests. More research is needed to clarify the dynamics of this system as it is sometimes confused with the relatively short-lived, mid-seral stages of conifer-dominated forest and woodland systems such as ~Rocky Mountain Subalpine Dry-Mesic Spruce-Fir Forest and Woodland (CES306.828)$$, ~Rocky Mountain Subalpine Mesic-Wet Spruce-Fir Forest and Woodland (CES306.830)$$, or ~Southern Rocky Mountain Mesic Montane Mixed Conifer Forest and Woodland (CES306.825)$$.

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 1810610). The model represents a fire maintained, seral mixed aspen - conifer types that succeeds to a conifer dominated types without mixed-severity fire (mean FRI of 20 years). The classes are summarized as:

A) Early Development 1 All Structures (14% of type in this stage): Grass/forb and aspen suckers <12 feet tall. Generally, this is expected to occur 1-3 years post-disturbance. Fire is absent. Succession to class B after 10 years.

B) Mid Development 1 Closed (tree-dominated - 40% of type in this stage): Tree cover is 41-100%. Aspen saplings over 12 feet tall dominate. Canopy cover is highly variable. Replacement fire occurs every 60 years on average. Mixed-severity fire (average FRI of 40 years) does not change the successional age of these stands, although this fire consumes litter and woody debris and may stimulate suckering. Succession to class C after 30 years.

C) Mid Development 1 Closed (tree-dominated - 35% of type in this stage): Tree cover is 41-100%. Aspen trees 5-16 inches dbh. Canopy cover is highly variable. Conifer seedlings and saplings may be present. Replacement fire occurs every 60 years on average. Mixed-severity fire (mean FRI of 40 years), while thinning some trees, promotes suckering and maintains vegetation in this class.

Insect/diseases outbreaks occur every 200 years on average with 80% of times causing stand thinning (transition to class B) and 20% of times causing stand replacement (transition to class A). Conifer encroachment causes a succession to class D after 40 years.

D) Late Development 1 Open (tree-dominated - 10% of type in this stage): Tree cover is 0-40%. Aspen dominate, making up ~80% of the overstory. Conifers which escape fire, or are the more fire-resistant species, are present in the understory and will likely cause the progressive suppression of aspen. Mixed-severity fire (20-year MFI) keeps this stand open, kills young conifers and maintains aspen (max FRI from Baker 1925). Replacement fire occurs every 60 years on average. In the absence of any fire for at least 100 years, the stand will become closed and dominated by conifers (transition to class E).

E) Late Development 1 Closed (conifer-dominated - 1% of type in this stage): Tree cover is 41-80%. Conifers dominate at 100+ years. Aspen over 16 inches dbh, uneven sizes of mixed conifer and main overstory is conifers. Greater than 50% conifer in the overstory. FRI for replacement fire is every 60 years. Mixed-severity fire (mean FRI of 20 years) causes a transition to class D. Insect/disease outbreaks will thin older conifers (transition to class D) every 300 years on average.

From (LANDFIRE 2007a, BpS 1810610): "This is a strongly fire-adapted community, more so than BpS 1011 (Rocky Mountains Aspen Woodland and Forest), with FRIs varying for mixed-severity fire with the encroachment of conifers. It is important to understand that aspen is considered a fire-proof vegetation type that does not burn during the normal lightning season, yet evidence of fire scars and historical studies show that native burning was the only source of fire that occurred mostly during the spring and fall. BpS 1061 has elements of Fire Regime Groups II, III and IV. Mean FRI for replacement fire is every 60 years on average in most development classes. Replacement fire is absent during early development (as for stable aspen, BpS 1011) and has a mean FRI of 100 years between 80 and 100 years in the open condition. The FRI of mixed-severity fire increases from 40 years in stands <100 years to 60 years in stands >100 years with conifer encroachment."

Under presettlement conditions, disease and insect mortality did not appear to have major effects; however, older aspen stands would be susceptible to outbreaks every 200 years on average. We assumed that 20% of outbreaks resulted in heavy insect/disease stand-replacing events (average return interval 1000 years), whereas 80% of outbreaks would thin older trees >40 years (average return interval 250 years). Older conifers (>100 years) would experience insect/disease outbreaks every 300 years on average (LANDFIRE 2007a, BpS 1810610).

Threats/Stressors: In the western U.S., *Populus tremuloides*-dominated and -codominated forests have been utilized primarily for livestock grazing. Stands typically have lush understories because the *Populus tremuloides* tree canopy allows significant light to pass through and sites tend to be relatively mesic (DeByle and Winokur 1985, Howard 1996). Heavy grazing by livestock can deplete or convert an understory dominated by shrubs and forbs to an understory dominated by grazing-tolerant grasses. Degraded stands were often seeded to grazing-tolerant introduced forage species such as *Bromus inermis, Dactylis glomerata, Phleum pratense*, and *Poa pratensis* (DeByle and Winokur 1985). Excessive browsing by livestock or wildlife can also significantly impact regeneration by suckers (DeByle and Winokur 1985, Howard 1996).

Logging, prescribed fire or some other stand-replacing disturbance will convert these conifer - *Populus tremuloides* mixed canopy stands to *Populus tremuloides*-dominated stands because disturbance will generally favor *Populus tremuloides* regeneration (DeByle and Winokur 1985, Howard 1996).

Human development has impacted many locations throughout its range. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES304.790 Inter-Mountain Basins Subalpine Limber-Bristlecone Pine Woodland

CES304.790 CLASSIFICATION

Concept Summary: This ecological system extends from the Mojave Desert and Sierra Nevada across the central Great Basin to the central Wasatch and western Uinta mountains. These open woodlands are typically found on high-elevation ridges and rocky slopes above subalpine forests and woodlands. Site are harsh, exposed to desiccating winds with rocky substrates and a short growing season that limit plant growth. Parent materials include dolomitic, limestone or granitic rocks. Occurrences can be found on all aspects but are more common on southwestern exposures on steep convex slopes and ridges between 2530 and 3600 m (8300-12,000 feet). Stands are strongly dominated by *Pinus flexilis* and/or *Pinus longaeva*. *Pinus monophylla* may be present in lower-elevation stands. If present, shrub and herbaceous layers are generally sparse and composed of xeric shrubs, graminoids and cushion plants. Associated species may include *Antennaria rosea, Arenaria kingii, Artemisia tridentata, Cercocarpus intricatus, Chamaebatiaria millefolium, Cymopterus cinerarius, Elymus elymoides, Erigeron pygmaeus, Eriogonum ovalifolium, Festuca brachyphylla, Koeleria macrantha, Linanthus pungens, Ribes cereum*, or *Ribes montigenum*.

CES304.790 CONCEPTUAL MODEL

Environment: This ecological system extends from the Mojave Desert and eastern Sierra Nevada across the central Great Basin to the central Wasatch and western Uinta mountains. These open woodlands are typically found on high-elevation ridges and rocky slopes above subalpine forests and woodlands, sometimes extending down into the montane zone. Sites are harsh, exposed to desiccating winds, with rocky substrates and a short growing season that limit plant growth. Occurrences can be found on all aspects but are more common on southwestern exposures on steep convex slopes and ridges between 2530 and 3600 m (8300-12,000 feet) elevation. Most sites are droughty, with gravel in the shallow subsurface horizons. Surface textures vary depending upon substrate, which are best represented on colluvium derived from limestone and dolomite or Tertiary and Cretaceous sandstone parent materials. Steep slopes, high-intensity summer convection storms, and only partial ground cover for interception often result in severe sheet erosion of fine particles. This usually leads to the development of gravel pavements. Additional erosion can be expected from wind action. High insolation and wind during the winter usually result in reduced snowpack accumulations. However, soils can be expected to freeze. The sparsity of shrubs, forbs, grasses, and litter, in addition to the widely spaced trees, usually means that fire does not carry easily. Individual trees may be ignited from lightning, but seldom is an entire occurrence burned. The environmental description is based on several other references, including Graybosch and Buchanan (1983), Lanner (1983), Holland (1986b), Holland and Keil (1995), Nachlinger and Reese (1996), Reid et al. (1999), Fryer (2004), Thorne et al. (2007), and Sawyer et al. (2009).

Key Processes and Interactions: Both *Pinus longaeva* and *Pinus flexilis* are slow-growing, long-lived trees that are intolerant of shade. *Pinus longaeva* may attain nearly 4900 years in age and 12 m in height, whereas *Pinus flexilis* may live 1000 years and attain 18 m in height. Bristlecone pine branches retain needles for as long as 30 years, whereas limber pine needles are lost after only several years. Bristlecone pine trees produce dense, resinous wood that is resistant to rot and disease. Mature trees have massive, contorted trunks with mostly dead and gnarled wood (Sawyer et al. 2009). Tree-ring data over the last 4000 years indicate that droughts of 200 years or more have occurred.

Natural regeneration of both species appears to be closely associated with caching of the large wingless seeds, primarily by Clark's nutcracker (*Nucifraga columbiana*) (Lanner and Vander Wall 1980). Germination of cached seeds often results in the multi-stemmed clumps characteristic of these sites, although the species may produce multiple stems from boles damaged near the ground. Germination and rooting will sometimes be restricted to crevices in rock. *Pinus longaeva* has smaller winged seeds and should be wind-disseminated. However, caching by nutcrackers does take place, especially when other *Pinus* species are also available (Dr. R. Lanner pers. comm.). The longevity of individuals enables stands to persist for centuries between times of favorable seedling establishment (Keeley and Zedler 1998). Stands are subject to long, intense droughts.

These pines have relatively thin bark adapted to survive only low-severity surface fires. However, fires seldom destroy stands due to the sparse nature of the canopy cover of trees and abundant bare ground. When fire occurs on high-elevation sites, they are usually small, low-severity surface fires (Bradley et al. 1992).

Pinus longaeva and *Pinus flexilis* are both experiencing mountain pine beetle (*Dendroctonus ponderosae*) infestations throughout much of their ranges (Lanner 1983). Logan and Powell (2001) provide information on the ecology and management of mountain pine beetles in high-elevation ecosystems. Gibson et al. (2008) reported recently detected mortality of *Pinus longaeva* in the Great Basin, including 100 acres in 2005, 60 acres in 2006, and 300 acres in 2007, all within the Snake Range in east-central Nevada (aerial detection surveys). Western dwarf mistletoe (*Arceuthobium campylopodum*) infests Great Basin bristlecone pines in southern Nevada and Utah (Mathiasen and Hawksworth 1990).

Threats/Stressors: Both pine species are five-needle white pines and are also susceptible to the exotic fungus white pine blister rust (*Cronartium ribicola*). The arid climate and isolated stands appear to have protected most *Pinus longaeva* and *Pinus flexilis* from infection in the Great Basin, although an incidental level of the infection was found in the Wasatch Mountains of Utah (Fryer 2004). There is potential for blister rust to spread into arid zones, especially during wet years. This system occurs in the White and Inyo mountains, which lie close to moderately high infestation centers in the Sierra Nevada, and may be at greatest risk for blister rust infestation and spread (Smith and Hoffman 2000).

Pinus longaeva populations are sensitive to fluctuations in climate. Low seedling establishments were documented in eastern Nevada populations during cool, dry periods approximately 900 and 2500-3000 BP (Hiebert and Hamrick 1984b). Effects of current climatic conditions on Great Basin bristlecone pine regeneration are uncertain. Regeneration is generally sparse, and there is concern that climate warming is hindering Great Basin bristlecone pine regeneration on sites in the interior Great Basin (Lanner 1983).

In most high-elevation five-needle pine stands throughout the West, populations of mountain bark beetles have increased dramatically since the late 1990s, and it is anticipated that populations will remain high as long as weather conditions are conducive to beetle survival and/or until most mature host trees have been killed (Gibson et al. 2008). The bark beetles are the most serious short-term threat, but the most serious long-term threat is white pine blister rust, which affects all aspects of the forest regeneration process and will impair ecosystem recovery long after the current beetle epidemic is over (Schoettle and Sniezko 2007a). Logan and Powell (2005) report range expansion into high-elevation, five-needle pines stands and loss of biodiversity.

Conversion of this type has commonly come from mining activities and other very localized removal of stands for various kinds of development, but conversion is not a major factor for this system. However, with loss of *Pinus longaeva* and *Pinus flexilis* trees from non-native white pine blister rust (*Cronartium ribicola*) or epidemics of mountain pine beetle (*Dendroctonus ponderosae*), some stands may be converted to non-tree-dominated vegetation or stands dominated by other tree species. Where infected, white pine blister rust will likely prevent successful stand regeneration.

Common stressors and threats include altered fire regime from fire suppression, fragmentation, and extended drought which may make individuals more susceptible to mortality from non-native white pine blister rust or epidemics of native mountain pine beetle (*Dendroctonus ponderosae*), and invasive non-native plant species. *Pinus longaeva* and *Pinus flexilis* are both experiencing mountain pine beetle infestations throughout much of their ranges (Lanner 1983). *Pinus flexilis* and possibly *Pinus longaeva* are dependent on animals for longer distance dispersal. Threats to these dispersers such as Clark's nutcracker are threats to the regeneration of these pines and the ecosystem in areas with high tree mortality.

Potential climate change effects could include a change in the current extent of the ecosystem with higher tree mortality and lower recruitment if climate change has the predicted effect of less effective moisture with increasing mean temperature (TNC 2013). McKinney et al. (2007) suggest limber pine will increase in area with climate change, but do not consider indirect stresses such as white pine blister rust and increased abundance of mountain pine beetle epidemics with warming climate (Schoettle et al. 2008).

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from loss of characteristic species *Pinus longaeva* and *Pinus flexilis* from white pine blister rust (*Cronartium ribicola*) or epidemics of mountain pine beetle (*Dendroctonus ponderosae*). Where infected, the white pine blister rust will likely prevent successful stand regeneration. Additionally, high-intensity fire may result after years of fire suppression has converted this open woodland ecosystem to a dense forest. These high-severity, stand-replacing fires kill vegetation and create hydrophobic soils that are vulnerable to water erosion during spring snowmelt and summer convective storms. Soil loss limits tree and grass regeneration. Additional surface disturbances allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<300 acres). Fragmentation from roads and/or from harvesting adjacent forests is prevalent. Historic and ongoing fire suppression has extended the fire-return interval and has resulted in a significant increase in tree cover making stands more vulnerable to high-severity, stand-replacing fire that could damage soils and make them less suitable to tree regeneration and more vulnerable to erosions. Moderate-severity environmental degradation appears where occurrences tend to be moderate to small (300-1000 acres). Fragmentation from roads and/or from harvesting adjacent forests is significant, but restorable. Historic and ongoing fire suppression has extended the fire-return interval and has resulted in a significant increase in tree cover making stands more vulnerable to high-severity, stand-replacing fire that could damage soils and make them less suitable to tree regeneration and more vulnerable to erosions.

High-severity disruption appears where occurrences have lost most of the characteristic *Pinus longaeva* and/or *Pinus flexilis* trees from white pine blister rust or epidemics of mountain pine beetle. Additionally, other more shade-tolerant trees such as *Pseudotsuga menziesii* and/or *Abies concolor* have colonized the site with high cover. Invasive non-native species may be abundant. Connectivity is moderately hampered by fragmentation from roads or timber harvests that severely restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species and abundance of animal populations are low when compared to an intact ecosystem. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low. Moderate-severity disruption appears where occurrences have lost many (over half) of the characteristic *Pinus longaeva* and/or *Pinus flexilis* trees from white pine blister rust or epidemics of mountain pine beetle. Additionally, other more shade-tolerant trees, such as *Pseudotsuga menziesii* and/or *Abies concolor* have colonized the site with moderate cover. Invasive non-native species may be present to abundant. Connectivity is moderately hampered by fragmentation from roads or timber harvests that moderately restrict natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species and abundance of animal populations are low when compared to an intact ecosystem.

CES306.807 Northern Rocky Mountain Subalpine Woodland and Parkland

CES306.807 CLASSIFICATION

Concept Summary: This ecological system of the Northern Rockies, Cascade Range, and northeastern Olympic Mountains is typically a high-elevation mosaic of stunted tree clumps, open woodlands, and herb- or dwarf-shrub-dominated openings, occurring above closed forest ecosystems and below alpine communities. It includes open areas with clumps of *Pinus albicaulis*, as well as woodlands dominated by *Pinus albicaulis* or *Larix lyallii*. In the Cascade Range and northeastern Olympic Mountains, the tree clump pattern is one manifestation, but these are also woodlands with an open canopy, without a tree clump/opening patchiness to them; in fact, that is quite common with *Pinus albicaulis*. The climate is typically very cold in winter and dry in summer. In the Cascades and Olympic Mountains, the climate is more maritime in nature and wind is not as extreme. The upper and lower elevational limits, due to climatic variability and differing topography, vary considerably; in interior British Columbia, this system occurs between 1000 and 2100 m elevation, and in northwestern Montana, it occurs up to 2380 m. Landforms include ridgetops, mountain slopes, glacial trough walls and moraines, talus slopes, landslides and rockslides, and cirque headwalls and basins. Some sites have little snow accumulation because of high winds and sublimation. *Larix lyallii* stands generally occur at or near upper treeline on north-facing cirques or slopes where snowfields persist until June or July. In this harsh, often windswept environment, trees are often stunted and flagged from damage associated with wind and blowing snow and ice crystals, especially at the upper elevations of the type. The stands or patches often originate when *Picea engelmannii, Larix lyallii*, or *Pinus albicaulis* colonize a sheltered site such as the lee side of a rock. *Abies lasiocarpa* can then colonize in the shelter of the *Picea engelmannii* and may form a dense canopy by branch-layering. Major disturbances are windthrow and snow avalanches. Fire is known to occur infrequently in this system, at least where woodlands are present; lightning damage to individual trees is common, but sparse canopies and rocky terrain limit the spread of fire.

These high-elevation coniferous woodlands are dominated by *Pinus albicaulis, Abies lasiocarpa*, and/or *Larix lyallii*, with occasional *Picea engelmannii*. In the Cascades and Olympics, *Abies lasiocarpa* sometimes dominates the tree layer without *Pinus albicaulis*, though in this dry parkland *Tsuga mertensiana* and *Abies amabilis* are largely absent. The undergrowth is usually somewhat depauperate, but some stands support a near sward of heath plants, such as *Phyllodoce glanduliflora, Phyllodoce empetriformis, Empetrum nigrum, Cassiope mertensiana*, and *Kalmia polifolia*, and can include a slightly taller layer of *Ribes montigenum, Salix brachycarpa, Salix glauca, Salix planifolia, Vaccinium membranaceum, Vaccinium myrtillus*, or *Vaccinium scoparium* that may be present to codominant. The herbaceous layer is sparse under dense shrub canopies or may be dense where the shrub canopy is open or absent. *Vahlodea atropurpurea, Luzula glabrata var. hitchcockii*, and *Juncus parryi* are the most commonly associated graminoids.

In the mountains of northwestern and west-central Wyoming, where this upper-treeline system reaches the edge of its geographic range, the vegetation usually has the form of an open woodland, and only rarely as scattered groves of trees. At the highest elevations, *Pinus albicaulis* usually has a wind-stunted shrub form. On lower, more favorable sites, upright but wind-shaped *Pinus albicaulis* forms woodlands, sometimes with *Pinus contorta* as a codominant or even the dominant species. With decreased altitude, where this system merges into the subalpine forests, *Picea engelmannii* and *Abies lasiocarpa* become common tree species as well.

CES306.807 CONCEPTUAL MODEL

Environment: This ecological system of the Northern Rockies, Cascade Range, and northeastern Olympic Mountains is typically a high-elevation mosaic of stunted tree clumps, open woodlands, and herb- or dwarf-shrub-dominated openings, occurring above closed forest ecosystems and below alpine communities. The upper and lower elevational limits, due to climatic variability and differing topography, vary considerably from 1000-3200 m depending on latitude. In interior British Columbia, this system occurs between 1000 and 2100 m elevation, and in northwestern Montana, it occurs up to 2380 m. In west-central Wyoming, this system occurs on various landforms over an elevational range from 2230 to 3200 m (Steele et al. 1983).

Climate: The climate is typically very cold in winter and dry in summer. Mean annual precipitation ranges from 60-180 cm, occurring mostly in the winter. Yearly snow accumulations are often over 3 m in the northern Cascades and 2-3 m in the Rockies. Some sites have little snow accumulation because of high winds and sublimation. In the Cascades and Olympic Mountains, the climate is more maritime in nature and wind is not as extreme.

Physiography/Landform: Landforms include ridgetops, mountain slopes, glacial trough walls and moraines, talus slopes, landslides and rockslides, and cirque headwalls and basins. Sites may be nearly level to steep sloping, on all aspects. Some stands occur at treeline in mesic, protected pockets away from the extremely harsh environmental conditions. It is not tied to particular aspects (Steele et al. 1983).

Soil/substrate/hydrology: Soils are generally lithic, well-to excessively drained, and coarse-textured such as shallow, gravelly sands or loams, but may include silt and clay loams. Soils are derived from colluvium, glacial till and residuum from a variety of volcanic, igneous, sedimentary and metamorphic geologic formations.

Key Processes and Interactions: *Pinus albicaulis* is a slow-growing, long-lived conifer that is common at higher elevations in the upper subalpine zone. It typically occurs in a mosaic of tree islands and meadows where it often colonizes sites and creates habitat for less hardy tree species. In lower subalpine forests, it is a seral species, establishing after a large disturbance such as stand-replacing fire or avalanche, or it is restricted to dry, rocky ridges where it competes well with shade-tolerant tree species. Without disturbance it will be overtopped in 100-120 years by faster growing, shade-tolerant species such as *Abies lasiocarpa, Picea engelmannii, Pseudotsuga menziesii*, and *Tsuga mertensiana*. Although crown fires and hot ground fires kill *Pinus albicaulis*, it tolerates low-intensity ground fires that will kill the shade-tolerant understory. Fire intervals range from 30-300 years.

In this harsh, often windswept environment, trees are often stunted and flagged from damage associated with wind and blowing snow and ice crystals, especially at the upper elevations of the type. The stands or patches often originate when *Picea engelmannii, Larix lyallii*, or *Pinus albicaulis* colonize a sheltered site such as the lee side of a rock. *Abies lasiocarpa* can then colonize in the shelter of the *Picea engelmannii* and may form a dense canopy by branch-layering. Major disturbances are windthrow and snow avalanches. Fire is known to occur infrequently in this system, at least where woodlands are present; lightning damage to individual trees is common, but sparse canopies and rocky terrain limit the spread of fire. *Larix lyallii* is a very slow-growing, long-lived tree, with individuals up to 1000 years in age. It is generally shade-intolerant; however, extreme environmental conditions limit potentially competing trees. In the Cascades and Olympic Mountains, the climate is more maritime in nature and wind is not as extreme, but summer drought is a more important process than in the related ~North Pacific Maritime Mesic Subalpine Parkland (CES204.837)$$. In northwestern and west-central Wyoming, *Pinus albicaulis* is the initial colonizer, and trees of other species become established in the micro-sites that it creates (Callaway 1998, cited in Greater Yellowstone Coordinating Committee 2011). In the highest-elevation stands where *Pinus albicaulis* usually is the only tree present, vegetation dynamics are relatively simple: stands start out with rather dense overstories and sparse undergrowth and develop more open overstories and denser undergrowth over time. At lower elevations, *Pinus contorta* dominates some stands soon after fire, and the long-lived, more shade-tolerant *Pinus albicaulis* become dominant over time (Steele et al. 1983). As in the Pacific Northwest, fire has, in the past, been a minor process (compared to the subalpine forests at lower elevations): lightning starts many fires, but they rarely spread (Steele et al. 1983).

Birds and small mammals often eat and cache the large, wingless pine seeds and are responsible for the dispersal of this species. Most important is the Clark's nutcracker, which can transport the seeds long distances and cache them on exposed windswept and burned-over sites. This results in the regeneration of pines in clumps from forgotten caches (Eyre 1980, Burns and Honkala 1990a, Schmidt and McDonald 1990, Steel et al. 1983).

The mountain pine beetle (*Dendroctonus ponderosae*) has killed many mature trees in the past, during epidemics where populations of the beetles build up in lower elevation *Pinus contorta* stands, then move up into the *Pinus albicaulis* (Burns and Honkala 1990a, Schmidt and McDonald 1990, Steel et al. 1983).

Threats/Stressors: From WNHP (2011): The primary land uses that alter the natural processes of this system are associated with exotic species, direct soil surface disturbance, timber management, livestock practices, and fragmentation. The introduced pathogen white pine blister rust (*Cronartium ribicola*) increases *Pinus albicaulis* mortality in these woodlands (Kendall and Keane 2001) and changes fire regime, mountain pine beetle (*Dendroctonus ponderosae*) effects and successional relationships. Exotic species threatening this ecological system through invasion and potential replacement of native species include *Poa pratensis*. Excessive grazing stresses the system through soil disturbance and perennial layers to the establishment of native disturbance-increasers (*Lupinus* spp., *Juncus parryi, Achillea millefolium*) in similar Northern Rocky Mountain systems (Johnson 2004). Persistent grazing will further diminish native perennial cover, expose bare ground, and increase erosion and exotics (Johnson and Swanson 2005). Grazing effects are usually concentrated in less steep slopes, although grazing does create contour trail networks that can lead to addition slope failures. Cattle and heavy use by elk can reduce fescue cover and lead to erosion during summer storms (Johnson and Swanson 2005). Introduction of exotic ungulates can have noticeable impacts (e.g., mountain goats in the Olympic Mountains and domestic sheep grazing in the bunchgrass habitats east of the Cascades). Historical domestic sheep grazing may have occurred in these systems but its cumulative effects are unknown (Landfire 2007a). Locally, trampling and associated recreational impacts can affect sites for decades or longer (Lillybridge et al. 1995). Sites are naturally low in timber productivity and in stocking rates such that removal of trees can have very long-lasting influence on ecological processes (Lillybridge et al. 1995).

Conversion of this type has commonly come from conversion to invasive non-native species such as *Poa pratensis*, which increase post disturbance including long-term excessive grazing by livestock, or direct soil disturbance from timber management, heavy recreational use, severe trampling by livestock, and roads. However, conversion is not a major factor for this system.

Common stressors and threats include fragmentation from roads, altered fire regime from fire suppression, and indirectly from livestock grazing and fragmentation the introduction of invasive non-native species (WNHP 2011). The introduced pathogen white pine blister rust causes considerable *Pinus albicaulis* mortality in these woodlands and parklands (Kendall and Keane 2001). Mountain pine beetle epidemics also cause significant *Pinus albicaulis* mortality, especially during dry years. *Pinus albicaulis* are large-seeded trees and are dependent on animals for longer distance dispersal. Threats to these dispersers such as Clark's nutcracker are threats to the regeneration of these pines and the ecosystem.

In this system in Wyoming and eastern Idaho (Steele et al. 1983), livestock grazing likely is a minor threat because there is little forage. Grazers can, though, easily degrade forb-dominated undergrowths, but the vegetation where *Vaccinium scoparium* dominates (as it does in a high proportion of stands) appears to be less susceptible to grazing and, in fact, has been shown to withstand heavy grazing by deer and elk. In Wyoming, 59% of the area predicted to support whitebark pine is within designated national forest wilderness areas or national parts (WNDD 2013). In the Greater Yellowstone area of Wyoming, Montana, and Idaho, 62% of the whitebark pine is within national parks or wilderness areas (Macfarlane et al. 2009, Appendix A; these authors apparently neglected to include 2 wilderness areas in Wyoming, so that percentage likely is higher). Hence a large percentage of this ecological system apparently is in areas managed to minimize threats. Heavy recreational use can damage undergrowth vegetation and cause soil erosion so severe that it prevents restoration (Steele et al. 1983), but such impacts likely are limited to few stands because of the management status of the lands and because, even outside of protected areas, *Pinus albicaulis* woodlands are largely inaccessible to most people.

White pine blister rust is a very serious threat, as only 26% of the *Pinus albicaulis* trees in the Greater Yellowstone area show resistance (Greater Yellowstone Coordinating Committee 2011). Monitored plots show infection rates ranging from 0-84% of trees and averaging 20% (several studies cited in Greater Yellowstone Coordinating Committee 2011). Because of blister rust, restoration projects in eastern Idaho and western Montana have failed to produce significant regeneration of *Pinus albicaulis* (Keane and Parsons 2010, cited in Rice et al. 2012). Mountain pine beetle, too, is a major threat to this ecological system in the Greater Yellowstone area. Aerial surveys in 2009 revealed that 50% of *Pinus albicaulis* stands had suffered severe to complete mortality of pines, and 95% of forest stands containing *Pinus albicaulis* had measurable pine beetle activity (Macfarlane et al. 2009, cited in Rice et al. 2011). Several species of *Dendroctonus* have also killed great numbers of *Pinus contorta* and *Picea engelmannii*, other constituents of the vegetation in this ecological system in the area.

Potential climate change effects in the Pacific Northwest region are based on downscaled climate models projecting increases in annual temperature of, on average, 3.2°F by the 2040s. Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models (Littell et al. 2009). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. This change will result in less winter snow accumulation, higher winter streamflows, earlier spring snowmelt, earlier peak spring streamflow, and lower summer streamflows in rivers that depend on snowmelt (Littell et al. 2009). These potential changes in climate could include Increased fire frequency due to warmer temperatures resulting in drier fuels; the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009). Additionally, likely climatic warming may stress host trees, so mountain pine beetle outbreaks are projected to increase in frequency and cause increased tree mortality. Finally, the amount of habitat with climate ranges required for these subalpine tree species, especially *Pinus albicaulis* which is susceptible to mountain pine beetle, will likely decline substantially by mid 21st century.

The ways in which the climate in the region where this system reaches its eastern limit is likely to change, and the effects of those changes on the structure and function of this system, are all hard to predict, and only broad generalizations can be made (Rice et al. 2012). Average annual temperature likely will increase by 1.7°C by 2050, and by 1.1° to 5.5°C by the end of this century. Annual precipitation may increase by 10%, with wetter winters and drier summers, but less certainty can be assigned to possible precipitation changes than temperature changes. The greatest direct impact of these changes on this ecological system likely would be that *Pinus albicaulis* retreats from the lower-elevation parts of its range and exists only at the highest elevations or disappears. Climate changes will also affect the ecological system indirectly, through changes in the fire regime (in general, more frequent and larger fires are likely), bark beetle populations, blister rust populations, and other ecological agents. Changes in the extremes of

temperature and precipitation likely will have a stronger effect than will changes in annual averages, and the patterns of these extremes are especially hard to predict. Climate changes almost certainly will disrupt the composition, structure, and function of the parkland ecological system, in ways that can only be very generally anticipated.
Ecosystem Collapse Thresholds: Ecological collapse tends to result from increased fire frequency that may remove tree species from this forest and parkland system. Additionally, severe overgrazing where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances allow invasive non-native species such as *Poa pratensis* to become established and outcompete and replace the dominant native perennial herbaceous species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<10 acres) and have evidence of excessive livestock grazing (low perennial herbaceous cover) and/or soil disturbance from vehicles or heavy recreational use resulting in soil compaction and sheet and rill erosion (WNHP 2011). Examples of soil disturbance include where wheel tracks or depressions are evident and deep, forest-floor layers are missing, surface soil is removed through gouging or piling, surface soil is displaced, soil burn severity from prescribed fires is high (white or reddish ash, all litter completely consumed, and soil structureless), soil compaction is persistent and deep (greater than 12 inches), and/or soil structure is changed from undisturbed and is platy or massive throughout (WNHP 2011); in addition, there is severe departure from historic fire regime (FRCC 3). Fire suppression may be evident with fuel laddering throughout much of the stand (WNHP 2011) or frequent fire (fire-return interval <50 years) maintains stands in an early-seral state (Landfire 2007a). Landscape Condition Model Index <0.65 (WNHP 2011). Moderate-severity environmental degradation appears where occurrences are moderate (10 -110 acres) in size and have evidence of heavy to moderate livestock grazing (low perennial herbaceous cover) and/or soil disturbance from vehicles or moderate recreational use resulting in soil compaction and sheet and rill erosion (WNHP 2011). Examples of soil disturbance include where wheel tracks or depressions are evident and moderately deep, forest-floor layers are partially missing, surface soil partially intact and maybe mixed with subsoil, soil burn severity from prescribed fires is moderate (black ash evident and water repellency may be increased compared to preburn condition), soil compaction is moderately deep (up to 12 inches), and/or soil structure is changed from undisturbed conditions and may be platy or massive (WNHP 2011); in addition, there is slight to moderate departure from historic fire regime (FRCC 2) (WNHP 2011). Landscape Condition Model Index 0.79 - 0.65 (WNHP 2011).

High-severity disruption appears where occurrences have low cover of native plant species (<50% relative cover) and invasive non-native species are abundant (>10% absolute cover) (WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or forest management practices that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Vegetation is severely altered from reference standard. Expected strata are absent or dominated by ruderal ("weedy") species, or comprised of planted stands of non-characteristic species, or unnaturally dominated by a single species (WNHP 2011). Introduced pathogens such as white pine blister rust are significantly affecting forest structure beyond NRV (WNHP 2011). Most or all indicator/diagnostic species are absent (WNHP 2011). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem (WNHP 2011). Moderate-severity disruption appears where occurrences have low cover of native plant species (50-80% relative cover) and invasive non-native species are abundant (3-10% absolute cover) (WNHP 2011). Connectivity is moderately reduced by fragmentation from roads and/or forest management practices that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Species diversity/abundance is different from reference standard condition, but still largely composed of native species characteristic of the type. This may include ruderal ("weedy") species. Introduced pathogens such as white pine blister rust are significantly affecting forest structure beyond NRV (WNHP 2011). Some to many indicator/diagnostic species may be absent (WNHP 2011). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES303.957 Northwestern Great Plains Highland White Spruce Woodland

CES303.957 CLASSIFICATION

Concept Summary: This uncommon system is limited to relatively high-elevation outliers of montane environments in the northwestern Great Plains. Best known areas of this system are small portions of the Black Hills of Wyoming and South Dakota and the Cypress Upland of southern Alberta and Saskatchewan. These highland areas have a cooler climate than surrounding mixedgrass prairie. In the Black Hills, these woodlands occur as small or large patches within the ponderosa pine matrix, from about 1740 to

2135 m (5700-7000 feet); at lower elevations, they are restricted to north-facing slopes. At the higher elevations, they are found on level or gently sloping areas. In other locations, this woodland system is limited to sideslopes and depressions, likely adjoining riparian zones, where snow is well-retained. Soils vary widely from deep to quite shallow. *Picea glauca* is the characteristic conifer, but other trees can include *Pinus ponderosa, Populus tremuloides*, and *Betula papyrifera*. Undergrowth shrubs typically include *Arctostaphylos uva-ursi, Juniperus communis, Linnaea borealis, Symphoricarpos albus*, and *Vaccinium scoparium*. Disturbance regimes are not well-documented for this system, but likely include periodic windthrow as well as fire spreading from adjacent, lower elevation woodlands and grasslands.

Related Concepts:

Distribution: This system is limited to relatively high-elevation outliers of montane environments in the northwestern Great Plains. Best known areas of this system are small portions of the Black Hills of Wyoming and South Dakota and the Cypress Upland of southern Alberta and Saskatchewan. It may also occur in very small stands of the Bighorn Mountains of north-central Wyoming and south-central Montana.

CES303.957 CONCEPTUAL MODEL

Environment: This system is limited to relatively high-elevation outliers of montane environments in the northwestern Great Plains of the U.S. and southern Canada. These highland areas have a cooler and more mesic climate than surrounding mixedgrass prairie. In the Black Hills, these woodlands occur as small or large patches within the ponderosa pine matrix, from about 1740 to 2135 m (5700-7000 feet) elevation; at lower elevations, they are restricted to north-facing slopes. At the higher elevations, they are found on level or gently sloping areas. In other locations, this woodland system is limited to sideslopes and depressions, likely adjoining riparian zones, where snow is well-retained. Geology is generally dominated by limestone, granite, slate and schist. Soils vary widely from deep to quite shallow. In the Cypress Hills of Alberta and Saskatchewan, the elevations where this system is found range up to 1466 m; generally these woodlands occur on north-facing slopes or near small springs and seeps.

Key Processes and Interactions: Disturbance regimes are not well-documented for this system, but likely include periodic windthrow as well as fire spreading from adjacent, lower elevation or drier woodlands and grasslands. There is some debate about whether mixed-severity fire would have occurred in this type based on tree-ring and historical evidence; estimated at a 100-year return interval (Landfire 2007a). Stand-replacing disturbances are primarily associated with climatic fluctuations and include fire and insect (in late-development classes only, mountain pine beetles create larger patch sizes; Ips beetles create smaller patches). Snowbreak and windthrow events may occur. The majority of the insect outbreaks generally occur in late-development stands but in periods of drought (such as that which the forest is currently experiencing), tree mortality is occurring in ponderosa pine that are less than 18 cm (7 inches) dbh. Surface and stand-replacing fire events occur in this system. Stand-replacing fires were likely most common in higher elevation and northern slopes that were primarily dominated by spruce, with surface fires occurring most often in the moist ponderosa pine.

Threats/Stressors: Conversion of this type has commonly come from logging or clearing for rangeland. This is not a heavily converted ecosystem. Historically, without fire suppression, it is expected that there would have been much less spruce than what currently exists on the landscape today in the U.S. part of the system's range Landfire (2007a). It is also expected that there is a greater canopy cover of conifer species (ponderosa pine and spruce) and less canopy cover of hardwoods (such as aspen and birch) and grassland openings (refer to historical photos from 1874 (Graves 1899) to current photos of the same areas). With denser canopies of conifers it is generally expected that there is less herbaceous understory growth than occurred historically with a less dense canopy. Other stressors include livestock grazing, mining, logging, oil and gas development in the adjacent foothills, fragmentation by roads, outdoor recreation, and tourism activity (Marriott et al. 1999). The Black Hills are considered the most productive timber source in the region, with harvesting occurring throughout; gold mining has also been a pervasive activity since the 1880s (Marriott et al. 1999). Recreational use in the Black Hills is also heavy; similar usage probably occurs in the Cypress Uplands. These highland "island forests" in the midst of the Great Plains grasslands are attractive to people because of their scenic and wildlife values, and valuable contributions of water to the surrounding lowlands. Invasive exotics are likely to occur in this system, but no documentation of such was found; probable species would include perennial (pasture) grasses associated with relatively mesic sites such as *Poa pratensis* and *Bromus inermis*.

Over the century to 2100, climate scenarios for Saskatchewan suggest (Henderson et al. 2002, Barrow 2009): a warmer climate - temperatures may generally rise 2° to 4°F; a longer growing season, but drier, despite an increase in precipitation. This is a result of increased summer temperatures and increased evapotranspiration. Expect more frequent and more intense extreme events (e.g., heavy precipitation or drought). Droughts will likely increase in intensity and frequency.

Henderson et al. (2002) project that by the 2050s natural regeneration of aspen, lodgepole pine or white spruce is very unlikely to be possible outside of very localized sites within the Cypress Hills. The future landscape is likely to be one of small patches of stressed woodland persisting only in the most favorable sheltered sites. By the 2080s it is very possible that there will be no regeneration of spruce or lodgepole anywhere in the hills. Alternatively, a few sheltered coulee slopes may remain moist enough to prevent complete extirpation of extant tree species. Lodgepole stands will be increasingly vulnerable to mountain pine beetle attack.

It is widely believed that periods of very cold winter weather act as an effective control on mountain pine beetle outbreaks. Periods of sanitizing cold are already less frequent. Spruce budworm attack is also possible, which could affect white spruce stands. There is a great and increasing risk of catastrophic fire. It is possible that post-burn forest regeneration would be slow and patchy even under today's climate conditions, as conditions are already drier than those under which the existing forest developed. Regeneration will be ever more difficult in future.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from a severe departure from historic fire regime, fire suppression is evident, fuel laddering is severe and throughout much of stand; the occurrence is embedded in <10% natural habitat; occurrences are small in size (less than 50 ha) and surrounded by non-natural land uses; exotic plant species have >10% absolute cover, and native plants have <50% cover; indicator or diagnostic species are absent, remaining native species are weedy; many, if not all, old (>150 years) *Picea glauca* trees have been harvested and remaining trees are of a single age class and younger than 100 years; connectivity between stands has been eliminated or reduced due to intervening areas of human land uses (adapted from WNHP 2011).

Environmental Degradation (adapted from WNHP 2011): High-severity environmental degradation appears where occurrence is less than 50 ha in size; the occurrence is no longer in a native land cover landscape, <10% natural or semi-natural habitat in surroundings; fire is no longer occurring or occurs too frequently, there is severe departure from the historic regime (FRCC = 3); fire suppression is evident; fuel laddering is severe and throughout much of stand. Moderate-severity appears where occurrence is 50-500 ha in size; embedded in 10-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2); evidence of at least one low- to moderate-severity fire since 1900 (Euro-American settlement period); fuel laddering may be present in these areas.

Disruption of Biotic Processes (adapted from WNHP 2011): High-severity disruption of biotic processes appears where greater than 10% absolute cover of exotic invasives; non-native species dominate understory with minor native component (native species relative cover in shrub and herb layers <50%); native increasers (indicative of grazing or soil disturbance) have >20% relative cover; many, if not all, old (>150 years) *Picea glauca* trees have been harvested; most or all indicator/diagnostic species are absent; native species consist mostly of weedy species; occurrences are fragmented, connectivity is essentially gone. Moderate-severity appears where exotic invasives prevalent with 3-10% absolute cover; native species have 50 to <85% cover, native bunch grasses have 25-50% cover; native increasers (indicative of grazing or soil disturbance) have 10-20% cover; non-natives can be codominant; many (over 50%) old (>150 years) *Picea glauca* trees have been harvested; native species characteristic of the type remain present but weedy (pioneer, early-successional) native species that develop after clearcutting or clearing are dominant; many indicator/diagnostic species may be absent.

CES306.813 Rocky Mountain Aspen Forest and Woodland

CES306.813 CLASSIFICATION

Concept Summary: This widespread ecological system is more common in the southern and central Rocky Mountains but occurs in the montane and subalpine zones throughout much of the western U.S. and north into Canada. An eastern extension occurs along the Rocky Mountains foothill front and in mountain "islands" in Montana (Big Snowy and Highwood mountains), and the Black Hills of South Dakota. In California, this system is only found on the east side of the Sierra Nevada adjacent to the Great Basin. Large stands are found in the Inyo and White mountains, while small stands occur on the Modoc Plateau. In western Alberta, it occurs only in the Upper Foothills subregion, and north of there transitions to ~Western North American Boreal Mesic Birch-Aspen Forest (CES105.108)$$. Elevations generally range from 1525 to 3050 m (5000-10,000 feet), but occurrences can be found at lower elevations in some regions, especially in the Canadian Rockies. Distribution of this ecological system is primarily limited by adequate soil moisture required to meet its high evapotranspiration demand. Secondarily, it is limited by the length of the growing season or low temperatures. These are upland forests and woodlands dominated by *Populus tremuloides* without a significant conifer component (<25% relative tree cover). The understory structure may be complex with multiple shrub and herbaceous layers, or simple with just an herbaceous layer. The herbaceous layer may be dense or sparse, dominated by graminoids or forbs. In California, *Symphyotrichum spathulatum* is a common forb. Associated shrub species include *Symphoricarpos* spp., *Rubus parviflorus, Amelanchier alnifolia*, and *Arctostaphylos uva-ursi*. Occurrences of this system originate and are maintained by stand-replacing disturbances such as avalanches, crown fire, insect outbreak, disease and windthrow, or clearcutting by man or beaver, within the matrix of conifer forests. It differs from ~Northwestern Great Plains Aspen Forest and Parkland (CES303.681)$$, which is limited to plains environments. In Texas, this system occurs as small patches within the higher elevation conifer systems of the Guadalupe, Davis, and Chisos mountains. These patches are considered relictual remnants in this southwestern extension of this more commonly encountered type further north.

Distribution: This system is more common in the central and southern Rocky Mountains extending south to the Sacramento Mountains, however, it occurs in the montane and subalpine zones throughout much of the western U.S. and north into Canada, as well as west into California. Elevations generally range from 1525 to 3050 m (5000-10,000 feet), but occurrences can be found at lower elevations in some regions. Very small occurrences may be found in a few scattered locations of the Trans-Pecos of Texas.

CES306.813 CONCEPTUAL MODEL

Environment: This widespread montane and subalpine ecological system is more common in the central and southern Rocky Mountains extending south to the Sacramento Mountains of New Mexico, west into the high plateaus of the Colorado Plateau and ranges of the Great Basin into the eastern Sierra Nevada, and north into the Canadian Rockies. Eastern extensions occur along the Rocky Mountains foothill front and in mountain "islands" in Montana (Big Snowy and Highwood mountains), and the Black Hills of South Dakota. Very small occurrences may be found in a few scattered locations of the Trans-Pecos of Texas. Elevations generally range from 1525 to 3050 m (5000-10,000 feet), but occurrences can be found at lower elevations in some regions. Climate is temperate with a relatively long growing season, typically cold winters and deep snow. Mean annual precipitation is greater than 38 cm (15 inches) and typically greater than 51 cm (20 inches), except in semi-arid environments where occurrences are restricted to mesic microsites such as seeps or large snow drifts. Distribution of this ecological system is primarily limited by adequate soil moisture required to meet its high evapotranspiration demand (Mueggler 1988). Secondarily, its range is limited by the length of the growing season or low temperatures (Mueggler 1988). Topography is variable; sites range from level to steep slopes. Aspect varies according to the limiting factors. Occurrences at high elevations are restricted by cold temperatures and are found on warmer southern aspects. At lower elevations occurrences are restricted by lack of moisture and are found on cooler north aspects and mesic microsites. The soils are typically deep and well-developed, with rock often absent from the soil. Soil texture ranges from sandy loam to clay loam. Parent materials are variable and may include sedimentary, metamorphic or igneous rocks, but it appears to grow best on limestone, basalt, and calcareous or neutral shales (Mueggler 1988). In Texas, this system occurs on high mountain slopes, valleys and ridges at higher elevations on Permian limestone (Guadalupe Mountains) and igneous substrates (Davis and Chisos mountains). The environmental description is based on several other references, including Henderson et al. (1977), Bartos (1979), Bartos and Mueggler (1979), Eyre (1980), Hess and Wasser (1982), DeByle and Winokur (1985), Johnston and Hendzel (1985), Youngblood and Mauk (1985), DeVelice et al. (1986), Mueggler (1988), Powell (1988a), Knight (1994), Shiflet (1994), Bartos and Campbell (1998), Reid et al. (1999), Neely et al. (2001), Comer et al. (2002), Tuhy et al. (2002), Minnich (2007), and NatureServe Explorer (2009).

Key Processes and Interactions: Occurrences in this ecological system often originate, and are likely maintained by, stand-replacing disturbances such as crown fire, disease and windthrow, or clearcutting by man or beaver. The stems of these thin-barked, clonal trees are easily killed by surface fires, but they can quickly and vigorously resprout in densities of up to 30,000 stems per hectare (Knight 1994). As dbh increases beyond 15 cm, *Populus tremuloides* stems become increasingly resistant to fire mortality, and large stems may survive low-severity surface fire but usually show fire damage (Brown and DeByle 1987). The stems are relatively short-lived (100-150 years), and the stand will succeed to longer-lived conifer forest if undisturbed. Occurrences are favored by fire in the conifer zone (Mueggler 1988). With adequate disturbance a clone may live many centuries. Although *Populus tremuloides* produces abundant seeds, seedling survival is rare because the long moist conditions required to establish them are rare in the habitats that it occurs in. Superficial soil drying will kill seedlings (Knight 1994).

Although many diseases and insects attack *Populus tremuloides* (DeByle and Winokur 1985), under presettlement conditions, disease and insect mortality did not appear to have major effects; however, older aspen stands would be susceptible to outbreaks every 200 years on average (LANDFIRE 2007a, BpS:1210110). Sudden aspen decline (SAD) results in root mortality with subsequent effects on tree canopy and clone persistence. It appears to be triggered by severe drought (Worrall et al. 2010).

This system is also important habitat and browse for many species of wildlife, including various birds, beaver, snowshoe hare and large ungulates such as deer, elk and moose (DeByle and Winokur 1985). Concentrated use by elk can significantly impact stands (DeByle and Winokur 1985).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has three classes in total (LANDFIRE 2007a, BpS 2810110). These are summarized as:

A) Early Development 1 All Structures (5% of type in this stage): Aspen suckers less than 6 feet tall and abundant. Grasses and forbs resprout vigorously with high cover. Often densely vegetated.

B) Mid Development 1 Closed (pole-sized tree-dominated - 35% of type in this stage): Tree cover is 21-100%. Aspen over 6 feet tall dominate. Canopy cover highly variable, but usually dense. Understory also usually dense.

C) Late Development 1 Closed (tree-dominated - 60% of type in this stage): Tree cover is 21-100%. Aspen trees 9+ inches dbh. Canopy cover is highly variable, but usually dense. Understory dense. Lots of dead and downed material.

Fire, insects and disease. In absence of disturbance, may stay aspen. Fire will generally come from adjacent systems. Surface fire would generally affect the margins of stands as a result of fire on adjacent vegetation types. Mixed fire may occur, but is undocumented (LANDFIRE 2007a, BpS 2810110).

Threats/Stressors: In the western U.S., *Populus tremuloides* forests have been utilized primarily for livestock grazing and to a lesser extent harvested for wood products. Stands typically have lush understory because tree canopy allows significant light to pass through, and sites tend to be relatively mesic (DeByle and Winokur 1985, Howard 1996). Heavy grazing by livestock can deplete or convert an understory dominated by shrubs and forbs to an understory dominated by grazing-tolerant grasses. Degraded stands were often seeded to grazing-tolerant introduced forage species such as *Bromus inermis, Dactylis glomerata, Phleum pratense*, and *Poa pratensis* (DeByle and Winokur 1985). Excessive browsing by livestock or wildlife can also significantly impact regeneration by suckers (DeByle and Winokur 1985, Howard 1996).

Harvesting *Populus tremuloides* trees greatly stimulates regeneration by suckering. Stand structure is obviously affected depending on silviculture treatment (clearcut versus partial cut) and management objectives (DeByle and Winokur 1985). Prescribed burning can also regenerate stands (DeByle and Winokur 1985, Howard 1996). Introduced species can be brought in during logging operations and other management actions that disturbed soil.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES306.814 Rocky Mountain Bigtooth Maple Ravine Woodland

CES306.814 CLASSIFICATION

Concept Summary: This ecological system occurs in cool ravines, on toeslopes and slump benches associated with riparian areas in the northern and central Wasatch Range and Tavaputs Plateau extending into southern Idaho, as well as in scattered localities in southwestern Utah, central Arizona and New Mexico. Substrates are typically rocky colluvial or alluvial soils with favorable soil moisture. These woodlands are dominated by *Acer grandidentatum* but may include mixed stands codominated by *Quercus gambelii* or with scattered conifers. Some stands may include *Acer negundo* or *Populus tremuloides* as minor components. It also occurs on steeper, north-facing slopes at higher elevations, often adjacent to ~Rocky Mountain Gambel Oak-Mixed Montane Shrubland (CES306.818)$$ or ~Rocky Mountain Aspen Forest and Woodland (CES306.813)$$.

Related Concepts:

- Bigtooth Maple (418) (Shiflet 1994) =

Distribution: Occurs in the northern and central Wasatch Range and Tavaputs Plateau extending into southern Idaho, as well as in scattered localities in southwestern Utah, central Arizona and New Mexico.

CES306.820 Rocky Mountain Lodgepole Pine Forest

CES306.820 CLASSIFICATION

Concept Summary: This ecological system is widespread in upper montane to subalpine elevations of the Rocky Mountains, Intermountain West region, north into the Canadian Rockies and east into mountain "islands" of north-central Montana. These are subalpine forests where the dominance of *Pinus contorta* is related to fire history and topo-edaphic conditions. Following stand-replacing fires, *Pinus contorta* will rapidly colonize and develop into dense, even-aged stands. Most forests in this ecological system occur as early- to mid-successional forests which developed following fires. This system includes *Pinus contorta*-dominated stands that, while typically persistent for >100-year time frames, may succeed to spruce-fir; in the southern and central Rocky Mountains it is seral to ~Rocky Mountain Subalpine Dry-Mesic Spruce-Fir Forest and Woodland (CES306.828)$$. More northern occurrences are seral to ~Rocky Mountain Subalpine Mesic-Wet Spruce-Fir Forest and Woodland (CES306.830)$$. Soils supporting these forests are typically well-drained, gravelly, coarse-textured, acidic, and rarely formed from calcareous parent materials. These forests are dominated by *Pinus contorta* with shrub, grass, or barren understories. Sometimes there are intermingled mixed conifer/*Populus tremuloides* stands, with the latter occurring with inclusions of deeper, typically fine-textured soils. The shrub stratum may be conspicuous to absent; common species include *Arctostaphylos uva-ursi, Ceanothus velutinus, Linnaea borealis, Mahonia repens, Menziesia ferruginea* (in northern occurrences), *Purshia tridentata, Rhododendron albiflorum* (in northern occurrences), *Spiraea betulifolia, Spiraea douglasii, Shepherdia canadensis, Vaccinium cespitosum, Vaccinium scoparium, Vaccinium membranaceum, Symphoricarpos albus*, and *Ribes* spp. In southern interior British Columbia, this system is usually an open lodgepole pine forest found extensively between 500 and 1600 m elevation in the Columbia Range. In the Interior Cedar Hemlock and Interior Douglas-fir zones, *Tsuga heterophylla* or *Pseudotsuga menziesii* may be present. In Alberta, species composition indicates the transition to more boreal floristics, including such species as *Empetrum nigrum, Ledum groenlandicum, Leymus innovatus*, and more abundant lichens or mosses such as *Cladonia* spp., *Hylocomium splendens*, and *Pleurozium schreberi*.

Distribution: This system occurs at upper montane to subalpine elevations of the Rocky Mountains, Intermountain West region, north into the Canadian Rockies, and east onto mountain "islands" of north-central Montana. In Washington, this system occurs mostly on the east side of the Cascade Crest. In Oregon, this system only occurs in the Blue Mountains; all Oregon Cascades lodgepole pine forests are included in other systems.

CES306.820 CONCEPTUAL MODEL

Environment: This system occurs in the upper montane to subalpine elevations of the Rocky Mountains, north into the Canadian Rockies and east into mountain "islands" of north-central Montana. Elevations range from just over 900 m in the northeastern Cascades to well over 3100 m in the Uinta Mountains in Utah and the southern Colorado Rockies. Temperature regimes are extreme throughout this region and frequent growing season frosts occur. Annual precipitation in these montane and subalpine habitats ranges from less than 40 cm to over 150 cm, usually with the majority falling as snow. Late-melting snowpacks provide the majority of growing-season moisture.

Soils are variable but are typically well-drained, gravelly, coarse-textured, acidic, rarely from calcareous parent materials with occasionally inclusions of deeper, typically fine-textured soils. Other stands occur on excessively well-drained pumice deposits,

glacial till and alluvium on valley floors where there is cold-air accumulation, warm and droughty shallow soils over fractured quartzite bedrock, and shallow moisture-deficient soils with a significant component of volcanic ash.
Key Processes and Interactions: *Pinus contorta* is an aggressively colonizing, shade-intolerant conifer which usually occurs in lower subalpine forests in the major ranges of the western United States. Establishment is episodic and linked to stand-replacing disturbances, primarily fire. The incidence of serotinous cones varies within and between varieties of *Pinus contorta*, being most prevalent in Rocky Mountain populations. Closed, serotinous cones appear to be strongly favored by fire, and allow rapid colonization of fire-cleared substrates (Burns and Honkala 1990a). Hoffman and Alexander (1980, 1983) report that in stands where *Pinus contorta* exhibits a multi-aged population structure, with regeneration occurring, there is typically a higher proportion of trees bearing nonserotinous cones.

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2810500). These are summarized as:

A) Early Development 1 All Structures (20% of type in this stage): Tree cover is 0-80%. Stand initiation: Grasses, forbs, low shrubs and lodgepole seedlings-saplings. This class does not last long; young lodgepole grows fast. If aspen is present, it grows faster and dominates lodgepole. Cover of trees (seedlings-saplings) varies widely.

B) Mid Development 1 Closed (20% of type in this stage): Tree cover is 51-100%. Stem exclusion (RMLANDS: Rocky Mountain Landscape Simulator): Moderate to dense pole-sized trees, sometimes very dense (dog-hair); longest time in this class without disturbance. Aspen usually not present.

C) Mid Development 1 Open (tree-dominated - 20% of type in this stage): Tree cover is 21-50%. Understory reinitiation: Variety of lodgepole size classes, some mature trees, often somewhat patchy. If aspen is present, lodgepole usually dominates it.

D) Late Development 1 Open (20% of type in this stage): Tree cover is 61-100%. Many mature lodgepole pine with closed canopy. Trees may vary in age, but consistent in size, diameters and heights.

E) Late Development 1 All Structures (10% of type in this stage): Tree cover is 31-60%. Many mature lodgepole pine, somewhat patchy, variety of lodgepole size classes, open canopies overall but patches of denser trees. Dead and downed woody materials increasing in volume, young trees infilling openings.

Before fire suppression began in the early 20th century, most fires were low-intensity, creeping, surface fires, whereas most fires today are high-intensity crown fires that occur during severe fire weather (dry and windy) (Lotan et al. 1985). The stand-replacing fire interval in lodgepole pine forests is about 215 years (LANDFIRE 2007a, BpS 2810500).

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. Biological decomposition in lodgepole pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994).
Threats/Stressors: Threats and stressors to this forest system include altered fire regime, altered stand structure from fragmentation due to roads, logging, mining, or other human disturbances (CNHP 2010). These disturbances can cause significant soil loss/erosion and negatively impact the water quality within the immediate watershed (CNHP 2010). Invasive exotic species can become abundant in disturbed areas and alter floristic composition. Direct and indirect effects of climate change may alter dynamics of indigenous insects such as mountain pine beetle (*Dendroctonus ponderosae*) and cause a buildup in population size with less extreme winters leading to large outbreaks the can cause high mortality in mature trees.

CES306.828 Rocky Mountain Subalpine Dry-Mesic Spruce-Fir Forest and Woodland

CES306.828 CLASSIFICATION

Concept Summary: Engelmann spruce and subalpine fir forests comprise a substantial part of the subalpine forests of the Cascades and Rocky Mountains from southern British Columbia east into Alberta, and south into New Mexico and the Intermountain region. They also occur on mountain "islands" of north-central Montana. They are the matrix forests of the subalpine zone, with elevations ranging from 1275 m in its northern distribution to 3355 m in the south (4100-11,000 feet). They often represent the highest elevation forests in an area. Sites within this system are cold year-round, and precipitation is predominantly in the form of snow, which may persist until late summer. Snowpacks are deep and late-lying, and summers are cool. Frost is possible almost all summer and may be common in restricted topographic basins and benches. Despite their wide distribution, the tree canopy characteristics are remarkably similar, with *Picea engelmannii* and *Abies lasiocarpa* dominating either mixed or alone. *Pseudotsuga menziesii* may persist in occurrences of this system for long periods without regeneration. *Pinus contorta* is common in many occurrences, and patches of pure *Pinus contorta* are not uncommon, as well as mixed conifer/*Populus tremuloides* stands. In some areas, such as Wyoming, *Picea engelmannii*-dominated forests are on limestone or dolomite, while nearby codominated spruce-fir forests are on granitic or volcanic rocks. Upper elevation examples may have more woodland physiognomy, and *Pinus albicaulis* can be a seral component. What have been called "ribbon forests" or "tree islands" by some authors are included here; they can be found at upper treeline in many areas of the Rockies, including the central and northern ranges in Colorado and the Medicine Bow and Bighorn ranges of Wyoming. These are more typically islands or ribbons of trees, sometimes with a krummholz form, with open-meadow areas in a mosaic. These patterns are controlled by snow deposition and wind-blown ice. Xeric species may include *Juniperus communis, Linnaea borealis, Mahonia repens*, or *Vaccinium scoparium*. In the Bighorn Mountains, *Artemisia tridentata* is a common shrub. More northern occurrences often have taller, more mesic shrub and herbaceous species, such as *Empetrum nigrum, Rhododendron albiflorum*, and *Vaccinium membranaceum*. Disturbance includes occasional blowdown, insect outbreaks and stand-replacing fire. Mean return interval for stand-replacing fire is 222 years as estimated in southeastern British Columbia.

- EF Engelmann Spruce - Sub-alpine Fir Dry Forested (Ecosystems Working Group 1998) **>**
- Engelmann Spruce - Subalpine Fir: 206 (Eyre 1980) **>**

Distribution: This system is found in the Cascades and Rocky Mountains from southern interior British Columbia east into Alberta, south into New Mexico and the Intermountain region. This type tends to be very limited in the northern Oregon Cascades.

Nations: CA, US

Concept Source: M.S. Reid

Description Author: R. Crawford, M.S. Reid, C. Chappell and G. Kittel

CES306.828 CONCEPTUAL MODEL

Environment:

Key Processes and Interactions: *Picea engelmannii* can be very long-lived, reaching 500 years of age. *Abies lasiocarpa* decreases in importance relative to *Picea engelmannii* with increasing distance from the region of Montana and Idaho where maritime air masses influence the climate. Fire is an important disturbance factor, but fire regimes have a long return interval and so are often stand-replacing. *Picea engelmannii* can rapidly recolonize and dominate burned sites, or can succeed other species such as *Pinus contorta* or *Populus tremuloides*. Due to great longevity, *Pseudotsuga menziesii* may persist in occurrences of this system for long periods without regeneration. Old-growth characteristics in *Picea engelmannii* forests will include treefall and windthrow gaps in the canopy, with large downed logs, rotting woody material, tree seedling establishment on logs or on mineral soils unearthed in root balls, and snags. Landfire VDDT models: #RSPFI.

CES306.830 Rocky Mountain Subalpine Mesic-Wet Spruce-Fir Forest and Woodland

CES306.830 CLASSIFICATION

Concept Summary: This is a high-elevation system of the Rocky Mountains, dry eastern Cascades and eastern Olympic Mountains dominated by *Picea engelmannii* and *Abies lasiocarpa*. It extends westward into the northeastern Olympic Mountains and the northeastern side of Mount Rainier in Washington, and as far east as mountain "islands" of north-central Montana. It also occurs northward into the Upper Foothills subregion of western Alberta. *Picea engelmannii* is generally more important in southern forests than those in the Pacific Northwest. Occurrences are typically found in locations with cold-air drainage or ponding, or where snowpacks linger late into the summer, such as north-facing slopes and high-elevation ravines. They can extend down in elevation below the subalpine zone in places where cold-air ponding occurs (as low as 970 m [3180 feet] in the Canadian Rockies); northerly and easterly aspects predominate. These forests are found on gentle to very steep mountain slopes, high-elevation ridgetops and upper slopes, plateau-like surfaces, basins, alluvial terraces, well-drained benches, and inactive stream terraces. In the northern Rocky Mountains of northern Idaho and Montana, *Tsuga mertensiana* occurs as small to large patches within the matrix of this mesic spruce-fir system and only in the most maritime of environments (the coldest and wettest of the more Continental subalpine fir forests). In the Olympics and northern Cascades, the climate is more maritime than typical for this system, but due to the lower snowfall in these rainshadow areas, summer drought may be more significant than snowpack in limiting tree regeneration in burned areas. *Picea engelmannii* is rare in these areas. Mesic understory shrubs include *Menziesia ferruginea, Vaccinium membranaceum, Rhododendron albiflorum, Amelanchier alnifolia, Rubus parviflorus, Ledum glandulosum, Phyllodoce empetriformis*, and *Salix* spp. Herbaceous species include *Actaea rubra, Maianthemum stellatum, Cornus canadensis, Erigeron eximius, Gymnocarpium dryopteris, Rubus pedatus, Saxifraga bronchialis, Tiarella* spp., *Lupinus arcticus ssp. subalpinus, Valeriana sitchensis*, and graminoids *Luzula glabrata var. hitchcockii* or *Calamagrostis canadensis*. In Alberta, species composition indicates the transition to more boreal floristics, including such species as *Ledum groenlandicum* and *Leymus innovatus*, and more abundant mosses such as *Hylocomium splendens* and *Pleurozium schreberi*. Disturbances include occasional blowdown, insect outbreaks (30-50 years), mixed-severity fire, and stand-replacing fire (every 150-500 years). The more summer-dry climatic areas also have occasional high-severity fires.

CES306.819 Rocky Mountain Subalpine-Montane Limber-Bristlecone Pine Woodland

CES306.819 CLASSIFICATION

Concept Summary: This ecological system occurs throughout the Rocky Mountains, south of Montana, on dry, rocky ridges and slopes near upper treeline above the matrix spruce-fir forest. It extends down to the lower montane in the northeastern Great Basin mountains where dominated by *Pinus flexilis*. Sites are harsh, exposed to desiccating winds, with rocky substrates and a short growing season that limit plant growth. Higher-elevation occurrences are found well into the subalpine-alpine transition on wind-blasted, mostly west-facing slopes and exposed ridges. Calcareous substrates are important for *Pinus flexilis*-dominated communities in the northern Rocky Mountains and possibly elsewhere. The open tree canopy is often patchy and is strongly dominated by *Pinus flexilis* or *Pinus aristata* with the latter restricted to southern Colorado, northern New Mexico and the San Francisco Mountains in Arizona. In the Wyoming Rockies and northern Great Basin, *Pinus albicaulis* is found in some occurrences, but is a minor component. Other trees such as *Juniperus* spp., *Pinus contorta, Pinus ponderosa*, or *Pseudotsuga menziesii* are occasionally present. *Arctostaphylos uva-ursi, Cercocarpus ledifolius, Juniperus communis, Mahonia repens, Purshia tridentata, Ribes montigenum*, or *Vaccinium* spp. may form an open shrub layer in some stands. The herbaceous layer, if present, is generally sparse and composed of xeric graminoids, such as *Calamagrostis purpurascens, Festuca arizonica, Festuca idahoensis, Festuca thurberi*, or *Pseudoroegneria spicata*, or more alpine plants.

Related Concepts:

- Bristlecone Pine: 209 (Eyre 1980) **>**
- Limber Pine: 219 (Eyre 1980) **><**

Distribution: This system occurs throughout the Rocky Mountains south of Montana on dry, rocky ridges and slopes near upper treeline, including the Uinta and northern Wasatch mountains, and the Jarbridge Mountains in northeastern Nevada. It also occurs farther east, in the Bighorn Range of north-central Wyoming, although it is not common there.

CES306.819 CONCEPTUAL MODEL

Environment: This system is found throughout the Rocky Mountains, south of Montana, on dry, rocky ridges and slopes near upper treeline above the matrix spruce-fir forest. It extends down to the lower montane in the northeastern Great Basin mountains. Sites are harsh, exposed to desiccating winds with rocky substrates and a short growing season that limit plant growth. Higher elevation occurrences are found well into the subalpine - alpine transition on wind-blasted, mostly south- to west-facing slopes and exposed ridges. *Pinus aristata* forests are typically found on steep, south-facing slopes from 2700 to 3700 m (8850-12,140 feet) elevation. *Pinus flexilis* woodlands occupy similar habitats, but may occur at lower elevations than *Pinus aristata*. When found in the same landscape, stands dominated by *Pinus aristata* occur at higher elevation.

Key Processes and Interactions: Both *Pinus flexilis* and *Pinus aristata* are short-statured, slow-growing, long-lived species in which individuals may live for 1000 or more years in fire-protected areas. They are adapted to cold, drought and extremely windy conditions with flexible branches that likely reduce wind damage. Fire is an important source of disturbance that facilitates stand regeneration in this system. Older woodlands are often broadly even-aged stands where seedlings are nearly absent, while areas that have recently burned may have abundant seedlings. Bristlecone pine is somewhat more tolerant of fire than is limber pine; however, both species appear to depend on fire for regeneration. Post-fire regeneration of bristlecone pine tends to be near burn edges and/or under surviving trees (Coop and Schoettle 2011). Regeneration of limber pine on burned areas is largely due to the germination of seeds cached primarily by Clark's nutcrackers (*Nucifraga columbiana*) and jays (i.e., corvid family), but also small mammals such as squirrels (Lanner and Vander Wall 1980, Tomback 2001, Lanner 2007, CNHP 2010b). Dispersal of the smaller winged seeds of bristlecone pine is primarily by wind, but seeds are likely to also be dispersed by birds (Coop and Schoettle 2011).

Fire occurrence in this ecosystem is low frequency and mixed severity. In the absence of wind, fires are likely limited in extent (two acres or less). Understories are often sparse, with little to carry fires across the surface (Landfire 2007a). Stand-replacement fires are usually wind-driven, especially in mid- and late-serial classes. Landfire (2007a) review estimated replacement fires occurring between 35-100+ years and 200+ years (Fire Regime Groups IV and V) with surface fires occurring every 1000 years. However, in northern New Mexico, some open stands transition into subalpine grasslands and have more frequent, less severe fires (Coop and Schoettle 2011).

Threats/Stressors: Conversion of this type has commonly come from mining activities and other very localized removal of stands for various kinds of development, but conversion is not a major factor for this system. However, some stands are converted to non-tree-dominated vegetation with loss of *Pinus longaeva* and *Pinus flexilis* from non-native, white pine blister rust (*Cronartium ribicola*) or epidemics of mountain pine beetle (*Dendroctonus ponderosae*).

Common stressors and threats include altered fire regime from fire suppression, fragmentation, extended drought which may make individuals more susceptible to mortality from non-native white pine blister rust or epidemics of native mountain pine beetle, and invasive non-native plant species (Schoettle and Sniezko 2007a, CNHP 2010b, Coop and Schoettle 2011). Threats to their seed dispersers, such as Clark's nutcracker (*Nucifraga columbiana*), are threats to the regeneration of limber pine and the ecosystem. Additionally, other plant species, such as *Pseudotsuga menziesii* and *Ribes cereum* (Baumeister and Callaway 2006), benefit from the presence of *Pinus flexilis*, which, if negatively influenced by threats or stress, could impact the entire ecosystem.

Potential climate change effects could include a change in the current extent of the ecosystem with higher tree mortality and lower recruitment if less moisture occurs with increasing mean temperature (Gibson et al. 2008, TNC 2013). Because *Pinus aristata* occurs within a narrow elevational gradient, its ability to adapt to changing climate might be limited (Gibson et al. 2008). McKinney et al. (2007) suggest *Pinus flexilis* shift will increase in areas with climate change. However, the influence of indirect stresses such as white pine blister rust and increased abundance of mountain pine beetle epidemics with warming climate (Schoettle and Sniezko 2007a, Schoettle et al. 2008) is unknown.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from complete mortality of characteristic species *Pinus aristata* and *Pinus flexilis* from white pine blister rust (*Cronartium ribicola*) or epidemics of mountain pine beetle (*Dendroctonus ponderosae*) (Schoettle et al. 2008, Coop and Schoettle 2011). Additionally, high-severity, stand-replacing fire may result after years of fire suppression, which has converted this open woodland ecosystem to a dense forest. These high-intensity fires kill vegetation and create hydrophobic soils that are vulnerable to water erosion during spring snowmelt and summer convective storms. Soil loss limits tree and grass regeneration. Additional surface disturbances allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<300 acres) (CNHP 2010b). Fragmentation from roads and/or from harvesting adjacent forests is prevalent (CNHP 2010b). Historic and ongoing fire suppression has extended the fire-return interval and has resulted in an increase in tree cover, thereby making stands more vulnerable to high-severity, stand-replacing fire that could damage soils and make them less suitable to tree regeneration and more vulnerable to erosions. Moderate-severity environmental degradation appears where occurrences tend to be moderate to small (300-1000 acres) (CNHP 2010b). Fragmentation from roads and/or from harvesting adjacent forests is significant, but restorable (CNHP 2010b). Historic and ongoing fire suppression has extended the fire-return interval and resulted in an increase in tree cover, thereby making stands more vulnerable to high-severity, stand-replacing fire that could damage soils and make them less suitable to tree regeneration and more vulnerable to erosions.

High-severity disruption appears where occurrences have lost most (>75%) of the characteristic trees *Pinus aristata* and/or *Pinus flexilis* from white pine blister rust or epidemics of mountain pine beetle. Additionally, other more shade-tolerant species, such as *Pseudotsuga menziesii* and/or *Abies concolor*, have colonized the site with high cover and eliminated the ability of *Pinus aristata* and/or *Pinus flexilis* to regenerate. Invasive non-native species may be abundant. Connectivity is moderately hampered by fragmentation from roads or timber harvests that severely restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species and abundance of animal populations are low when compared to an intact ecosystem. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low. Moderate-severity disruption appears where occurrences have lost many (50-75%) of the characteristic trees *Pinus aristata* and/or *Pinus flexilis* from white pine blister rust or epidemics of mountain pine beetle. Additionally other more shade-tolerant species, such as *Pseudotsuga menziesii* and/or *Abies concolor*, have colonized the site with moderate cover and reduced the ability of *Pinus aristata* and/or *Pinus flexilis* to regenerate. Invasive non-native species may be present to abundant. Connectivity is moderately hampered by fragmentation from roads or timber harvests that moderately restrict natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species and abundance of animal populations are low when compared to an intact ecosystem.

M021. Sierra Madre High Montane Forest

CES305.283 Madrean Subalpine Fir Forest

CES305.283 CLASSIFICATION

Concept Summary: This system occurs on high volcanic and montane slopes from the southern Sierra Madre Occidental, Transvolcanic ranges, and high mountain slopes extending into northern Central America. These forests are dominated by *Pinus hartwegii* (Hartweg's pine), but other pines, alder, and evergreen oaks intermingle with patchy shrublands on most upper-elevation slopes (3350-3570 m elevation). The following list of species is diagnostic for this system: *Abies religiosa, Abies concolor, Abies guatemalensis, Pinus* spp., *Cupressus* spp., *Quercus* spp., *Pseudotsuga* spp., *Alnus* spp., *Arbutus* spp., *Salix* spp., *Senecio angulifolius, Roldana barba-johannis*, and *Senecio toluccanus*.

Related Concepts:

M022. Southern Rocky Mountain Lower Montane Forest

CES306.823 Southern Rocky Mountain Dry-Mesic Montane Mixed Conifer Forest and Woodland

CES306.823 CLASSIFICATION

Concept Summary: This is a highly variable ecological system of the montane zone of the Rocky Mountains. It occurs throughout the southern Rockies, north and west into Utah, Nevada, Wyoming and Idaho. These are mixed-conifer forests occurring on all aspects at elevations ranging from 1200 to 3300 m. Rainfall averages less than 75 cm per year (40-60 cm), with summer "monsoons" during the growing season contributing substantial moisture. The composition and structure of the overstory are dependent upon the temperature and moisture relationships of the site and the successional status of the occurrence. *Pseudotsuga menziesii* and *Abies concolor* are most frequent, but *Pinus ponderosa* may be present to codominant. *Pinus flexilis* is common in Nevada. *Pseudotsuga menziesii* forests occupy drier sites, and *Pinus ponderosa* is a common codominant. *Abies concolor*-dominated forests occupy cooler sites, such as upper slopes at higher elevations, canyon sideslopes, ridgetops, and north- and east-facing slopes which burn somewhat infrequently. *Picea pungens* is most often found in cool, moist locations, often occurring as smaller patches within a matrix of other associations. As many as seven conifers can be found growing in the same occurrence, and there are a number of cold-deciduous shrub and graminoid species common, including *Arctostaphylos uva-ursi, Mahonia repens, Paxistima myrsinites, Symphoricarpos oreophilus, Jamesia americana, Quercus gambelii*, and *Festuca arizonica*. This system was undoubtedly

characterized by a mixed-severity fire regime in its "natural condition," characterized by a high degree of variability in lethality and return interval.
Related Concepts:

- Interior Douglas-fir: 210 (Eyre 1980) **><**
- White Fir: 211 (Eyre 1980) **><**

Distribution: This system occurs throughout the southern Rockies, north and west into Utah, Nevada, eastern Wyoming (very southern in the Laramie Range and possibly on Sheep Mountain) and Idaho. Although not common, it does occur in southeastern Oregon but does not extend farther west into the Cascades.
Nations: US
Concept Source: M.S. Reid
Description Author: M.S. Reid and K.A. Schulz

CES306.823 CONCEPTUAL MODEL

Environment: These are mixed-conifer forests occurring on all aspects at elevations ranging from 1200 to 3300 m. Landforms are variable and can include canyons, plateaus, draws, benches, hills, mesas, ravines, shoulders, sideslopes and toeslopes. Slopes can be gentle to extremely steep. Rainfall averages less than 75 cm per year (40-60 cm), with summer "monsoons" during the growing season contributing substantial moisture. Geologic substrates include volcanic andesite, rhyolite, rhyolitic tuffs, colluvium, shale gneiss, granite, sandstone and limestone. Soils are variable from cobbles, clay loam, silt loam, sandy loam, sand, and gravel.
Key Processes and Interactions: Forests in this ecological system represent the gamut of fire tolerance. Formerly, *Abies concolor* in the Utah High Plateaus were restricted to rather moist or less fire-prone areas by frequent surface fires. These areas experienced mixed fire severities, with patches of crowning in which all trees are killed, intermingled with patches of underburn in which larger *Abies concolor* survived (www.fs.fed.us/database/feis/). With fire suppression, *Abies concolor* has vigorously colonized many sites formerly occupied by open *Pinus ponderosa* woodlands. These invasions have dramatically changed the fuel load and potential behavior of fire in these forests. In particular, the potential for high-intensity crown fires on drier sites now codominated by *Pinus ponderosa* and *Abies concolor* has increased. Increased landscape connectivity, in terms of fuel loadings and crown closure, has also increased the potential size of crown fires.

Pseudotsuga menziesii forests are the only true "fire-tolerant" occurrences in this ecological system. *Pseudotsuga menziesii* forests were probably subject to a moderate-severity fire regime in presettlement times, with fire-return intervals of 30-100 years. Many of the important tree species in these forests are fire-adapted (*Populus tremuloides, Pinus ponderosa, Pinus contorta*) (Pfister et al. 1977), and fire-induced reproduction of *Pinus ponderosa* can result in its continued codominance in *Pseudotsuga menziesii* forests (Steele et al. 1981). Seeds of the shrub *Ceanothus velutinus* can remain dormant in forest occurrences for 200 years (Steele et al. 1981) and germinate abundantly after fire, competitively suppressing conifer seedlings. Successional relationships in this system are complex. *Pseudotsuga menziesii* is less shade-tolerant than many northern or montane trees such as *Tsuga heterophylla, Abies concolor, Picea engelmannii*, and seedlings compete poorly in deep shade. At drier locales, seedlings may be favored by moderate shading, such as by a canopy of *Pinus ponderosa*, which helps to minimize drought stress. In some locations, much of these forests have been logged or burned during European settlement, and present-day occurrences are second-growth forests dating from fire, logging, or other occurrence-replacing disturbances (Mauk and Henderson 1984, Chappell et al. 1997).

Picea pungens is a slow-growing, long-lived tree which regenerates from seed (Burns and Honkala 1990a). Seedlings are shallow-rooted and require perennially moist soils for establishment and optimal growth. *Picea pungens* is intermediate in shade tolerance, being somewhat more tolerant than *Pinus ponderosa* or *Pseudotsuga menziesii*, and less tolerant than *Abies lasiocarpa* or *Picea engelmannii*. It forms late-seral occurrences in the subhumid regions of the Utah High Plateaus. It is common for these forests to be heavily disturbed by grazing or fire.

In general, fire suppression has lead to the encroachment of more shade-tolerant, less fire-tolerant species (e.g., climax) into occurrences and an attendant increase in landscape homogeneity and connectivity (from a fuels perspective). This has increased the lethality and potential size of fires.

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2810510). These are summarized as:

A) Early Development 1 All Structures (15% of type in this stage): Shrub cover is 0-80%. Succession after a lethal fire will depend on what vegetation was on site before. In a general conifer-dominated scenario, some ponderosa pines are likely to survive. Fire will be an opportunity for new ponderosa pine establishment. On site Gambel oak will resprout. White fir will also be regenerating. If aspen cover is 50-100% prior to disturbance, the stand would regenerate back to aspen.

B) Mid Development 1 Closed (tree-dominated - 15% of type in this stage): Tree cover is 51-80%. If aspen is dominant the stand will achieve a mid-closed stage. Conifers such as white fir and Douglas-fir could be regenerating with it. Any surviving conifers such as ponderosa pine would be canopy dominants. If aspen canopy cover is 50-100%.

C) Mid Development 1 Open (tree-dominated - 10% of type in this stage): Tree cover is 21-50%. Ponderosa pine is the canopy dominant with an understory dominated by white fir. Douglas-fir present and some of its regeneration is entering the canopy. If aspen were present, the stand would have undergone some self-thinning that would have opened up the canopy. The conifers in the stand create a more flammable litter bed with their needles so that patchy surface fire could carry. Any fire would further open the stand by thinning aspen and fir. Eventually the aspen stand would become very open sharing the canopy with ponderosa pine and Douglas-fir.

D) Late Development 1 Open (conifer-dominated - 50% of type in this stage): Tree cover is 21-50%. Ponderosa pine is the canopy dominant. Douglas-fir can also be a canopy dominant. Recurrent fire maintains white fir as an understory tree, but a rare white fir will join the other two species in the canopy. If aspen is present, its numbers are few. Low levels of suckering may keep it in the stand. Open aspen stands are not common in the warm/dry mixed conifer.

E) Late Development 1 Closed (tree-dominated - 10% of type in this stage): Tree cover is 51-80%. Aspen stand is mature to over-mature with a heavy understory of conifers, mainly white fir and some Douglas-fir.

This BpS has a fire regime very similar to ponderosa pine. Frequent low-intensity surface fire is the dominant mode of disturbance. Fire intervals range from 2-71 years with a mean of 15 years. Lethal fires can occur on a limited scale, but this is not the norm unless aspen is involved. These will be characterized as mixed fires because they most likely occur as a part of a more widespread surface fire. Bark beetles may impact this BpS in isolated areas at small scales (LANDFIRE 2007a, BpS 2810510).

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. Biological decomposition in ponderosa pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994, Graham and Jain 2005).

Threats/Stressors: Threats and stressors to this forest and woodland system include altered fire regime, altered stand structure from fragmentation due to roads, logging, mining, or other human disturbances (CNHP 2010). These disturbances can cause significant soil loss/erosion and negatively impact the water quality within the immediate watershed (CNHP 2010). Invasive exotic species can become abundant in disturbed areas and alter floristic composition. Direct and indirect effects of climate change may alter dynamics of indigenous insects such as Douglas-fir beetle (*Dendroctonus pseudotsugae*) or mountain pine beetle (*Dendroctonus ponderosae*) causing a buildup in population size (with less extreme winters) leading to large outbreaks that can cause high mortality in mature trees.

CES306.825 Southern Rocky Mountain Mesic Montane Mixed Conifer Forest and Woodland

CES306.825 CLASSIFICATION

Concept Summary: These are mixed conifer forests of the Rocky Mountains west into the ranges of the Great Basin, occurring predominantly in cool ravines and on north-facing slopes. Elevations range from 1200 to 3300 m. Occurrences of this system are found on cooler and more mesic sites than ~Southern Rocky Mountain Dry-Mesic Montane Mixed Conifer Forest and Woodland (CES306.823)$$. Such sites include lower and middle slopes of ravines, along stream terraces, moist, concave topographic positions and north- and east-facing slopes which burn somewhat infrequently. *Pseudotsuga menziesii* and *Abies concolor* are most common canopy dominants, but *Picea engelmannii, Picea pungens*, or *Pinus ponderosa* may be present. This system includes mixed conifer - *Populus tremuloides* stands. A number of cold-deciduous shrub species can occur, including *Acer glabrum, Acer grandidentatum, Alnus incana, Betula occidentalis, Cornus sericea, Jamesia americana, Physocarpus malvaceus, Robinia neomexicana, Vaccinium* *membranaceum*, and *Vaccinium myrtillus*. Herbaceous species include *Bromus ciliatus, Carex geyeri, Carex rossii, Carex siccata, Muhlenbergia straminea, Pseudoroegneria spicata, Erigeron eximius, Fragaria virginiana, Luzula parviflora, Osmorhiza berteroi, Packera cardamine, Thalictrum occidentale*, and *Thalictrum fendleri*. Naturally occurring fires are of variable return intervals and mostly light, erratic, and infrequent due to the cool, moist conditions.

Related Concepts:
- Blue Spruce: 216 (Eyre 1980) **<**
- Interior Douglas-fir: 210 (Eyre 1980) **><**
- White Fir: 211 (Eyre 1980) **><**

Distribution: This system is found in the southern Rocky Mountains of Arizona and New Mexico north and west into the ranges of the Great Basin, Wyoming and southeastern Idaho, occurring predominantly in cool ravines and on north-facing slopes.

Nations: US

Concept Source: M.S. Reid

Description Author: M.S. Reid and K.A. Schulz

CES306.825 CONCEPTUAL MODEL

Environment: This system includes conifer, mixed conifer, and some deciduous montane forests of the southern Rocky Mountains west into the ranges of the Great Basin. Stands occur predominantly in cool ravines and on north-facing slopes with elevations from 1200 to 3300 m. Occurrences of this system are found on cooler and more mesic sites than those in ~Southern Rocky Mountain White Fir - Douglas-fir Dry Forest Group (G226)$$. Such sites include lower and middle slopes of ravines, along stream terraces, moist, concave topographic positions, and north- and east-facing slopes. Naturally occurring fires are of variable return intervals and mostly light, erratic, and infrequent due to the cool, moist conditions.

Key Processes and Interactions: Fire is the primary disturbance although insects can also play a major role especially in tree-gap dynamics. Fire frequencies are variable with a mixed-severity fire regime in the relatively cool/moist environments where this system occurs. In the absence of stand-replacing disturbance such as fire, this mesic mixed conifer and aspen forest system will slowly convert to forests dominated by more shade-tolerant trees such as *Picea pungens* and *Abies concolor*. However, these forests are linked to smaller, gap-forming disturbances, such as mixed-severity fire or windthrow facilitated by insect outbreaks and disease. These gaps allow regeneration of *Populus tremuloides* and other less shade-tolerant species such as *Pinus ponderosa* and *Pseudotsuga menziesii* and limits the abundances of *Abies concolor* (Mueggler and Campbell 1986, Mueggler 1988).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2810520). These are summarized as:

A) Early Development 1 All Structures (10% of type in this stage): Post-lethal fire vegetation will depend on what was on site before it burned. Aspen may or may not be present, depending on what was present prior to the fire or other replacement disturbance. The site will start as grass/forb/shrub; aspen may also be present. Fire will maintain or prolong this stage. Conifers may be present. Any surviving conifers will be seed source. This class may look like a pure aspen stand from above.

B) Mid Development 1 Closed (tree-dominated - 40% of type in this stage): Tree cover is 41-100%. If present, aspen will be over 10 feet tall and very dense. Seedling-medium-sized conifers can be found mixed with aspen, if present. Understory may include mountain snowberry, common juniper, wild rose, and many species of grasses and forbs.

C) Mid Development 1 Open (tree-dominated - 25% of type in this stage): Tree cover is 11-40%. If present, aspen will be over 10 feet tall and patchy. Seedling-medium-sized conifers can be found mixed with aspen, if present. Understory may include mountain snowberry, common juniper, wild rose, and many species of grasses and forbs. Canopy cover is low.

D) Late Development 1 Open (tree-dominated - 10% of type in this stage): Tree cover is 11-40%. Aspen will be rare and mid-level. Understory will be sparse.

E) Late Development 1 Closed (tree-dominated - 15% of type in this stage): Tree cover is 41-100%. Dense conifer stand. Blue spruce and subalpine fir can come in. Aspen present in small amounts. Lots of dead and downed material. Understory possibly depauperate.

Fire is the primary disturbance although insects can also play a major role. Fire frequencies are variable and the cool/moist conditions support a mixed fire regime. Mixed-severity fires occurred every 6-60 years. Lethal fires are usually at longer intervals, 100+ years (LANDFIRE 2007a, BpS 2810520).

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. Biological decomposition in ponderosa pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994, Graham and Jain 2005).

Threats/Stressors: Threats and stressors to this forest and woodland system include altered fire regime, altered stand structure from fragmentation due to roads, logging, mining, or other human disturbances (CNHP 2010). These disturbances can cause significant soil loss/erosion and negatively impact the water quality within the immediate watershed (CNHP 2010). Invasive exotic species can become abundant in disturbed areas and alter floristic composition. Direct and indirect effects of climate change may alter dynamics of indigenous insects such as Douglas-fir beetle (*Dendroctonus pseudotsugae*) and spruce beetle (*Dendroctonus rufipennis*) (spruce beetle) causing a buildup in population size (with less extreme winters) leading to large outbreaks that can cause high mortality in mature trees.

CES306.649 Southern Rocky Mountain Ponderosa Pine Savanna

CES306.649 CLASSIFICATION

Concept Summary: This ecological system is found predominantly in the Colorado Plateau region, west into scattered locations in the Great Basin, and north along the eastern front of the southern Rocky Mountains into southeastern Wyoming. These savannas occur at the lower treeline/ecotone between grassland/or shrubland and more mesic coniferous forests typically in warm, dry, exposed sites. Elevations range from less than 1900 m in central and northern Wyoming to 2800 m in the New Mexico mountains to well over 2700 m on the higher plateaus of the Southwest. It is found on rolling plains, plateaus, or dry slopes usually on more southerly aspects. This system is best described as a savanna that has widely spaced (<25% tree canopy cover) (>150 years old) *Pinus ponderosa* (primarily *var. scopulorum* and *var. brachyptera*) as the predominant conifer. It is maintained by a fire regime of frequent, low-intensity surface fires. A healthy occurrence often consists of open and park-like stands dominated by *Pinus ponderosa*. Understory vegetation in the true savanna occurrences is predominantly fire-resistant grasses and forbs that resprout following surface fires; shrubs, understory trees and downed logs are uncommon. Important and often dominant species include *Festuca arizonica, Koeleria macrantha, Muhlenbergia montana, Muhlenbergia straminea*, and *Pseudoroegneria spicata*. Other important grasses, such as *Andropogon gerardii, Bouteloua gracilis, Elymus elymoides, Festuca idahoensis, Piptatheropsis micrantha*, and *Schizachyrium scoparium*, dominate less frequently. A century of anthropogenic disturbance and fire suppression has resulted in a higher density of *Pinus ponderosa* trees, altering the fire regime and species composition. Presently, many stands contain understories of more shade-tolerant species, such as *Pseudotsuga menziesii* and/or *Abies* spp., as well as younger cohorts of *Pinus ponderosa*. ~Northern Rocky Mountain Ponderosa Pine Woodland and Savanna (CES306.030)$$ in the eastern Cascades, Okanogan, and Northern Rockies regions receives winter and spring rains, and thus has a greater spring "green-up" than the drier woodlands in the Central Rockies.

Related Concepts:

- Interior Ponderosa Pine: 237 (Eyre 1980) **>**

Distribution: This ecological system is found predominantly in the Colorado Plateau region, west into scattered locations of the Great Basin, and north along the eastern front of the Rocky Mountains of Colorado and Wyoming. Pine woodlands and savannas of the Black Hills and central Montana are now included in ~Northwestern Great Plains-Black Hills Ponderosa Pine Woodland and Savanna (CES303.650)$$, as are woodlands and savannas in Nebraska and northeastern Colorado.

Concept Source: M.S. Reid

Description Author: M.S. Reid and K.A. Schulz

CES306.649 CONCEPTUAL MODEL

Environment: These savannas occur at the lower elevation ecotone between pinyon conifer woodlands, grassland/or shrubland and upper elevation, more mesic coniferous forests typically in warm, dry, exposed sites. Elevations range from less than 1900 m in

central and northern Wyoming to 2800 m in the New Mexico mountains to well over 2700 m on the higher plateaus of the Southwest. It is found on rolling plains, plateaus, or dry slopes usually on more southerly aspects; however, it can occur on all slopes and aspects. Stands occur on soils derived from igneous, metamorphic, and sedimentary material, including basalt, andesite, intrusive granitoids and porphyrites, and tuffs (Youngblood and Mauk 1985). Characteristic soil features include good aeration and drainage, coarse textures, circumneutral to slightly acidic pH, an abundance of mineral material, and periods of drought during the growing season. Surface textures are highly variable in this ecological system ranging from sand to loam and silt loam. Exposed rock and bare soil consistently occur to some degree in all the associations. Annual precipitation is 25-60 cm (8-24 inches), mostly through winter storms and some monsoonal summer rains. Typically, a seasonal drought period occurs throughout this system distribution as well.
Key Processes and Interactions: *Pinus ponderosa* is a drought-resistant, typically open-grown conifer, which usually occurs at lower treeline in the major ranges of the western United States. Mature trees have thick bark that protects the cambium layer from fire. Historically, fires and drought were influential in maintaining open-canopy conditions in these woodlands. Low-intensity surface fire would burn through these stands every 5-15 year, killing young trees, but not the fire-resistant mature ponderosa pine trees or grass understory maintaining an open park-like stand (Harrington and Sackett 1992, Mehl 1992, Swetnam and Baisan 1996). Infrequent stand-replacement fire on the order of a few hundred years (300-500 years) is possible (LANDFIRE 2007a). Drought and other weather events (e.g., blowdown), parasites and disease may play a minor role, and have very long rotations (LANDFIRE 2007a). Impacts from insects such as mountain pine beetles (*Dendroctonus ponderosae*) may be significant during outbreaks, but infrequent in occurrence (LANDFIRE 2007a). Beetles attack less vigorously growing trees, e.g., old, crowded, diseased, damaged, or growing on poor sites) especially during droughts (Leatherman et al. 2013). Winter mortality of beetles is a significant factor; however, a severe freeze of at least -30 degrees F is necessary for at least five days during midwinter (Leatherman et al. 2013).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2811170). These are summarized as:

A) Early Development 1 All Structures (Shrub-dominated - 10% of type in this stage): Bunchgrass-dominated (0-49 years). Some ponderosa pine individuals also becoming established.

B) Mid Development 1 Closed (tree-dominated - 5% of type in this stage): Small and medium-sized ponderosa pine (50-149 years), still with high bunchgrass cover. Closed canopy defined as >50%.

C) Mid Development 1 Open (tree-dominated - 20% of type in this stage): Small and medium-sized ponderosa pine (50-149 years), with moderate bunchgrass cover. Open canopy defined as 10-49%.

D) Late Development 1 Open (conifer-dominated - 60% of type in this stage): Large and very large old-growth ponderosa pine, with medium to high cover of bunchgrasses. Old-growth attributes prominent, including downed wood, snags and diseased trees.

E) Late Development 1 Open (conifer-dominated - 5% of type in this stage): Large and very large old-growth ponderosa pine, with medium cover of bunchgrasses. Old-growth attributes prominent, including downed wood, snags and diseased trees.

Mean composite surface fire intervals have been found to be 5-15 years (Swetnam and Baisan 1996a). Infrequent stand-replacement fire on the order of a few hundred years possible (300-500 years?). Drought and other weather events (e.g., blowdown), parasites and disease may play a minor role, and have very long rotations. Insects may be a significant, but infrequent occurrence (LANDFIRE 2007a, BpS 2811170).

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. However, biological decomposition in ponderosa pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994, Graham and Jain 2005).
Threats/Stressors: With settlement and a century of anthropogenic disturbance and fire suppression, stands now have a higher density of *Pinus ponderosa* trees, altering the fire regime and species composition. Presently, many stands contain understories of more shade-tolerant species, such as *Pseudotsuga menziesii* and/or *Abies* spp., as well as younger cohorts of *Pinus ponderosa*. These altered structures have affected fuel loads and fire regimes. Presettlement fire regimes were primarily frequent (5- to 15-year return intervals), low-intensity ground fires triggered by lightning strikes or deliberately set by Native Americans. With fire suppression and increased fuel loads, fire regimes are now less frequent and often become intense crown fires, which can kill mature *Pinus ponderosa* (Reid et al. 1999).

Conversion of this type has commonly come from urban and exurban development especially along the Front Range, water developments and reservoirs. With long-term fire suppression, stands have converted through succession to ~Southern Rocky Mountain Ponderosa Pine Woodland (CES306.648)$$ or ~Southern Rocky Mountain Dry-Mesic Montane Mixed Conifer Forest and Woodland (CES306.823)$$. Restoration to savanna is difficult or impossible when adjacent to housing development.

Common stressors and threats include fragmentation from housing and water developments, altered fire regime from fire suppression and indirectly from livestock grazing and fragmentation, and introduction of invasive non-native species (CNHP 2010b). Potential climate change effects could include a change in the current extent of this ecosystem with tree mortality in lower elevation stands converting to ~Western Great Plains Foothill and Piedmont Grassland (CES303.817)$$, if climate change has the predicted effect of less effective moisture with increasing mean temperature (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from high-intensity fire after years of fire suppression and converts this savanna ecosystem to a dense forest. Hot stand-replacing fire kills vegetation (both trees and grasses) and creates hydrophobic soils that are vulnerable to water erosion during spring snowmelt and summer convective storms. Soil loss limits tree and grass regeneration. Perennial plant cover is reduced enough from overgrazing or other disturbance to allow removal of topsoil by sheet and rill erosion. Soil disturbance allows invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<30,000 acres) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Urban or exurban development and fragmentation from roads and transmission lines greatly impacts stands with <25% of adjacent landscapes in natural or semi-natural vegetation (CNHP 2010b). Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval from 5-15 years to >160 years and has resulted in a significant increase in tree cover (>50%) converting this savanna/open woodland into a forest. A subcanopy of ponderosa pine and sometimes Douglas-fir is often present. There is significant regeneration of ponderosa pine and Douglas-fir (saplings and seedlings) creating ladder fuels so a low-intensity surface fire can move into the tree canopy causing a high-intensity, stand-replacing crown fire. There is typically low density of shrub and herbaceous cover, and very low species diversity. Moderate-severity environmental degradation appears where occurrences tend to be moderate to small (30,000-50,000 acres) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion (CNHP 2010b). Urban or exurban development and fragmentation from roads and transmission lines greatly impacts stands with <25% of adjacent landscapes in natural or semi-natural vegetation (CNHP 2010b). Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval from 5-15 years to >80 years and has resulted in a significant increase in tree cover (>50%) converting this savanna/open woodland into a forest. A subcanopy of ponderosa pine and sometimes Douglas-fir is often present. There is significant regeneration of ponderosa pine and Douglas-fir (saplings and seedlings) creating ladder fuels so a low-intensity surface fire can move into the tree canopy causing a high-intensity, stand-replacing crown fire. There is typically low density of shrub and herbaceous cover, and very low species diversity.

High-severity disruption appears where occurrences have high cover (>50%) of trees, altering vegetation structure and species composition with the subcanopy converted to more shade-tolerant species, such as *Pseudotsuga menziesii* and/or *Abies* concolor, as well as younger cohorts of *Pinus ponderosa*. The understory is converted from moderately dense to dense perennial grasses to shade-tolerant shrub and forb species. Invasive non-native species such as *Bromus tectorum* may be present to abundant. Connectivity is severely hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity (shade-intolerant grass species) and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low. Moderate-severity disruption appears here occurrences have high cover (30-50%) of trees, altering vegetation structure and species composition with understory of *Pinus ponderosa* saplings as well as more shade-tolerant species, such as *Pseudotsuga menziesii* and/or *Abies concolor*. The moderately dense to dense perennial grass layer is much reduced and converting to more shade-tolerant forb species. Invasive non-native species such as *Bromus tectorum* may be present to abundant. Connectivity is moderately hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity (shade-intolerant grass species) and abundance of animal populations are low when compared to an intact ecosystem.

CES306.648 Southern Rocky Mountain Ponderosa Pine Woodland

CES306.648 CLASSIFICATION

Concept Summary: This very widespread ecological system is most common throughout the cordillera of the Rocky Mountains, from the Greater Yellowstone region south. It is also found in the Colorado Plateau region, west into scattered locations of the Great Basin. Its easternmost extent in Wyoming is in the Bighorn Mountains. These woodlands occur at the lower treeline/ecotone between grassland or shrubland and more mesic coniferous forests typically in warm, dry, exposed sites. Elevations range from less than 1900 m in northern Wyoming to 2800 m in the New Mexico mountains. Occurrences are found on all slopes and aspects; however, moderately steep to very steep slopes or ridgetops are most common. This ecological system generally occurs on soils derived from igneous, metamorphic, and sedimentary material, with characteristic features of good aeration and drainage, coarse textures, circumneutral to slightly acidic pH, an abundance of mineral material, rockiness, and periods of drought during the growing season. ~Northern Rocky Mountain Ponderosa Pine Woodland and Savanna (CES306.030)$$ in the eastern Cascades, Okanogan, and Northern Rockies regions receives winter and spring rains, and thus has a greater spring "green-up" than the drier woodlands in the Central Rockies. *Pinus ponderosa* (primarily *var. scopulorum* and *var. brachyptera*) is the predominant conifer; *Pseudotsuga menziesii, Pinus edulis, Pinus contorta, Populus tremuloides*, and *Juniperus* spp. may be present in the tree canopy. The understory is usually shrubby, with *Artemisia nova, Artemisia tridentata, Arctostaphylos patula, Arctostaphylos uva-ursi, Cercocarpus montanus, Purshia stansburiana, Purshia tridentata, Quercus gambelii, Symphoricarpos* spp., *Prunus virginiana, Amelanchier alnifolia* (less so in Montana), and *Rosa* spp. common species. *Pseudoroegneria spicata, Pascopyrum smithii*, and species of *Hesperostipa, Achnatherum, Festuca, Muhlenbergia*, and *Bouteloua* are some of the common grasses. Mixed fire regimes and surface fires of variable return intervals maintain these woodlands, depending on climate, degree of soil development, and understory density.

- Interior Ponderosa Pine: 237 (Eyre 1980) **>**

Distribution: This system is found throughout the southern Rocky Mountains and extends into northern Utah and western Wyoming, in the Uinta and Wasatch ranges, and south into New Mexico. It also occurs in northern Arizona on the Mogollon Rim, north on the high plateaus and ranges in the Colorado Plateau region and scattered locations of the Great Basin.

CES306.648 CONCEPTUAL MODEL

Environment: This ecological system within the region occurs in the southern Rocky Mountains at the lower treeline/ecotone between grassland or shrubland and more mesic coniferous forests. Stands are typically found in warm, dry, exposed sites at elevations ranging from 1980-2800 m (6500-9200 feet).

Climate: Climate is temperate with cold winter and warm summers. Precipitation generally contributes 25-60 cm annually to this system, mostly through winter snow and some monsoonal summer rains. Typically, a seasonal drought period occurs throughout this system as well.

Physiography/Landform: Stands can occur on all slopes and aspects; however, it commonly occurs on moderately steep to very steep slopes or ridgetops in foothills and lower montane slopes.

Soil/substrate/hydrology: Soils are variable. This ecological system generally occurs on soils derived from igneous, metamorphic, and sedimentary material, including basalt, basaltic, andesitic flows, intrusive granitoids and porphyrites, and tuffs (Youngblood and Mauk 1985). Characteristic soil features include good aeration and drainage, coarse textures, circumneutral to slightly acidic pH, an abundance of mineral material, and periods of drought during the growing season. Some occurrences may occur as edaphic climax communities on very skeletal, infertile, and/or excessively drained soils, such as pumice, cinder or lava fields, and scree slopes. Surface textures are highly variable in this ecological system ranging from sand to loam and silt loam. Exposed rock and bare soil consistently occur to some degree in all the associations. *Pinus ponderosa / Arctostaphylos patula* represents the extreme with typically a high percentage of rock and bare soil present.

Fire plays an important role in maintaining the characteristics of these open-canopy woodlands. However, soil infertility and drought may contribute significantly in some areas as well.

Key Processes and Interactions: *Pinus ponderosa* is a drought-resistant, shade-intolerant conifer which usually occurs at lower treeline in the major ranges of the western United States. Historically, surface fires and drought were influential in maintaining open-canopy conditions in these woodlands. With settlement and subsequent fire suppression, occurrences have become denser. Presently, many occurrences contain understories of more shade-tolerant species, such as *Pseudotsuga menziesii* and/or *Abies* spp., as well as younger cohorts of *Pinus ponderosa*. These altered structures have affected fuel loads and alter fire regimes. Presettlement fire regimes were primarily frequent (5- to 15-year return intervals), low-intensity surface fires triggered by lightning strikes or deliberately set fires by Native Americans. With fire suppression and increased fuel loads, fire regimes are now less frequent and often become intense crown fires, which can kill mature *Pinus ponderosa* (Reid et al. 1999).

Establishment is erratic and believed to be linked to periods of adequate soil moisture and good seed crops, as well as fire frequencies, which allow seedlings to reach sapling size. Longer fire-return intervals have resulted in many occurrences having dense subcanopies of overstocked and unhealthy young *Pinus ponderosa* (Reid et al. 1999). Mehl (1992) states the following: "Where fire has been present, occurrences will be climax and contain groups of large, old trees with little understory vegetation or down woody material and few occurring dead trees. The age difference of the groups of trees would be large. Where fire is less frequent, there will also be smaller size trees in the understory giving the occurrence some structure with various canopy layers. Dead, down material will be present in varying amounts along with some occurring dead trees. In both cases the large old trees will have irregular open, large branched crowns. The bark will be lighter in color, almost yellow, thick and some will like have basal fire scars."

Grace's warbler, pygmy nuthatch, and flammulated owl are indicators of a healthy ponderosa pine woodland. All of these birds prefer mature trees in an open woodland setting (Winn 1998, Jones 1998, Levad 1998 as cited in Rondeau 2001).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2810540). These are summarized as:

A) Early Development 1 All Structures (pole-sized tree-dominated - 10% of type in this stage): Openings with up to 10% cover by overstory dominated by ponderosa pine and sometimes Douglas-fir. Some openings may persist.

B) Mid Development 1 Closed (tree-dominated - 10% of type in this stage): Greater than 50% canopy cover in the northern Front Range (above c. 6500 feet) and >30% canopy cover in the southern Front Range.

C) Mid Development 1 Open (tree-dominated - 25% of type in this stage): Greater than 50% canopy cover in the northern Front Range (above c. 6500 feet) and <30% canopy cover in the southern Front Range

D) Late Development 1 Open (tree-dominated - 40% of type in this stage): Less than 50% canopy cover in the northern Front Range (above c. 6500 feet) and <30% canopy cover in the southern Front Range.

E) Late Development 1 Closed (tree-dominated - 15% of type in this stage): Less than 50% canopy cover in the northern Front Range (above c. 6500 feet) and <30% canopy cover in the southern Front Range.

Mixed-severity fire regime - typically an average fire frequency ranges from 40-100 years (5-100 ha) (Kaufmann et al. 2000, Veblen et al. 2000, Ehle and Baker 2003, Sherriff 2004). These fires range from low-severity to high-severity fires, and the forest structure was shaped by the pattern of fire at a landscape scale. Drought and other weather events (e.g., blowdown); insects such as mountain pine beetle, Douglas-fir beetle and western spruce budworm (Swetnam and Lynch 1993, Negron 1998, 2004); and pathogens such as dwarf mistletoe (Hawksworth 1961) also play important roles in this type.

Replacement-fire rotation uncertain, and this affects the amount of forest in each class. Cheesman Lake - fire rotation (all fires 75 years) and stand-replacement (460 years) estimation (LANDFIRE 2007a, BpS 2810540).

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. However, biological decomposition in ponderosa pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994, Graham and Jain 2005).

Threats/Stressors: With settlement and a century of anthropogenic disturbance and fire suppression, stands now have a higher density of *Pinus ponderosa* trees, altering the fire regime and species composition. Presently, many stands contain understories of more shade-tolerant species, such as *Pseudotsuga menziesii* and/or *Abies* spp., as well as younger cohorts of *Pinus ponderosa*. These altered structures have affected fuel loads and fire regimes. Presettlement fire regimes were primarily frequent (5- to 15-year return intervals), low-intensity ground fires triggered by lightning strikes or deliberately set by Native Americans. With fire suppression and increased fuel loads, fire regimes are now less frequent and often become intense crown fires, which can kill mature *Pinus ponderosa* (Reid et al. 1999).

Conversion of this type has commonly come from urban and exurban development, especially along the Front Range, water developments and reservoirs. With long-term fire suppression, stands have converted through succession to ~Southern Rocky Mountain Dry-Mesic Montane Mixed Conifer Forest and Woodland (CES306.823)$$. Restoration to open woodland is difficult or impossible when adjacent to housing development. Common stressors and threats include fragmentation from housing and water developments, altered fire regime from fire suppression and indirectly from livestock grazing and fragmentation, and introduction of invasive non-native species (CNHP 2010).

1.B.2.Nc. Western North American Cool Temperate Woodland & Scrub

M026. Intermountain Singleleaf Pinyon - Juniper Woodland

CES304.082 Columbia Plateau Western Juniper Woodland and Savanna

CES304.082 CLASSIFICATION

Concept Summary: This woodland system is found along the northern and western margins of the Great Basin, from southwestern Idaho, along the eastern foothills of the Cascades, south to the Modoc Plateau of northeastern California. Elevations range from under 200 m along the Columbia River in central Washington to over 1500 m. Generally, soils are medium-textured, with abundant coarse fragments, and derived from volcanic parent materials. In central Oregon, the center of distribution, all aspects and slope positions occur. Where this system grades into relatively mesic forest or grassland habitats, these woodlands become restricted to rock outcrops or escarpments with excessively drained soils. The vegetation is characterized by an open stand of *Juniperus occidentalis* with an understory of open shrub-steppe (big sage, bitterbrush and/or rabbitbrush) with perennial bunchgrasses representing the dominant vegetation. *Pinus monophylla* is not present in this region, so *Juniperus occidentalis* is typically the only tree species, although *Pinus ponderosa* or *Pinus jeffreyi* may be present in some stands. *Cercocarpus ledifolius* may occasionally codominate. *Artemisia tridentata* is the most common shrub; others are *Purshia tridentata, Ericameria nauseosa, Chrysothamnus viscidiflorus, Ribes cereum*, and *Tetradymia* spp. Graminoids include *Carex filifolia, Festuca idahoensis, Poa secunda*, and *Pseudoroegneria spicata*. These woodlands are generally restricted to rocky areas where fire frequency is low. Throughout much of its range, fire exclusion and removal of fine fuels by grazing livestock have reduced fire frequencies and allowed *Juniperus occidentalis* seedlings to colonize adjacent alluvial soils and expand into the sagebrush shrub-steppe and grasslands. *Juniperus occidentalis* savanna may occur on the drier edges of the woodland where trees are intermingling with or invading the surrounding grasslands and where local edaphic or climatic conditions favor grasslands over shrublands.

CES304.082 CONCEPTUAL MODEL

Environment: This woodland system is found along the northern and western margins of the Great Basin, from southwestern Idaho, along the eastern foothills of the Cascades, south to the Modoc Plateau of northeastern California (Tirmenstein 1999h, Sawyer et al. 2009). Elevations range from under 200 m along the Columbia River in central Washington to over 1500 m. In northwestern California stands range from 700 to 2300 m elevation (Tirmenstein 1999h, Sawyer et al. 2009).

Climate: Throughout the range the climate is cool, semi-arid, continental with 200-360 mm of precipitation annually, with the majority falling in winter. The temperature regime is cool in summer, with a wide range in diurnal temperatures and night frosts occurring most of the year. Summer lightning storms and associated fire are common and are presumably important in structuring the vegetation. (Franklin and Dyrness 1973).

Physiography/landform: In central Oregon, the center of the woodland's range, stands are found on all aspects and slope positions. Where this type grades into relatively mesic forest or grassland habitats, the vegetation becomes restricted to rock outcrops or escarpments with excessively drained soils.

Soils/substrate/hydrology: Juniperus occidentalis stands occur on a wide variety of soil types. Generally, soils are well-drained, shallow and stony with rock outcrops common, but soils may be deeper. They are medium-textured, with abundant coarse fragments, and derived from volcanic parent materials such as basalt, andesite, rhyolite, pumice, volcanic ash, tuff, welded tuff, as well as colluvial, alluvial, or eolian material (Tirmenstein 1999h, LANDFIRE 2007a). Soils derived from pumice ash are the most common edaphic characteristic of this woodland (LANDFIRE 2007a). Origins of the pumice sands are Mount Mazama and Newberry Crater (Miller et al. 1999). In most other areas, it occurs on rimrock, shallow soil scablands and in other isolated pockets.
Key Processes and Interactions: *Juniperus occidentalis* is a long-lived tree that can exceed 3000 years in age in rocky, fire-protected areas such as along rimrock (Waigchler et al. 2001, Thorne et al. 2007). These fire sensitive trees do not sprout following fire and are typically killed by moderate to severe fires (Tirmenstein 1999h, Sawyer et al. 2009). Young junipers have thin bark and are readily killed by surface fires (Martin et al. 1978), whereas mature trees with thicker bark are described as "moderately resistant" (Fowells 1965). Reproductive age begins at about 20 years, peaks after 50 years and continues for many years (Miller and Rose 1995,

Tirmenstein 1999h). Following stand-replacing fire, recovery time is relatively slow and depends on stand maturity, the size and season of burn, fire severity and juniper mortality, the persistence of the seeds in the seed bank, location of seed source, the presence of animal dispersers such as Clark's nutcrackers, competition from herbaceous species and shrubs, and the amount of post-fire precipitation (Burkhardt and Tisdale 1976, Tirmenstein 1999h). Large burns and long distances from seed sources slow recovery rates because seed dispersal is dependent on water and animals (Tirmenstein 1999h).

Juniperus occidentalis woodlands become "closed" at about 40% canopy cover when lateral tree roots fill interspaces between trees (Young et al. 1982, Thorne et al. 2007). At this stage cover of shrub and herbaceous layers begin to rapidly decline (Thorne et al. 2007).

Juniperus occidentalis savanna often occurs on the drier edges of the woodland where trees are intermingling with or invade the surrounding grasslands where local edaphic or climatic conditions favor grasslands over shrublands. Stands occur between the ponderosa zones and the sagebrush moisture zones and are expanding into big sagebrush steppe areas at a fairly rapid rate, creating extensive young stands, increasing the acreage of this type by more than five times (LANDFIRE 2007a, BpS 0910170). Western juniper woodlands and savannas experienced both large- and small-scale natural disturbances (LANDFIRE 2007a). Small-scale fires (less than 5 acres) and insects and disease kill single trees to small patches of trees throughout the stand on a frequent interval. Large-scale fires (>1000 acres) are less common, occurring once every 500 years or more (Miller et al. 1999). Drought can cause dieback and death of trees.

Areas where this system occurs contain some of the largest concentrations of ancient trees. Individuals may exceed 2000 years of age. These ancient western juniper woodlands provide important wildlife habitat. Cavities form in older trees and are important for many neotropical migrants. Western juniper cone-berries provide food for many animals, including elk, deer, coyotes, and small mammals such as mice, chipmunks, rabbits, squirrels, and woodrats; many such as coyotes serve as important dispersing agents of the junipers (Schupp et al. 1997, Tirmenstein 1999h). They are also used by wintering birds such as the American robin and Townsend solitaire (Burkhardt and Tisdale 1969, Eddleman 1984, Tirmenstein 1999h). This juniper is also an important food source for insects with 25 species of bark and wood boring beetles identified (Miller et al. 2005).

LANDFIRE developed a VDDT model for this system which has five classes (LANDFIRE 2007a, BpS 0910170):

A) Early Development (herbaceous-dominated with 0-60% cover - 2% of type in this stage): Herbaceous plants dominate this stage immediately following disturbance. Perennial bunchgrasses dominate the plant community. However, in the first few years following disturbance annual plants may dominate while perennial grasses and forbs recover. Succession to class B after 30 years. (Replacement and mixed fires).

B) Mid Development 1 Open (shrub-dominated with 0-30% cover - 5% of type in this stage): Shrubs dominate this stage. The composition of the shrub layer will be dependent on soil depth and climatic factors. Rabbitbrush will most likely be the dominant shrub following disturbance. However, big sagebrush, bitterbrush and wax current may also be found. Western juniper seedlings and saplings are present throughout the shrub layer. Western juniper has established below the canopy of the shrub layer. Shrub cover is approaching 20% on more productive sites but is most likely <15%. Herbaceous plants are being suppressed by the increase in woody plants. Succession to class C after 45 years. (Mixed and replacement fires).

C) Mid Development 2 Open (shrub/tree mix, tree cover 0-20% - 15% of type in this stage): Western juniper forms an even-aged woodland. Trees are characterized by regular conical shapes. Shrubs are being suppressed by the emerging woodland. Herbaceous vegetation is also being suppressed by the competition from woody plants. Succession to class E (late closed) after 45 years. (Mixed and replacement fires. Certain sites are edaphically constrained and thus transition to class D - late-open).

D) Late Development 2 Open (shrub/tree mix, tree cover 0-20% - 35% of type in this stage): Ancient western juniper savanna or open woodland composed of multiple structural layers. Some western juniper trees have dead portions in their canopies. Canopies are irregular in shape. Young trees can be found in open areas where recent small-scale disturbances occurred. Edaphic factors often maintain wide spacing between junipers. Understory grasses remain dominant and variable. (Maintains in class D. Many disturbances cause transitions to younger or more open conditions).

E) Late Development 1 Open (tree-dominated 20-40% cover - 43% of type in this stage): Ancient western juniper woodland composed of multiple structural layers. Some western juniper trees have dead portions in their canopies. Canopies are irregular in shape. Young trees can be found in open areas where recent small-scale disturbances occurred. Understory grasses are variable, based on slope, aspect and soil depth. (Maintains in class E. Many disturbances cause transitions to younger or more open conditions) (LANDFIRE 2007a).

Threats/Stressors: Conversion of this type has commonly come from catastrophic crown fires and "chaining" or mechanical removal of trees by land management agencies to convert woodlands to grasslands for livestock (Stevens 1999a, 199b, Stevens and Monsen 2004). Common stressors and threats include heavy grazing by livestock which removes the fine fuel layer that carries low-intensity fire. This results in an unnatural build-up of woody fuels, so when fires occur, they are large, high-intensity, severe fires that remove juniper from the system. If exotic species are present, post-crown fire and post-treatment outcomes may result in conversion to exotic species. Exotic annual grasses such as *Bromus tectorum* can replace the community creating an annual grassland which will be maintained by frequent fires (Mack 1981b, D'Antonio and Vitousek 1992, D'Antonio et al. 2009).

Some stands of this system contain ancient trees over 2000 years old. These ancient western juniper woodlands provide important wildlife habitat such as nesting cavities for neotropical migrants and berries for food (LANDFIRE 2007a). Uncharacteristic stand-replacing fire threatens these ancient stands.

Throughout much of the range of this system, *Juniperus occidentalis* populations are expanding into contiguous *Artemisia* shrub-steppe (Burkhardt and Tisdale 1976, Miller and Rose 1995, Bates et al. 2014). The reasons for this are not entirely clear, but *Juniperus occidentalis* has been documented to germinate and grow preferentially under the canopy of *Artemisia* and other shrubs (Everett 1986). Burkhardt and Tisdale (1969) noted that larger, older trees are often associated with rock outcrops, while younger trees are prevalent on adjacent alluvial soils. This pattern has also been observed in northeastern California (Barbour and Major 1988). This pattern has been interpreted to mean that *Juniperus occidentalis* is colonizing out from rocky refuges which offer shelter from fire, and that the recent expansion of *Juniperus occidentalis* woodlands can be linked to fire suppression (Bates et al. 2014). Active fire suppression and removal of fine fuels by grazing livestock have reduced fire frequency and allowed *Juniperus occidentalis* seedlings to colonize adjacent alluvial soils and expand into the shrub-steppe and grasslands (Tirmenstein 1999h, Bates et al. 2014).

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirect through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Management actions such as chaining juniper stands creates a large food source of injured junipers for insects such as western juniper bark beetle (Miller et al. 2005). However, insect attacks usually do not result in the killing of live trees, unless combined with drought such as in the 1920s and 1930s when western junipers were killed by insects in central Oregon (Furniss and Carolin 1977).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated stand-replacing fire. Because of increased FRI from cheatgrass invasion, mortality of juniper trees and reduction of the juniper regeneration will result in loss of trees and conversion of woodland to annual grassland or shrublands adapted to frequent fire. With loss of ecosystem structure many of the animals that depend on juniper berries will also be gone. In addition, severe soil loss may occur where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion and surface disturbances may allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<5000 acres) for this large-patch type. Occurrence is surrounded primarily by urban or agricultural landscape, with <25% landscape cover of natural or semi-natural vegetation. The fire regime has high departure (VCC 3) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed high woody fuel load buildup. Surficial disturbances occur on more than 50% of the area (e.g., mines or ranch activities and buildings; off-road vehicle use). Up to 50% of the stand may have been "chained" and re-seeded. Microbiotic crusts are >75% removed, occurring only in small pockets naturally protected from livestock and off-road vehicle use. Soil erosion may be severe in places.

Moderate-severity environmental degradation appears where occurrences are moderate (5000-10,000 acres) in size for this large-patch type. Landscape is a mosaic of agricultural or semi-developed areas and natural or semi-natural vegetation, the latter composing 25-80% of the landscape. The fire regime has moderate departure (VCC 2) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed moderate woody fuel load buildup. Surficial disturbances occur on more than 20% of the area. Up to 50% of the stand may have been "chained" and re-seeded. There are more than a few roads found within the occurrence. Microbiotic crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence. Soil erosion and gullying may be observed in patches (up to 30%) within the stand.

High-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) present and abundant throughout much of the stand. Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) may be present and even dominant in spots, but not throughout the stand. Connectivity is moderately hampered by fragmentation from roads and/or agriculture that restrict natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.773 Great Basin Pinyon-Juniper Woodland

CES304.773 CLASSIFICATION

Concept Summary: This ecological system occurs on dry mountain ranges of the Great Basin region and eastern foothills of the Sierra Nevada extending south in scattered locations throughout southern California. This woodland is typically found at lower elevations ranging from 1600-2800 m. These woodlands occur on warm, dry sites on mountain slopes, mesas, plateaus and ridges. Woodlands dominated by a mix of *Pinus monophylla* and *Juniperus osteosperma*, pure or nearly pure occurrences of *Pinus monophylla*, or woodlands dominated solely by *Juniperus osteosperma* comprise this system, but in some regions of southern California, *Juniperus osteosperma* is replaced by *Juniperus californica*. *Cercocarpus ledifolius* is a common associate. On the east slope of the Sierras in California, *Pinus jeffreyi* and *Juniperus grandis* may be components of these woodlands. Understory layers are variable. Associated species include shrubs such as *Arctostaphylos patula, Artemisia arbuscula, Artemisia nova, Artemisia tridentata, Cercocarpus ledifolius, Cercocarpus intricatus, Coleogyne ramosissima, Yucca brevifolia, Quercus gambelii, Quercus turbinella, Quercus john-tuckeri, Juniperus californica, Quercus chrysolepis*, and bunchgrasses *Hesperostipa comata, Festuca idahoensis, Pseudoroegneria spicata, Leymus cinereus*, and *Poa fendleriana*. This system occurs at lower elevations than ~Colorado Plateau Pinyon-Juniper Woodland (CES304.767)$$ where sympatric.

Related Concepts:
- Juniper - Pinyon Woodland (412) (Shiflet 1994) **>**
- Pinyon - Juniper: 239 (Eyre 1980) **>**

Distribution: This system occurs on dry mountain ranges of the Great Basin region and eastern foothills of the Sierra Nevada, typically at lower elevations ranging from 1600-2800 m. It extends southwest in California to the northern Transverse Ranges (Ventura County) and San Jacinto Mountains (Riverside County).

Nations: US

Description Author: T. Keeler-Wolf, M.S. Reid, K.A. Schulz

CES304.773 CONCEPTUAL MODEL

Environment: This system occurs on dry mountain ranges of the Great Basin region and eastern foothills of the Sierra Nevada extending south into the Mojave Desert ranges and southwest in to the northern Transverse Ranges and San Jacinto Mountains. Elevations range from 1000 to 2800 m. Upper elevation limits are determined by local climate and/or the presence of competing tree species. Stands generally occur on sites with shallow rocky soils or rock-dominated sites that are protected from frequent fire (rocky ridges, broken topography and mesatops).

Climate: Climate is temperate, continental, and semi-arid with cold winters. Precipitation ranges from 20 to 45 cm annually, mostly occurring during fall and winter months (Brown 1982a). Summers are typically dry and there is usually extreme variation in annual precipitation. Severe climatic events occurring during the growing season, such as frosts and drought, are thought to limit the distribution of pinyon-juniper woodlands to relatively narrow altitudinal belts on mountainsides.

Physiography/landform: These woodlands occur on warm, dry sites on mountain slopes, mesas, plateaus, ridges, foothills, and upper alluvial fans.

Soil/substrates/hydrology: Soils supporting this system vary in texture, ranging from stony, cobbly, gravelly sandy loams to clay loam or clay. Adjacent upland systems include ~Inter-Mountain Basins Montane Sagebrush Steppe (CES304.785)$$, ~Inter-Mountain Basins Curl-leaf Mountain-mahogany Woodland and Shrubland (CES304.772)$$, ~Inter-Mountain Basins Aspen-Mixed Conifer Forest and Woodland (CES304.776)$$ above and at lower elevations, ~Great Basin Xeric Mixed Sagebrush Shrubland (CES304.774)$$, ~Inter-Mountain Basins Big Sagebrush Shrubland (CES304.777)$$, and ~Mojave Mid-Elevation Mixed Desert Scrub (CES302.742)$$.

Key Processes and Interactions: *Pinus monophylla, Juniperus osteosperma*, and *Juniperus scopulorum* are slow-growing, long-lived trees (about 650 years for *Juniperus osteosperma*, 300 years for *Juniperus scopulorum*, and 800 years for *Pinus monophylla*, although older individuals are known) (Burns and Honkala 1990a, Zlatnik 1999e, Zouhar 2001b, Scher 2002, Sawyer et al. 2009). These trees are killed by severe fire because of thin bark and lack of self-pruning; however, mature trees can survive low-intensity fires (Zouhar 2001b, Sawyer et al. 2009). Although there is variation in fire frequency because of the diversity of site characteristics, stand-replacing fire was uncommon in this ecological system historically, with an average fire-return interval (FRI) of 100-1000 years occurring primarily during extreme fire behavior conditions and during long droughts (Zouhar 2001b) (LF BpS model 1210190). Mixed-severity fire (average FRI of 100-500 years) was characterized as a mosaic of replacement and surface fires distributed through stands in patches at a fine scale (<0.1 acre) (LF BpS model 1210190).

Fire rotation in the San Bernardino Mountains was determined to be 480 years (Wangler and Minnich 2006). These woodlands have a truncated long fire-return interval of 200+ years with surface to passive crown fires of medium size, low complexity, high intensity, and very high severity (Sawyer et al. 2009). After a stand-replacing fire, the site is usually colonized by herbaceous plants and shrubs. The shrubs act as nurse plants, with *Pinus monophylla* seedlings establishing 20-30 years post fire after shrub density increases, and then a tree canopy forms after 100-150 years (Minnich 2007). As tree canopy becomes denser there is a decline in shrub cover (Minnich 2007). Fires are associated with herbaceous fuel buildup following a wet period (Minnich 2007).

Other important ecological processes include drought, insect infestations, pathogens, herbivory, and seed dispersal by birds and mammals. Juniper berry and pinyon nut crops are primarily utilized by birds and small mammals (Johnsen 1962, McCulloch 1969, Short et al. 1977, Salomonson 1978, Balda 1987, Gottfried et al. 1995). Large mammals, such as mule deer (*Odocoileus hemionus*), white-tailed deer (*Odocoileus virginianus*) and elk (*Cervus elaphus*), eat leaves and seeds of both species and they browse woodland grasses, forbs and shrubs, including *Artemisia tridentata, Cercocarpus montanus, Quercus gambelii*, and *Purshia stansburiana* (Short and McCulloch 1977).

The principal dispersers of juniper and pinyon seeds are birds, although many mammals also feed on them. These animals consume juniper berries and excrete viable scarified juniper seeds over extensive areas, which germinate faster than uneaten seeds (Johnsen 1962, Meeuwig and Bassett 1983). Primary juniper seed dispersers are Bohemian waxwing (*Bombycilla garrulus*), cedar waxwing (*Bombycilla cedrorum*), American robin (*Turdus migratorius*), turkey (*Meleagris gallopavo*), and five species of jays (Scher 2002). Pinyon seeds are a critically important food source for western scrub jay (*Aphelocoma californica*), pinyon jay (*Gymnorhinus cyanocephalus*), Steller's jay (*Cyanocitta stelleri*) and Clark's nutcracker (*Nucifraga columbiana*). These birds are primary dispersers of pinyon seeds and during mast crop years cache hundreds of thousands of pinyon seeds, many of which are never recovered (Balda and Bateman 1971, Vander Wall and Balda 1977, Ligon 1978). Many mammals are also known to eat singleleaf pinyon seeds, including several species of mice (*Peromyscus* spp.), woodrats (*Neotoma* spp.), squirrels (*Sciurus* spp.), chipmunks (*Neotamias* spp.), deer, black bear (*Ursus americanus*), and desert bighorn sheep (*Ovis canadensis nelsoni*) (Christensen and Whitham 1993, Zouhar 2001b). Because singleleaf pinyon seeds are heavy and totally wingless, seed dispersal is dependent on vertebrate dispersers that store seeds in food caches, where unconsumed seeds may germinate. This seed dispersal mechanism is a good example of a co-evolved, mutualistic, plant-vertebrate relationship (Vander Wall et al. 1981, Evans 1988, Lanner 1996) and would be at risk with loss of trees or dispersers.

There are many insects, pathogens, and plant parasites that attack pinyon and juniper trees (Gottfried et al. 1995, Rogers 1995, Weber et al. 1999). Juniper mistletoe (*Phoradendron juniperinum*) occurs on junipers and pinyon dwarf mistletoe (*Arceuthobium divaricatum*) occurs on pines. Both mistletoes reduce vigor and cause dieback but rarely cause mortality (Meeuwig and Bassett 1983). For pinyon, there are at least seven insects, and fungi such as blackstain root-rot (*Leptographium wageneri*), pinyon needle rust (*Coleosporium ribicola*), and pinyon blister rust (*Cronartium occidentale*) (Skelly and Christopherson 2003). The insects are normally present in these woodland stands, and during drought-induced water stress, outbreaks may cause local to regional mortality (Wilson and Tkacz 1992, Gottfried et al. 1995, Rogers 1995). Most insect-related pinyon mortality in the West is caused by pinyon Ips bark beetle (*Ips confusus*) (Rogers 1993). The current epidemic of ips beetles in many areas that has killed numerous pinyons has created high fuel loads that further threaten stands (Thorne et al. 2007).

LANDFIRE modelers predict severe weather (usually drought), insects and tree pathogens are coupled disturbances that thin trees to varying degrees and kill small patches every 250-500 years on average, with greater frequency in more closed stands (LF BpS model 1210190).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 1210190). These are summarized as:

A) Early Development 1 Open (herbaceous-dominated - 5% of type in this stage): Herbaceous cover is 0-15%. Shrub cover is 0%. Initial post-fire community dominated by annual grasses and forbs. Later stages of this class contain greater amounts of perennial grasses and forbs. Evidence of past fires (burnt stumps and charcoal) should be observed. Duration is 10 years with succession to class B, mid-development closed. Replacement fire occurs every 300 years on average.

B) Mid Development 1 Open (shrub-dominated - 5% of type in this stage): Shrub cover is 5-20%. Dominated by shrubs, perennial forbs and grasses. Tree seedlings starting to establish on favorable microsites. Total cover remains low due to shallow unproductive soil. Duration is 20 years with succession to class C unless infrequent replacement fire (FRI of 200 years) returns the vegetation to class A. It is important to note that replacement fire at this stage does not eliminate perennial grasses. Mixed-severity fire (average FRI of 200 years) thins the woody vegetation but does not change its succession age.

C) Mid Development 2 Open (shrub-dominated - 20% of type in this stage): Tree cover is 5-20%. Tree height <5 m. Shrub- and tree-dominated community with young juniper and pinyon seedlings becoming established. Duration is 70 years with succession to class D unless replacement fire (average FRI of 250 years) causes a transition to class A. It is important to note that replacement fire at this stage does not eliminate perennial grasses. Mixed-severity fire as in class B. Mortality from insects, pathogens, and drought occurs at a rotation of approximately 500 years and causes a transition to class B by killing older trees.

D) Late Development 1 Open (conifer-dominated - 35% of type in this stage): Tree cover is 5-40%. Tree height <10 m. Community dominated by young to mature juniper and pine of mixed age structure. Juniper and pinyon becoming competitive on site and beginning to affect understory composition. Duration 200 years with succession to class E unless replacement fire (average FRI of 1000 years) causes a transition to class A. Mixed-severity fire is less frequent than in previous states (500 years). Surface fire (mean FRI of 500 years) is infrequent and does not change successional dynamics. Tree pathogens and insects such as pinyon Ips become more important for woodland dynamics occurring at a rotation of 250 years, including both patch mortality (500-year rotation) and thinning of isolated individual trees (500-year rotation).

E) Late Development 2 Open (conifer-dominated - 35% of type in this stage): Tree cover is 5-50%. Tree height 5-25 m. Some sites dominated by widely spaced old juniper and pinyon, while elsewhere there are dense, old-growth stands with multiple layers. May have all-aged, multi-storied structure. Occasional shrubs with few grasses and forbs and often much rock. Understory depauperate and high amounts of bare ground present. Grasses present on microsites with deeper soils (>50 cm [20 inches]) with restricting clay subsurface horizon. Potential maximum overstory replacement fire and mixed-severity fires are rare (average FRIs of 1000 and 500 years, respectively). Surface fire occurs when especially dry years follow wet years (500-year rotation) and will scar ancient trees. Tree pathogens and insects associated with drought conditions kill patches of trees (1000-year rotation), with succession to class C, and individual trees (1000-year rotation) with succession to class D. Duration 800+ years.

Most pinyon-juniper woodlands in the southwest have high soil erosion potential (Baker et al. 1995). Several studies have measured present-day erosion rates in pinyon-juniper woodlands, highlighting the importance of herbaceous cover and cryptogamic soil crusts (Baker et al. 1995, Belnap et al. 2001) in minimizing precipitation runoff and soil loss in pinyon-juniper woodlands.

Threats/Stressors: Threats to pinyon-juniper woodlands include invasion by introduced annual grasses, livestock grazing, development, and fire suppression. Before 1900, this system was mostly open woodland restricted to fire-safe areas on rocky ridges, etc., where the low cover of fine fuels reduced the spread of fires. Over the last 100 years fire regimes were altered because of fire suppression and grazing by livestock, which reduces the amount of fine fuels (grasses) that carry fire thus reducing fire frequency (Swetnam and Baisan 1996a). Currently, much of this system has a more closed canopy than historical conditions. Fire suppression has led to a buildup of woody fuels that in turn increases the likelihood of high-intensity, stand-replacing fires. Heavy grazing, in contrast to fire, removes the grass cover and tends to favor shrub and conifer species (Swetnam and Baisan 1996a).

These woodlands have been expanding into adjacent steppe grasslands and shrublands in many areas, reportedly in connection with livestock grazing and altered fire regimes (Blackburn and Tueller 1970, Tausch et al. 1981, Chambers 2001, Wangler and Minnich 2006, LANDFIRE 2007a, Weisberg et al. 2007). Historical fire suppression has resulted in denser tree canopies and a pinyon-juniper woodland expansion especially into big sagebrush shrublands (Wangler and Minnich 2006) and shrub-steppe and grassland (Blackburn and Tueller 1970). This may also allow the presence of relatively fire-intolerant species such as *Artemisia tridentata, Coleogyne ramosissima*, or *Larrea tridentata* in stands of this system in relatively mesic sites (Keeler-Wolf and Thomas 2000).

Denser canopies in pinyon-juniper woodland can also increase fire severity, as well as increasing soil erosion because of reduction in ground cover with shading by tree canopy (Tausch and West 1988, Zouhar 2001b). Recently, significant losses in pinyon-juniper woodlands are a result of shortening of fire-return intervals (FRI) because of invasion by introduced *Bromus tectorum* and other annuals that provide fine fuels that carry fire (Thorne et al. 2007).

Currently, epidemics of the native pinyon ips beetle (*Ips confusus*) often occur during drought periods when mature trees are weakened and vulnerable to ips beetle attacks, which kill many pinyons in turn creating very high fuel loads throughout much of the system's range (Furniss and Carolin 2002, Thorne et al. 2007). In addition, many of these communities have been severely impacted by past range practices of chaining, tilling, and reseeding with exotic forage grasses. Although the dominant trees appear to regenerate after such disturbances, the effects on native understory species are poorly known (Thorne et al. 2007).

Human development has impacted some locations throughout the Great Basin. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Management actions such as chaining pinyon-juniper stands creates a large food source of injured pines for ips beetles to feed on that can quickly multiply creating epidemic outbreaks of beetles that attack and kill many healthy pinyons (Furniss and Carolin 2002). Drought stresses pinyon trees and makes them less able to survive Ips attacks (Furniss and Carolin 2002, Thorne et al. 2007).

Ecosystem Collapse Thresholds: Ecosystem collapse can occur after repeated stand-replacing fires. The increased fire frequency is a consequence of cheatgrass invasion, which provides fine fuels that carry fire. Burning causes mortality of pinyon and juniper trees and reduces pinyon and juniper regeneration will result in loss of trees and conversion of woodland to grasslands or shrublands that are adapted to frequent fire (Brooks and Minnich 2006, Thorne et al. 2007).

High-severity environmental degradation appears where occurrences tend to be relatively small (<5000 acres) for this type. Stands are surrounded primarily by urban or agricultural landscape, with <25% landscape cover of natural or semi-natural vegetation. The fire regime has high departure (VCC 3) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed high woody fuel load buildup. Surficial disturbances occur on more than 50% of the area (e.g., mines or ranch activities and buildings; off-road vehicle use). Up to 50% of the stand may have been "chained" and re-seeded. Microbiotic crusts are >75% removed, occurring only in small pockets naturally protected from livestock and off-road vehicle use. Soil erosion may be severe in places.

Moderate-severity environmental degradation appears where occurrences are moderate (5000-10,000 acres) in size for this large-patch type. Landscape is a mosaic of agricultural or semi-developed areas and natural or semi-natural vegetation, the latter composing 25-80% of the landscape. The fire regime has moderate departure (VCC 2) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed moderate woody fuel load buildup. Surficial disturbances occur on more than 20% of the area. Up to 50% of the stand may have been "chained" and re-seeded. There are more than a few roads found within the occurrence. Microbiotic crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence. Soil erosion and gullying may be observed in patches (up to 30%) within the stand.

High-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) present and abundant throughout much of the stand. Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) may be present and even dominant in spots, but not throughout the stand. Connectivity is moderately hampered by fragmentation from roads and/or agriculture that restrict natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.772 Inter-Mountain Basins Curl-leaf Mountain-mahogany Woodland and Shrubland

CES304.772 CLASSIFICATION

Concept Summary: This ecological system occurs in hills and mountain ranges of the Intermountain West basins from the eastern foothills of the Sierra Nevada northeast to the foothills of the Bighorn Mountains. It typically occurs from 600 m to over 2650 m in elevation on rocky outcrops or escarpments and forms small- to large-patch stands in forested areas. Most stands occur as shrublands on ridges and steep rimrock slopes, but they may be composed of small trees in steppe areas. Scattered junipers or pines may also occur. This system includes both woodlands and shrublands dominated by *Cercocarpus ledifolius*. *Artemisia tridentata ssp. vaseyana, Purshia tridentata*, with species of *Arctostaphylos, Ribes*, or *Symphoricarpos* are often present. Undergrowth is often very sparse and dominated by bunchgrasses, usually *Pseudoroegneria spicata* and *Festuca idahoensis*. *Cercocarpus ledifolius* is a slow-growing, drought-tolerant species that generally does not resprout after burning and needs the protection from fire that rocky sites provide.

Related Concepts:

- Curlleaf Mountain-Mahogany (415) (Shiflet 1994) **<**
- Curlleaf Mountain-Mahogany - Bluebunch Wheatgrass (322) (Shiflet 1994) **<**

Distribution: This system occurs in hills and mountain ranges of the Intermountain West basins from the eastern foothills of the Sierra Nevada northeast to the foothills of the Bighorn Mountains.

Nations: US

Concept Source: K.A. Schulz

Description Author: M.S. Reid, G. Kittel and K.A. Schulz

CES304.772 CONCEPTUAL MODEL

Environment: This ecological system is widespread in semi-arid hills and mountain ranges of the intermountain western U.S. from the eastern foothills of the Sierra Nevada and Cascade Range east into the Rocky Mountains including the foothills of the Bighorn Mountains. It also occurs south into the Mojave Desert and the Grand Canyon in northern Arizona. Stands mostly occur below

montane conifer forests and above desert scrub from 1500 to 3200 m in elevation, extending down to 600 m in the north (Gucker 2006c). Higher-elevation stands typically occur on warmer and drier southerly slopes. Annual precipitation averages 25-45 cm, with a significant proportion falling as winter snow. Sites typically have shallow to deep, well-drained, often rocky, nutrient-poor, sandy loam soils frequently derived primarily from carbonate sediments (limestone or dolomite) or on sandstones rich in calcium carbonate (Reid et al. 1999). Other rock types include quartz, gneiss, and basalt.
Key Processes and Interactions: *Cercocarpus ledifolius* is a slow-growing, drought-tolerant species which can inhabit very poor sites, such as cliffs, stony slopes, and outcrops. Stands are often small and clumped near ridgetops. These sites may also afford the species some protection from fire as the oldest individuals have been observed in these stands (Ross 1999). Succession in these stands is variable depending on site conditions and disturbance as *Cercocarpus ledifolius* is both a primary early-successional colonizer that rapidly invades bare mineral soils after disturbance and the dominant long-lived species in mid- and late-seral stands (Duncan 1975, Gruell et al. 1985). Shade tolerance is low so higher-elevation stands on sites where conifers can grow will eventually be overtopped by taller conifer trees forming woodlands with a *Cercocarpus ledifolius* subcanopy or shrub layer until replaced by more shade-tolerant shrubs such as *Physocarpus malvaceus* or *Acer glabrum* (Gruell et al. 1985, Steele and Geier-Hayes 1995).

Mature *Cercocarpus ledifolius* have thick bark and may survive "light" fires (Schultz 1987). However, more often they are killed by fire, and regeneration is by seedling establishment as sprouts following fire are rare and short-lived (Gruell et al. 1985, Gucker 2006c). Range expansion of this system in the last century has been attributed to decreased fire frequency (Gruell 1982, Gruell et al. 1994). From 1750 to the early 1900s, a mean fire-return interval was between 13 and 22 years, and stands were likely restricted to rocky sites where fuel levels were low. Since 1900 the fire-return interval has increased substantially because of fine fuel reductions with heavy livestock grazing, fire exclusion practices, and/or decreased human-caused fires (Arno and Wilson 1986). However, in the Petersen Mountains of western Nevada, the extent of curl-leaf mountain-mahogany has "decreased dramatically" from 1954 to 1997 as a result of increased fire incidence linked to increased cheatgrass dominance (Ross 1999).

Cercocarpus ledifolius is highly favored by native ungulates for winter range. Excessive browsing by deer and other wildlife has "high-lined" individual shrubs and reduced regeneration (West and Young 2000). Seeds are consumed by a variety of small mammals (Plummer et al. 1968). Mortality from bark damage (drilling) by red-breasted sapsuckers has been reported from Bald Mountain near the California-Nevada border (Ross 1999).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 1210620). These are summarized as:

A) Early Development 1 All Structures (10% of type in this stage): Curl-leaf mountain-mahogany rapidly invades bare mineral soils after fire. Litter and shading by woody plants inhibits establishment. Bunchgrasses and disturbance-tolerant forbs and resprouting shrubs, such as snowberry, may be present. Rabbitbrush and sagebrush seedlings are present. Vegetation composition will affect fire behavior, especially if chaparral species are present. Replacement fire (average FRI of 500 years), mixed-severity fire (average FRI of 100 years) and native herbivory of seedlings (2 out every 100) all affect this class. Replacement fire and native herbivory will reset the ecological clock to zero. Mixed-severity fire does not affect successional age. Succession to class C after 20 years.

B) Mid Development 1 Closed (10% of type in this stage): Young curl-leaf mountain-mahogany are common, although shrub diversity is very high. One out of every 1000 mountain-mahogany are taken by herbivores but this has no effect on model dynamics. Replacement fire (mean FRI of 150 years) causes a transition to class A. Mixed-severity fire can result in either maintenance (mean FRI of 80 years) in the class or a transition to class D (mean FRI of 200 years). Succession to class E after 90 years.

C) Mid Development 1 Open (15% of type in this stage): Curl-leaf mountain-mahogany may codominate with mature sagebrush, bitterbrush, snowberry and rabbitbrush. Few mountain-mahogany seedlings are present. Replacement fire (mean FRI is 150 years) will cause a transition to class A, whereas mixed-severity fire (mean FRI of 50 years) will thin this class but not cause a transition to another class. Native herbivory of seedlings and young saplings occurs at a rate of 1/100 seedlings but does not cause an ecological setback or transition. Succession to class B after 40 years.

D) Late Development 1 Open (20% of type in this stage): Moderate cover of mountain-mahogany. This class represents a combined Mid2-Open and Late1-Open cover and structure combination resulting from mixed-severity fire in class C (note: the combined class results in a slightly inflated representation in the landscape). Further, this class describes one of two late-successional endpoints for curl-leaf mountain-mahogany that is maintained by surface fire (mean FRI of 50 years). Evidence of infrequent fire scars on older trees and presence of open savanna-like woodlands with herbaceous-dominated understory are evidence for this condition. Other shrub species may be abundant, but decadent. In the absence of fire for 150 years (2-3 FRIs for mixed-severity and surface fires), the stand will become closed (transition to class E) and not support a herbaceous understory. Stand-replacement fire every 300 years on average will cause a transition to class A. Class D maintains itself with infrequent surface fire and trees reaching very old age.

E) Late Development 1 Closed (45% of type in this stage): High cover of large shrub or tree-like mountain-mahogany. Very few other shrubs are present and herb cover is low. Duff may be very deep. Scattered trees may occur in this class. This class describes one of two late-successional endpoints for curl-leaf mountain-mahogany. Replacement fire every 500 years on average is the only disturbance and causes a transition to class A. Class will become old-growth with trees reported to reach 1000+ years.

Curl-leaf mountain-mahogany is easily killed by fire and does not resprout (Marshall 1995b, Gucker 2006c). It is a primary early succession colonizer rapidly invading bare mineral soils after disturbance. Fires are not common in early-seral stages, when there is little fuel, except in chaparral. Replacement fires (mean FRI of 150-500 years) become more common in mid-seral stands, where herbs and smaller shrubs provide ladder fuels. By late succession, two classes and fire regimes are possible depending on the history of mixed-severity and surface fires. In the presence of surface fire (FRI of 50 years) and past mixed-severity fires in younger classes, the stand will adopt a savanna-like woodland structure with a grassy understory, spiny phlox and currant. Trees can become very old and will rarely show fire scars. In late, closed stands, the absence of herbs and small forbs makes replacement fires uncommon (FRI of 500 years), requiring extreme winds and drought. In such cases, thick duff provides fuel for more intense fires. Mixed-severity fires (mean FRI of 50-200 years) are present in all classes, except the late-closed one, and more frequent in the mid-development classes (LANDFIRE 2007a, BpS 1210620).

Ungulate herbivory: Heavy browsing by native medium-sized and large mammals reduces mountain-mahogany productivity and reproduction (Marshall 1995b, Gucker 2006c). This is an important disturbance in early- and mid-seral stages, when mountain-mahogany seedlings are becoming established. Browsing by small mammals has been documented (Marshall 1995b, Gucker 2006c), but is relatively unimportant and was incorporated as a minor component of native herbivory mortality.

Avian-caused mortality: In western Nevada, for ranges in close proximity to the Sierra Nevada, sapsucker's drilling of young curl-leaf mountain-mahogany has been observed to cause stand-replacement mortality (C. Ross, NV BLM, pers. comm. 2018). Windthrow and snow creep on steep slopes are also sources of mortality.

Threats/Stressors: *Cercocarpus ledifolius* browse may have limited livestock use including domestic goats, sheep, or cattle in spring, fall, and/or winter but rarely in the summer (Gucker 2006c). Stands often occur on steep rocky slopes, but open shrubland or open woodland stands with grassy understory could provide significant livestock forage.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Curl-leaf mountain-mahogany seedlings appear to be sensitive to drought, frost, and competition from exotic vegetation, especially *Bromus tectorum* (Plummer et al. 1968, Shaw et al. 2004, Gucker 2006c). High seedling mortality can also result from heavy browsing by wildlife and mature shrubs can be heavily pruned and suppressed as well (Gucker 2006c).

Fire suppression and exclusion have facilitated an increase in abundance of this system in the Intermountain West (Gruell et al. 1994, Gucker 2006c). However, increased fire frequency and severity from excessive fine-fuel buildup due to cheatgrass invasion may negatively impact some stands.

Ecosystem Collapse Thresholds:

CES304.782 Inter-Mountain Basins Juniper Savanna

CES304.782 CLASSIFICATION

Concept Summary: This ecological system occupies dry foothills and sandsheets of western Colorado, northwestern New Mexico, northern Arizona, Utah, and west into the Great Basin of Nevada and southern Idaho. It is typically found at lower elevations ranging from 1000-2300 m. This system is generally found at lower elevations and more xeric sites than ~Great Basin Pinyon-Juniper Woodland (CES304.773)$$ or ~Colorado Plateau Pinyon-Juniper Woodland (CES304.767)$$. These occurrences are found on lower mountain slopes, hills, plateaus, basins and flats often where juniper is expanding into semi-desert grasslands and steppe. The vegetation is typically open savanna, although there may be small-patch inclusions of juniper woodlands. This savanna is typically dominated by an open canopy of *Juniperus osteosperma* trees with high cover of perennial bunchgrasses and forbs, with *Bouteloua gracilis, Hesperostipa comata*, and *Pleuraphis jamesii* being most common. In the southern Colorado Plateau, *Juniperus monosperma* or juniper hybrids may dominate the tree layer. Pinyon trees are typically not present because sites are outside the ecological or geographic range of *Pinus edulis* and *Pinus monophylla*. It has been suggested that all *Juniperus osteosperma* stands in Wyoming be placed in ~Colorado Plateau Pinyon-Juniper Woodland (CES304.767)$$. This savanna system does not occur in Wyoming. Extensive *Juniperus osteosperma* woodlands should be included in one of the pinyon-juniper woodland systems or ~Rocky Mountain Foothill Limber Pine-Juniper Woodland (CES306.955)$$.

Related Concepts:

- Juniper - Pinyon Woodland (412) (Shiflet 1994) **><**
- Rocky Mountain Juniper: 220 (Eyre 1980) **><**

Distribution: This juniper savanna occurs from northwestern New Mexico, northern Arizona, western Colorado, Utah, west into the Great Basin of Nevada and southern Idaho. Where it occurs in California, it is found only in the far eastern edges of the state adjacent to other Great Basin systems.

Nations: US

Concept Source: K.A. Schulz

Description Author: K.A. Schulz

CES304.782 CONCEPTUAL MODEL

Environment: This widespread ecological system occupies dry foothills and sandsheets of western Colorado, northwestern New Mexico, northern Arizona, Utah, and west into the Great Basin of Nevada and southern Idaho. It is typically found at lower elevations ranging from 1000-2300m, but may extend up to 2650 m.

Climate: Climate is cool, semi-arid, and continental. Summers are generally hot and dry. Winters are typically cold with occasional snow and there can be extended periods of freezing temperatures. Mean annual precipitation is 25-35 cm, but the seasonal distribution varies across the range of the system. Generally, winter precipitation in the form of westerly storms is maximal along the northwest edge of the range, and summer moisture increases to the east and south (monsoons). Annual precipitation on the Colorado Plateau has a bimodal distribution with moisture peaking in winter and summer.

Physiography/landform: Stands occur on lower to middle elevation mountain slopes and foothills of the many ranges and plateaus of the region.

Soil/substrate/hydrology: Substrates are typically moderately deep to deep, coarse- to fine-textured soils that readily support a variety of growth forms, including trees, grasses, and other herbaceous plants (Stuever and Hayden 1997a, Romme et al. 2009).

Key Processes and Interactions: *Juniperus osteosperma* is a relatively short (generally <10 m tall), shade-intolerant, drought-tolerant, slow-growing, long-lived tree (up to 650 years old) (Meeuwig and Bassett 1983, Zlatnik 1999e). *Juniperus osteosperma* is non-sprouting and may be killed by fire (Wright et al. 1979). Litter from juniper has an allelopathic effect on some grasses such as *Bouteloua gracilis, Festuca idahoensis*, and *Poa secunda* (Jameson 1970, Zlatnik 1999e).

Within a given region, the density of juniper trees, both historically and currently, is strongly related to topo-edaphic gradients. Less steep sites, especially those with finer-textured soils are where savannas, grasslands, and shrub-steppes have occurred in the past. Stands in this system occurred on these gentler slopes and historically may have been large and savanna-like with a very open upper canopy and high grass production. Juniper savanna is usually distributed across the landscape in patches that range from 10s to 100s of acres in size (LANDFIRE 2007a). In areas with very broken topography and/or mesa landforms, this type may have occurred in patches of several hundred acres (LANDFIRE 2007a). In Utah and Nevada pinyon and juniper landscape patches tended to be 10-100s of acres in size (LANDFIRE 2007a).

Key ecological processes are fire, climate fluctuations, grazing/herbivory, and insect/disease outbreaks. The effect of a fire on these stands is largely dependent on the tree height and density, fine-fuel load on the ground, weather conditions and season (Wright et al. 1979). Large trees generally survive unless the fire gets into the crown due to heavy fuel loads in the understory. In this system fire acts to open stands, kill young trees, increase diversity and productivity in understory species, and create a mosaic of stands of different sizes and ages across the landscape (Bradley et al. 1992).

Uncertainty exists about the fire frequencies of this ecological system, though it is predominantly Fire Regime Group III (fire frequency 30-100 years) (LANDFIRE 2007a); the fire regime is primarily determined by fire occurrence in the surrounding matrix vegetation (LANDFIRE 2007a). Lightning-ignited fires were common but typically did not affect more than a few individual trees. Replacement fires were uncommon to rare (average FRI of 100-500 years) and occurred primarily during extreme fire behavior conditions (LANDFIRE 2007a). Mixed-severity fire (average FRI of 100-500 years) was characterized as a mosaic of replacement and surface fires distributed through the patch at a fine scale (<0.1ac) (LANDFIRE 2007a). Surface fires could occur in stands where understory grass cover is high and provides adequate fuel. Surface fires were primarily responsible for producing fire scars on juniper trees and killing juniper seedlings and saplings (average FRI of 100 years).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2411150). The model was reviewed and references to pinyon were removed, then summarized as:

A) Early Development 1 Open (herbaceous-dominated - 5% of type in this stage): Initial post-fire community dominated by annual forbs. Later stages of this class contain greater amounts of perennial grasses and forbs. Duration 10 years with succession to class B, mid-development closed. Replacement fire occurs every 100 years on average. Infrequent mixed-severity fire (average FRI of 300 years) thins vegetation.

B) Mid Development 1 Open (herbaceous-dominated - 5% of type in this stage): Dominated by perennial forbs and grasses. Total cover remains low due to shallow, unproductive soil. Duration 20 years with succession to class C unless infrequent replacement fire (FRI of 100 years) returns the vegetation to A. It is important to note that replacement fire at this stage does not eliminate perennial grasses, thus, succession age in A after this type of fire would be older than zero and <10. Mixed-severity fire (average FRI of 100 years) thins the woody vegetation.

C) Mid Development 2 Open (15% of type in this stage): Shrub-dominated community with young juniper seedlings becoming established. Duration 70 years with succession to class D unless replacement fire (average FRI of 200 years) causes a transition to class A. It is important to note that replacement fire at this stage does not eliminate perennial grasses, thus, succession age in class A after this type of fire would be older than zero and <10. Mixed-severity fire as in class B.

D) Late Development 1 Open (tree-dominated - 35% of type in this stage): Community dominated by young juniper of mixed age structure. Juniper becoming competitive on site and beginning to affect understory composition. Duration 300 years with succession to class E unless replacement fire (average FRI of 500 years) causes a transition to class A. Mixed-severity fire is less frequent than in previous states (200 years), whereas surface fire every 100 years on average becomes more important at this age in succession.

E) Late Development 2 Open (tree-dominated - 40% of type in this stage): Site dominated by widely spaced old juniper trees. Grasses (e.g., *Bouteloua gracilis, Hesperostipa comata*) present on microsites sites with deeper soils (>20 in) with restricting clay subsurface horizon. Replacement fire and mixed-severity fires are rare (average FRIs of 500 years). Surface fire every 100 years on average will scar ancient trees. Duration 600+ years.

Drought is an important ecological process which limits seedling recruitment and survival and causes mortality of mature trees (Romme et al. 2009). Other important ecological variables include insect infestations, pathogens, herbivory, and seed dispersal by birds and mammals. Juniper berries crops are primarily utilized by birds and small mammals (Johnsen 1962, McCulloch 1969, Short et al. 1977, Salomonson 1978, Balda 1987, Gottfried et al. 1995). The most important dispersers of juniper seeds are birds although mammals also feed on them (Scher 2002). These animals consume juniper berries and excrete viable scarified juniper seeds, which germinate faster than uneaten seeds, over extensive areas (Johnsen 1962, Meeuwig and Bassett 1983). Primary juniper seed dispersers are Bohemian waxwings (*Bombycilla garrulus*), but cedar waxwings (*Bombycilla cedrorum*), American robins (*Turdus migratorius*), turkeys (*Meleagris gallopavo*), and several species of jays are also dispersers (Scher 2002).

There are several insects, plant parasites and pathogens (*Cercospora sequoiae*, a blight, and *Gymnosporangium* spp., stem rusts) that attack juniper trees (Burns and Honkala 1990a, Rogers 1995). Two insects, western cedar borer (*Trachykele blondeli*) and juniper twig pruner (*Styloxus bicolor*), damage mature trees and can cause mortality (Rogers 1995). Juniper mistletoe (*Phoradendron juniperinum*) occurs on junipers where it reduces vigor and causes dieback, but rarely causes mortality (Meeuwig and Bassett 1983).

Biological soils crusts (BSC) are important for soil fertility, soil moisture, and soil stability in many semi-arid ecosystems and may be important on juniper savanna sites, especially on those with more exposed soil surface and less herbaceous and litter cover, and low disturbance (Belnap et al. 2001, Belnap and Lange 2003). Cyanobacteria (especially *Nostoc*) fix large amounts of soil nitrogen and carbon (Evans and Belnap 1999, Belnap 2001).

Threats/Stressors: Numerous threats influence juniper savannas, including warming climate, heavy livestock grazing, tree harvest, and insect-pathogen outbreaks (West 1999b). The altered fire regime (intensity and frequency) in this savanna system in the form of fire exclusion has also allowed for juniper infill in some stands as well as expansion of juniper trees into the surrounding grasslands (West 1999b, Romme et al. 2009). Heavy grazing by livestock reduces fine fuels and indirectly decreases fire frequency, favoring fire-sensitive woody species such as *Juniperus osteosperma*. This results in uncharacteristically high cover of trees that shade out the grassy understory as it transitions from savanna to woodland. Some people confuse these younger juniper woodlands with true woodlands dependent on naturally fire-protected features such as rock outcrops. Lacking understory to carry fire, these woodlands only burn under extreme fire conditions resulting in high-intensity, high-severity stand-replacing fires. With loss of perennial grass cover with tree shading, these stands may have difficulty re-establishing the native perennial grass-dominated juniper savanna. Additionally, these stands are vulnerable to invasion by non-native annual grasses such as *Bromus tectorum* that can increase fire frequency beyond the natural fire regime.

Many stands within this system have been impacted by past range practices of chaining, tilling, and reseeding with exotic forage grasses. Although the dominant trees appear to regenerate after such disturbances, the effects on understory species are poorly known.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from catastrophic fire, stand-replacing fire and invasion and conversion to non-native, annual species. Extended fire suppression results in uncharacteristically dense tree canopy and loss of perennial grass understory (Romme et al. 2009). Under extreme fire conditions the stand burns severely causing mortality of juniper and leaving soil bare and exposed to erosion. Severe soil loss may occur where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion. Surface disturbances may allow invasive non-native species to become established and outcompete and replace the dominant native perennial species. Non-native species such as *Bromus tectorum* provide fine fuels that increase fire frequency, mortality of juniper trees and reduce or eliminate tree regeneration resulting in the conversion of savanna to invasive annual grassland or shrublands adapted to frequent fire. With loss of ecosystem structure many of the animals that depend on juniper berries will also be gone.

High-severity environmental degradation appears where occurrences tend to be relatively small (<1000 acres) for this large-patch type (CNHP 2010). Occurrence is surrounded primarily by urban or agricultural landscape, with <25% landscape cover of natural or semi-natural vegetation (CNHP 2010). The fire regime has high departure (VCC 3) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed high woody fuel load buildup. Surficial disturbances occur on more than 50% of the area (e.g., mines or ranch activities and buildings; off-road vehicle use). Up to 50% of the stand may have been "chained" and re-seeded (CNHP 2010). Microbiotic crusts are >75% removed, occurring only in small pockets naturally protected from livestock and off-road vehicle use. Soil erosion may be severe in places.

Moderate-severity environmental degradation appears where occurrences are moderate (1000-5000 acres) in size for this large-patch type (CNHP 2010). Landscape is a mosaic of agricultural or semi-developed areas and natural or semi-natural vegetation, the latter composing 25-80% of the landscape (CNHP 2010). The fire regime has moderate departure (VCC 2) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed moderate woody fuel load buildup. Surficial disturbances occur on more than 20% of the area. Up to 50% of the stand may have been "chained" and re-seeded. There are more than a few roads found within the occurrence (CNHP 2010). Microbiotic crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence. Soil erosion and gullying may be observed in patches (up to 30%) within the stand (CNHP 2010).

High-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) present and abundant throughout much of the stand. Tree density is very high (>800 tree/ha) (CNHP 2010). Connectivity is highly hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) may be present and even dominant in spots, but not throughout the stand. Tree density is high (>600 tree/ha on poor sites, >40 trees /ha on favorable sites) (CNHP 2010). Connectivity is moderately hampered by fragmentation from roads and/or agriculture that restrict natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

M027. Southern Rocky Mountain-Colorado Plateau Two-needle Pinyon - Juniper Woodland

CES304.766 Colorado Plateau Pinyon-Juniper Shrubland

CES304.766 CLASSIFICATION

Concept Summary: This ecological system is characteristic of the rocky mesatops and slopes on the Colorado Plateau and western slope of Colorado, but these stunted tree shrublands may extend further upslope along the low-elevation margins of taller pinyon-juniper woodlands. Sites are drier than ~Colorado Plateau Pinyon-Juniper Woodland (CES304.767)$$. Substrates are shallow/rocky and shaly soils at lower elevations (1200-2000 m). Sparse examples of the system grade into ~Colorado Plateau Mixed Bedrock Canyon and Tableland (CES304.765)$$. The vegetation is dominated by dwarfed (usually <3 m tall) *Pinus edulis* and/or *Juniperus osteosperma* trees forming extensive tall shrublands in the region along low-elevation margins of pinyon-juniper woodlands. Other shrubs, if present, may include *Artemisia nova, Artemisia tridentata ssp. wyomingensis, Chrysothamnus viscidiflorus*, or *Coleogyne ramosissima*. Herbaceous layers are sparse to moderately dense and typically composed of xeric graminoids.

Related Concepts:

- Juniper - Pinyon Pine Woodland (504) (Shiflet 1994) **><**
- Juniper - Pinyon Woodland (412) (Shiflet 1994) **><**

Distribution: This system occurs on rocky mesatops and slopes on the Colorado Plateau.
Nations: US
Concept Source: K.A. Schulz
Description Author: K.A. Schulz

CES304.766 CONCEPTUAL MODEL

Environment: This tree-dominated ecological system is characteristic of the dry, lower elevation sites in the rocky canyons of the Colorado Plateau and Western Slope of Colorado (1200-1600 m elevation), but these stunted-tree shrublands may extend further upslope to 2000 m on locally xeric sites (Stuever and Hayden 1997a).

Climate: Climate is semi-arid to arid with hot summers and cold winters. Based on data from Moab, Utah, average annual precipitation is approximately 25 cm. Precipitation mostly occurs as rain during monsoons (late July to October) and spring (March to May). June is the driest month.

Physiography/landform: Stands occur on the rocky mesatops, canyon rims, and dry slopes and ridges that are too dry for woodlands.

Soil/substrate/hydrology: Substrates are shallow/rocky and shaly soils at lower elevations. Sandstone is the most common parent material.

Key Processes and Interactions: *Pinus edulis* is extremely drought-tolerant and slow-growing (Little 1987). It is also non-sprouting and may be killed by fire (Wright et al. 1979, Wright and Bailey 1982a). This shrubland or stunted woodland (<3 m tall) is characteristic of the drier, hotter low-elevation sites (usually <1600 m), rock outcrops and sites with shallow soils that limit tree growth. The understory is typically sparser than ~Colorado Plateau Pinyon-Juniper Woodland (CES304.767)$$ and this system is more affected by drought than fires; however, occurrences of this system will burn under extreme fire conditions. The effect of fire on a stand is largely dependent on tree height and density, fine-fuel load on the ground, weather conditions, and season (Dwyer and Pieper 1967, Wright et al. 1979, Wright and Bailey 1982a). Trees are more vulnerable in open stands where fires frequently occur in the spring, when the relative humidity is low, wind speeds are over 10-20 mph, and there are adequate fine fuels to carry fire (Wright et al. 1979, Wright and Bailey 1982a). Under other conditions, burns tend to be spotty with low tree mortality. Large trees are generally not killed unless fine fuels, such as tumbleweeds, have accumulated beneath the trees to provide ladder fuels for the fire to reach the crown (Jameson 1962). Closed-canopy stands burn infrequently because they typically do not have enough understory or wind to carry fire (Wright et al. 1979).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2311020). These are summarized as:

A) Early Development 1 Open (herbaceous-dominated - 5% of type in this stage): Initial post-fire community dominated by annual forbs. Later stages of this class contain greater amounts of perennial grasses and forbs. Duration 10 years with succession to class B, mid-development closed. Replacement fire occurs every 100 years on average. Infrequent mixed-severity fire (average FRI of 300 years) thins vegetation.

B) Mid Development 1 Open (shrub-dominated - 5% of type in this stage): Dominated by shrubs, perennial forbs and grasses. Total cover remains low due to shallow, unproductive soil. Duration 20 years with succession to class C unless infrequent replacement fire (FRI of 100 years) returns the vegetation to class A. It is important to note that replacement fire at this stage does not eliminate perennial grasses, thus, succession age in class A after this type of fire would be older than zero and <10. Mixed-severity fire (average FRI of 100 years) thins the woody vegetation but does not cause a transition to another class.

C) Mid Development 2 Open (shrub-dominated - 10% of type in this stage): Shrub-dominated community with young juniper and pinyon seedlings becoming established. Duration 70 years with succession to class D unless replacement fire (average FRI of 200 years) causes a transition to class A. It is important to note that replacement fire at this stage does not eliminate perennial grasses, thus, succession age in class A after this type of fire would be older than zero and <10. Mixed-severity fire as in class B.

D) Late Development 1 Open (conifer-dominated - 35% of type in this stage): Community dominated by young and stunted juniper and pinyon of mixed age structure. Juniper and pinyon becoming competitive on site and beginning to affect understory composition. Duration 300 years with succession to E unless replacement fire (average FRI of 500 years) causes a transition to A. Mixed-severity fire is less frequent than in previous states (200 years), whereas surface fire every 100 years on average becomes more important at this age in succession.

E) Late Development 2 Open (conifer-dominated - 45% of type in this stage): Site dominated by widely spaced old and stunted juniper and pinyon. Understory depauperate and high amounts of bare ground and rock present. Grasses present on microsites with deeper soils (>50 cm [20 inches]) with restricting clay subsurface horizon. Potential maximum overstory coverage is greater in those stands with pinyon as compared to those with only juniper. Replacement fire and mixed-severity fires are rare (average FRIs of 500 years). Surface fire every 100 years on average will scar ancient stunted trees. Duration 600 years+.

Other important ecological processes include drought, insect infestations, pathogens, herbivory and seed dispersal by birds and mammals. Juniper berries and pinyon nut crops are primarily utilized by birds and small mammals (Johnsen 1962, McCulloch 1969, Short et al. 1977, Salomonson 1978, Balda 1987, Gottfried et al. 1995). The most important dispersers of juniper and pinyon seeds are birds, although many mammals also feed on them. These animals consume juniper berries and excrete viable scarified juniper seeds, which germinate faster than uneaten seeds, over extensive areas (Johnsen 1962, Meeuwig and Bassett 1983). Primary juniper seed dispersers are Bohemian waxwing (*Bombycilla garrulus*), but others include cedar waxwing (*Bombycilla cedrorum*), American robin (*Turdus migratorius*), turkey (*Meleagris gallopavo*), and several species of jays (Scher 2002). Pinyon seeds are a critically important food source for scrub jay (*Aphelocoma californica*), pinyon jay (*Gymnorhinus cyanocephalus*), Steller's jay (*Cyanocitta stelleri*) and Clark's nutcracker (*Nucifraga columbiana*). These birds are the primary dispersers of pinyon pine seeds and, during mast crop years, cache hundreds of thousands of pinyon seeds, many of which are never recovered (Balda and Bateman 1971, Vander Wall and Balda 1977, Ligon 1978). Because pinyon seeds are heavy and totally wingless, seed dispersal is dependent on vertebrate dispersers that store seeds in food caches, where unconsumed seeds may germinate. This dispersal mechanism is a good example of a co-evolved, mutualistic, plant-vertebrate relationship (Vander-Wall et al. 1981, Evans 1988, Lanner 1996) and would be at risk with loss of trees or dispersers. Many mammals are also known to eat pinyon seeds, such as several species of mice (*Peromyscus* spp.), woodrats (*Neotoma* spp.), squirrels (*Sciurus* spp.), chipmunks (*Neotamias* spp.), and desert bighorn sheep (*Ovis canadensis nelsoni*) and, although less effective, they may inadvertently disperse seeds (Anderson 2002).

Although *Pinus edulis* is drought-tolerant, prolonged droughts will weaken trees and promote mortality by secondary agents. Periodic die-offs of pinyon pine caused by insects, such as the pinyon ips beetle (*Ips confusus*), or fungal agents, such as blackstain root-rot (*Leptographium wageneri*), tend to be correlated with droughts (Anhold 2005). These mortality events may be localized or widespread but can result in 50 to 90% mortality of *Pinus edulis* in affected areas (Harrington and Cobb 1988). There are many insects, pathogens, and plant parasites that attack pinyon and juniper trees (Meeuwig and Bassett 1983, Gottfried et al. 1995, Rogers 1995, Weber et al. 1999). Juniper mistletoe (*Phoradendron juniperinum*) occurs on junipers and pinyon dwarf mistletoe (*Arceuthobium divaricatum*) occurs on pines. Both mistletoes reduce vigor and cause dieback but rarely cause mortality (Meeuwig and Bassett 1983). For pinyon and juniper, there are at least seven insects, and fungi such as black stain root-rot (*Leptographium wageneri*), and pinyon needle rust and pinyon blister rust (Skelly and Christopherson 2003). The insects are normally present in these woodland stands and during drought-induced water stress, outbreaks may cause local to regional mortality (Wilson and Tkacz 1992, Gottfried et al. 1995, Rogers 1995). Most insect-related pinyon mortality in the West is caused by pinyon ips bark beetle (*Ips confusus)* (Rogers 1993).

Most pinyon-juniper woodlands and shrublands in the Southwest have high soil erosion potential (Baker et al. 1995). Several studies have measured present-day erosion rates in pinyon-juniper woodlands, highlighting the importance of herbaceous cover and biological soil crusts in minimizing precipitation runoff and soil loss (Baker et al. 1995, Ladyman and Muldavin 1996, Belnap et al. 2001).

Threats/Stressors: Conversion of this type has commonly come from catastrophic crown fires and "chaining" or mechanical removal of trees by land management agencies to convert these wooded areas to grasslands for livestock (Stevens 1999, Tausch 1999a, Tausch and Hood 2007). Before 1900, this system was mostly open shrubland restricted to fire-safe areas on rocky ridges and outcrops where the low cover of fine fuels reduced the spread of fires. Over the last 100 years fire regimes were altered by fire suppression and grazing by livestock, which reduces the amount of fine fuels (grasses) that carry fire, thus reducing fire frequency (Pieper and Wittie 1990, Swetnam and Baisan 1996, Miller and Tausch 2001). Consequently, some stands of this system have a more closed canopy. Direct and indirect fire suppression has led to a buildup of woody fuels that increases the likelihood of high-intensity, stand-replacing fires. If exotic species are present, post-crown fire and post-treatment outcomes may result in conversion to exotic species.

In addition, energy exploration and development and mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Invasion by introduced annual grass, such as *Bromus tectorum* and other annuals, provide fine fuels that carry fire (Tausch 1999a, Miller and Tausch 2001, Tausch and Hood 2007), although the sites where this system occurs may be too dry for cheatgrass to become abundant.

Management actions such as chaining pinyon-juniper stands creates a large food source of injured pines for native ips beetles (*Ips confusus*) to feed on that can quickly multiply, creating epidemic outbreaks of beetles that attack and kill many healthy pinyons (Furniss and Carolin 2002). Increasingly frequent drought stresses pinyons and makes them less able to survive ips attacks (Furniss and Carolin 2002).

Other human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. This system is popular for outdoor recreation (e.g., hiking, camping, mountain biking, and off-road vehicle recreation) in canyons and mesas in southern Utah. Recreationalists are vectors for invasive species and likely degrade these shrublands in other ways such as soil compaction, soil erosion, and damage to biological soil crusts (Schwinning et al. 2008).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from repeated stand-replacing fire. Because of increased FRI from cheatgrass invasion, mortality of mature pinyon and juniper and reduction of pinyon and juniper regeneration will result in loss of these tree species and conversion of this shrubland to annual grassland or other shrublands adapted to frequent fire. With loss of ecosystem structure many of the animals that depend pinyon seeds and juniper berries will also be gone. In addition, severe soil loss may occur where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion and surface disturbances may allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<5000 acres) for this large-patch type (CNHP 2010). Occurrence is surrounded primarily by urban or agricultural landscape, with <25% landscape cover of natural or semi-natural vegetation CNHP 2010). The fire regime has high departure (VCC 3) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed high woody fuel load buildup. Surficial disturbances occur on more than 50% of the area (e.g., mines or ranch activities and buildings; off-road vehicle use). Up to 50% of the stand may have been "chained" and re-seeded (CNHP 2010). Microbiotic crusts are >75% removed, occurring only in small pockets naturally protected from livestock and off-road vehicle use. Soil erosion may be severe in places.

Moderate-severity environmental degradation appears where occurrences are moderate (5000-10,000 acres) in size for this large-patch type (CNHP 2010). Landscape is a mosaic of agricultural or semi-developed areas and natural or semi-natural vegetation, the latter composing 25-80% of the landscape (CNHP 2010). The fire regime has moderate departure (VCC 2) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed moderate woody fuel load buildup. Surficial disturbances occur on more than 20% of the area. Up to 50% of the stand may have been "chained" and re-seeded. There are more than a few roads found within the occurrence (CNHP 2010). Microbiotic crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence. Soil erosion and gullying may be observed in patches (up to 30%) within the stand (CNHP 2010).

High-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) present and abundant throughout much of the stand. Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) may be present and even dominant in spots, but not throughout the stand. Connectivity is moderately hampered by fragmentation from roads and/or agriculture that restrict natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.767 Colorado Plateau Pinyon-Juniper Woodland

CES304.767 CLASSIFICATION

Concept Summary: This ecological system occurs in dry mountains and foothills of the Colorado Plateau region including the Western Slope of Colorado to the Wasatch Range, south to the Mogollon Rim, and east into the northwestern corner of New Mexico. It is typically found at lower elevations ranging from 1500-2440 m. These woodlands occur on warm, dry sites on mountain slopes, mesas, plateaus, and ridges. Soils supporting this system vary in texture, ranging from stony, cobbly, gravelly sandy loams to clay loam or clay. *Pinus edulis* and/or *Juniperus osteosperma* dominate the tree canopy. In the southern portion of the Colorado Plateau in northern Arizona and northwestern New Mexico, *Juniperus monosperma* and hybrids of *Juniperus* spp. may dominate or codominate the tree canopy. *Juniperus scopulorum* may codominate or replace *Juniperus osteosperma* at higher elevations. Understory layers are variable and may be dominated by shrubs, graminoids, or be absent. Associated species include *Arctostaphylos patula, Artemisia tridentata, Cercocarpus intricatus, Cercocarpus montanus, Coleogyne ramosissima, Purshia stansburiana, Purshia tridentata, Quercus gambelii, Bouteloua gracilis, Pleuraphis jamesii, Pseudoroegneria spicata, Poa secunda*, or *Poa fendleriana*. This system occurs at higher elevations than ~Great Basin Pinyon-Juniper Woodland (CES304.773)$$ and Colorado Plateau shrubland systems where sympatric.

Distribution: This system occurs on dry mountains and foothills of the Colorado Plateau region from the Western Slope of Colorado to the Wasatch Range, south to the Mogollon Rim, and east into the northwestern corner of New Mexico. It is typically found at lower elevations, ranging from 1500-2440 m. In Wyoming, it would occur only in the southern portions of mapzone 22.

Nations: US

Description Author: K.A. Schulz and M.S. Reid

CES304.767 CONCEPTUAL MODEL

Environment: This ecological system occurs in dry mountains and foothills of the Colorado Plateau region, including the western slope of Colorado to the Wasatch Range, south to the Mogollon Rim, and east into the northwestern corner of New Mexico. It is typically found at lower elevations ranging from 1500-2440 m (Hess and Wasser 1982, Stuever and Hayden 1997a).

Climate: Climate is semi-arid. Annual precipitation is usually from 30-55 cm in the form of rain and snow. Severe climatic events occurring during the growing season, such as frosts and drought, are thought to limit the distribution of pinyon-juniper woodlands to relatively narrow altitudinal belts on mountainsides.

Physiography/landform: These woodlands occur on warm, dry sites on mountain slopes, mesas, plateaus, and ridges. Stands occur on a variety of aspects and slopes. Slope may range from nearly level to steep (up to 80%).

Soil/substrates/hydrology: Soils supporting this system vary in depth and texture, ranging from shallow, stony, cobbly, gravelly sandy loams to often deeper clay loam or clay. Parent materials likewise vary widely from granite, basalt, limestone, and sandstone to mixed alluvium (Springfield 1976). Soil depths may range from shallow to deep.

Key Processes and Interactions: Key ecological processes are drought, fire, herbivory, and insect/disease outbreaks. Both *Pinus edulis* and *Juniperus osteosperma* are relatively short (generally <15 m tall), shade-intolerant, drought-tolerant, slow-growing, long-lived trees (especially *Juniperus osteosperma* can reach 650 years old) (Meeuwig and Bassett 1983, Little 1987, Zlatnik 1999e, Romme et al. 2003). Both tree species are also non-sprouting and may be killed by fire (Wright et al. 1979). The effect of a fire on these stands is largely dependent on the tree height and density, fine fuel load on the ground, weather conditions and season (Wright et al. 1979). Large trees generally survive unless the fire gets into the crown due to heavy fuel loads in the understory. In this system fire acts to open stands, increase diversity and productivity in understory species, and create a mosaic of stands of different sizes and ages across the landscape while maintaining the boundary between woodlands and adjacent shrublands or grasslands (Bradley et al. 1992).

As modeled by LANDFIRE (2007a), the fire regime is characterized by somewhat frequent mixed-severity mosaic fires (mean FRI of 150-200 years) with very infrequent replacement fires (mean FRI of 200-500 years) (Rondeau 2001). Surface fire occurs only in the earliest succession class every 200 years on average (LANDFIRE 2007a). There is frequent fire spread from adjacent types (LANDFIRE 007a). Severe climatic events occurring during the growing season, such as frosts and drought, are thought to limit the distribution of pinyon-juniper woodlands to relatively narrow altitudinal belts on mountainsides. Weather-related stress thins trees every 145 years on average in more closed stands (LANDFIRE 2007a). Insects/disease has a similar effect, but with a greater frequency in closed stands (mean return interval of 100 years) than open ones (mean return interval of 1000 years) (LANDFIRE 2007a). Competition from grasses and older trees in late-open stands is also included as a disturbance that maintains stand openness (LANDFIRE 2007a).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2310160). These are summarized as:

A) Early Development 1 All Structures (10% of type in this stage): Grass/forb/shrub/seedling - usually post-fire. Cover is 0-30%. Shrub height 0.5 m. Both replacement fire and surface fire occur in this class (mean FRI of 200 years for both). The dominant succession path is to class C (mid, open) after 60 years, although the model allows for an alternate succession pathway to class B (mid, closed) 1/100 times to represent tree invasion.

B) Mid Development 1 Closed (20% of type in this stage): Tree cover is 40-70%. Tree height <5 m. Mid-development, dense (>40% cover) pinyon-juniper woodland; understory is sparse. Replacement fire occurs every 400 years on average. Three disturbances cause a transition to class C (mid, open): mixed-severity fire (mean FRI of 150 years), insects/disease (mean return interval of 100 years) and weather-related stress (mean return interval of 150 years). Succession to class E, late-closed, after 120 years.

C) Mid Development 1 Open (25% of type in this stage): Tree cover is 10-40%. Tree height <5 m. Mid-development, open (<40% cover) pinyon-juniper stand with mixed shrub/herbaceous community in understory. The mean FRI for replacement fire is 500 years. Mixed-severity fire (mean FRI of 200 years) and insects/disease (mean return interval of 1000 years) maintain stand structure. Primary succession pathway to class D, late-open, after 100 years, although an alternate succession pathway to class B 2/100 times is included to represent tree invasion;

D) Late Development 1 Open (35% of type in this stage): Tree cover is 10-40%. Tree height 5-10 m. Late-development, open juniper-pinyon stand with "savanna-like" appearance; mixed grass/shrub/herbaceous community. Replacement fire is infrequent (mean FRI of 500 years). Mixed-severity fire (mean FRI of 200 years), insects/disease (mean return interval of 1000 years) and competition (1/100 prob/year) maintain vegetation in class D, which is the primary succession endpoint. Alternate succession to class E, late-closed, occurs 1/200 times to represent tree invasion;

E) Late Development 2 Open (conifer-dominated - 35% of type in this stage): Tree cover is 40-70%. Tree height 5-10 m. Dense, old-growth stands with multiple layers. Late-development, closed pinyon-juniper forest. May have all-aged, multi-storied structure. Moderate mortality within stand. Occasional shrubs with few grasses and forbs and often rock or bare soil. The mean FRI of replacement fire is 500 years. Mixed-severity fire (mean FRI of 150 years), insects/disease (mean return interval of 100 years) and weather-related stress (mean return interval of 100 years) thin tree cover, therefore causing a transition to class D. Succession maintains vegetation in class E.

Other important ecological processes include drought, insect infestations, pathogens, herbivory, and seed dispersal by birds and mammals. Juniper berry and pinyon nut crops are primarily utilized by birds and small mammals (Johnsen 1962, McCulloch 1969, Short et al. 1977, Salomonson 1978, Balda 1987, Gottfried et al. 1995). Large mammals, such as mule deer (*Odocoileus hemionus*), white-tailed deer (*Odocoileus virginianus*) and elk (*Cervus elaphus*), eat leaves and seeds of both species and they browse woodland grasses, forbs and shrubs, including *Artemisia tridentata, Cercocarpus montanus, Quercus gambelii*, and *Purshia stansburiana* (Short and McCulloch 1977).

The most important dispersers of juniper and pinyon seeds are birds, although many mammals also feed on them. These animals consume juniper berries and excrete viable scarified juniper seeds over extensive areas, which germinate faster than uneaten seeds (Johnsen 1962, Meeuwig and Bassett 1983). Primary juniper seed dispersers are Bohemian waxwing (*Bombycilla garrulus*), cedar waxwing (*Bombycilla cedrorum*), American robin (*Turdus migratorius*), turkey (*Meleagris gallopavo*), and several species of jays (Scher 2002). Pinyon seeds are a critically important food source for western scrub jay (*Aphelocoma californica*), pinyon jay (*Gymnorhinus cyanocephalus*), Steller's jay (*Cyanocitta stelleri*) and Clark's nutcracker (*Nucifraga columbiana*). These birds are the primary dispersers of pinyon seeds and during mast crop years cache hundreds of thousands of pinyon seeds, many of which are never recovered (Balda and Bateman 1971, Vander Wall and Balda 1977, Ligon 1978). Many mammals are also known to eat pinyon seeds, such as several species of mice (*Peromyscus* spp.), woodrats (*Neotoma* spp.), squirrels (*Sciurus* spp.), chipmunks (*Neotamias* spp.), deer, black bear (*Ursus americanus*), and desert bighorn sheep (*Ovis canadensis nelsoni*) (Anderson 2002). Because pinyon seeds are heavy and totally wingless, seed dispersal is dependent on vertebrate dispersers that store seeds in food caches, where unconsumed seeds may germinate. This dispersal mechanism is a good example of a co-evolved, mutualistic, plant-vertebrate relationship (Vander Wall et al. 1981, Evans 1988, Lanner 1996) and would be at risk with loss of trees or dispersers.

There are many insects, pathogens, and plant parasites that attack pinyon and juniper trees (Meeuwig and Bassett 1983, Gottfried et al. 1995, Rogers 1995, Weber et al. 1999). For pinyon and juniper, there are at least seven insects, plus a fungus (blackstain root-rot (*Leptographium wageneri*)), juniper mistletoe (*Phoradendron juniperinum*) and pinyon dwarf mistletoe (*Arceuthobium divaricatum*). Both mistletoes reduce vigor and cause occasional dieback but rarely cause mortality (Meeuwig and Bassett 1983). The insects are normally present in these woodland stands, and during drought-induced water stress periods, outbreaks may cause local to regional mortality (Wilson and Tkacz 1992, Gottfried et al. 1995, Rogers 1995). Most insect-related pinyon mortality in the West is caused by pinyon ips beetle (*Ips confusus*) (Rogers 1993). Pinyons cannot repel pinyon ips beetles when weakened by drought and many are killed. During the drought of 2002-2003, populations of ips beetles increased to epidemic levels that killed millions of pinyon trees in the southwestern U.S. (Thorne et al. 2007).

Most pinyon-juniper woodlands in the southwest have high soil erosion potential (Baker et al. 1995). Several studies have measured present-day erosion rates in pinyon-juniper woodlands, highlighting the importance of herbaceous cover and cryptogamic soil crusts (Baker et al. 1995, Belnap et al. 2001) in minimizing precipitation runoff and soil loss in pinyon-juniper woodlands.

Threats/Stressors: Before 1900, this system was mostly open woodland restricted to fire-safe areas on rocky ridges and outcrops where the low cover fine fuels reduced the spread of fires. Over the last 100 years fire regimes were altered by fire suppression and grazing by livestock, which reduces the amount of fine fuels (grasses) that carry fire thus reducing fire frequency (Pieper and Wittie 1990, Swetnam and Baisan 1996a, Miller and Tausch 2001). Currently, much of this system distribution has a more closed canopy than historically. Fire suppression has led to a buildup of woody fuels that in turn increases the likelihood of high-intensity, stand-replacing fires. Heavy grazing, in contrast to fire, removes the grass cover and tends to favor shrub and conifer species. Fire suppression combined with grazing creates conditions that support invasion by pinyon and juniper trees into adjacent shrublands and grasslands. Under most management regimes, typical tree size decreases and tree density increases in this habitat.

Other common stressors include invasive species, insect/disease outbreaks, fuel wood cutting, and increased soil erosion, all of which affect stand quality and fire behavior. Significant losses in pinyon-juniper woodlands are a result of shortening of fire-return intervals (FRI) because of invasion by introduced *Bromus tectorum* and other annuals that provide fine fuels that carry fire (Tausch 1999, Miller and Tausch 2001, Tausch and Hood 2007). Livestock are also vectors for invasive species and disturb biological soil crusts.

Currently, epidemics of the native pinyon ips beetle (*Ips confusus*) often occur during drought periods when mature trees are weakened and vulnerable to ips beetle attacks killing many pinyons and creating very high fuel loads throughout much of the system's range (Furniss and Carolin 2002). In addition, many of these communities have been severely impacted by past range practices of chaining, tilling, and reseeding with exotic forage grasses.

Human development has impacted some locations throughout the distribution of this type. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Management actions such as chaining pinyon-juniper stands creates a large food source of injured pines for ips beetles (*Ips confusus*) to feed on that can quickly multiply creating epidemic outbreaks of beetles that attack and kill many healthy pinyons (Furniss and Carolin 2002). Drought stresses pinyon trees and makes them less able to survive ips beetle attacks (Furniss and Carolin 2002).

Conversion of this type has resulted from catastrophic crown fires and "chaining" or mechanical removal of trees by land management agencies to convert woodlands to grasslands for livestock (Stevens 1999, Tausch 1999, Tausch and Hood 2007). If exotic species are present, post crown fire and post-treatment outcomes may result in conversion to exotic species.

Ecosystem Collapse Thresholds: Ecosystem collapse can occur after repeated stand-replacing fires. The increased fire frequency is a consequence of cheatgrass invasion, which provides fine fuels that carry fire. Burning causes mortality of pinyon and juniper trees and reduces pinyon and juniper regeneration will result in loss of trees and conversion of woodland to grasslands or shrublands that are adapted to frequent fire (Brooks and Minnich 2006, Thorne et al. 2007). With loss of ecosystem structure many of the animals that depend on pinyon seeds and juniper berries will also be affected. In additional, severe soil loss may occur where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion and surface disturbances may allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<5000 acres) for this type (CNHP 2010). Occurrence is surrounded primarily by urban or agricultural landscape, with <25% landscape cover of natural or semi-natural vegetation (CNHP 2010). The fire regime has high departure (VCC 3) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed high woody fuel load buildup. Surficial disturbances occur on more than 50% of the area (e.g., mines or ranch activities and buildings; off-road vehicle use). Up to 50% of the stand may have been "chained" and re-seeded (CNHP 2010). Microbiotic crusts are >75% removed, occurring only in small pockets naturally protected from livestock and off-road vehicle use. Soil erosion may be severe in places.

Moderate-severity environmental degradation appears where occurrences are moderate (5000-10,000 acres) in size for this large-patch type (CNHP 2010). Landscape is a mosaic of agricultural or semi-developed areas and natural or semi-natural vegetation, the latter composing 25-80% of the landscape (CNHP 2010). The fire regime has moderate departure (VCC 2) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed moderate woody fuel load buildup. Surficial disturbances occur on more than 20% of the area. Up to 50% of the stand may have been "chained" and re-seeded. There are more than a few roads found within the occurrence (CNHP 2010). Microbiotic crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence. Soil erosion and gullying may be observed in patches (up to 30%) within the stand (CNHP 2010).

High-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) present and abundant throughout much of the stand. Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) may be present and even dominant in spots, but not throughout the stand. Connectivity is moderately hampered by fragmentation from roads and/or agriculture that restrict natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES306.834 Southern Rocky Mountain Juniper Woodland and Savanna

CES306.834 CLASSIFICATION

Concept Summary: This ecological system occupies the lower and warmest elevations, growing from 1370 to 1830 m in a semi-arid climate, primarily along the east and south slopes of the Southern Rockies and Arizona-New Mexico mountains. It is best represented just below the lower elevational range of ponderosa pine and often intermingles with grasslands and shrublands. This system is best described as a savanna that has widely spaced, mature (>150 years old) juniper trees and occasionally *Pinus edulis*. *Juniperus monosperma* and *Juniperus scopulorum* (at higher elevations) are the dominant tall shrubs or short trees. These savannas may have inclusions of denser juniper woodlands and they have expanded into adjacent grasslands during the last century. Graminoid species are similar to those found in ~Western Great Plains Shortgrass Prairie (CES303.672)$$, with *Bouteloua gracilis* and *Pleuraphis jamesii* being most common. In addition, succulents such as species of *Yucca* and *Opuntia* are typically present.

Related Concepts:
- Pinyon - Juniper: 239 (Eyre 1980) **><**
- Sideoats Grama - Sumac - Juniper (735) (Shiflet 1994) **><**

Distribution: This system occupies the lower and warmest elevations, growing from 1370 to 1830 m elevation in a semi-arid climate, primarily along the east and south slopes of the Southern Rockies and central New Mexico mountains. This includes the Sacramento Mountains, especially the east side; the west side has Madrean elements but is mostly southern Rocky Mountains. This system also occurs in the canyons and tablelands of the southwestern Great Plains extending some distance from the mountains. It may occur along the Cimarron River in the panhandle regions of Oklahoma and Texas, and in the very southwestern corner of Kansas.

Nations: US

Concept Source: M.S. Reid

Description Author: K.A. Schulz

CES306.834 CONCEPTUAL MODEL

Environment: This ecological system occupies the lower and warmest elevations, growing from 1370 to 1830 m primarily along the east and south slopes of the Southern Rockies and Arizona-New Mexico mountains. It is best represented just below the lower elevational range of ponderosa pine and often intermingles with grasslands. In the canyons and tablelands of the southern Great Plains, this system forms extensive cover at some distance from the mountain front.

Climate: Climate is cool-temperate, continental, and semi-arid. Precipitation ranges from approximately 33-46 cm (13-18 inches) annually and has a bimodal distribution with moisture peaking in winter and summer. However, most precipitation generally occurs during the summer growing season.

Physiography/landform: Stands occur on gentle upland and transitional valley locations, where soil conditions favor grasses (or other grass-like plants) but can support at least some tree cover. Some savannas apparently have sparse tree cover because of edaphic or climatic limitations on woody plant growth (Romme et al. 2009).

Soil/substrate/hydrology: Savannas are found on moderately deep to deep, coarse- to fine-textured soils that readily support a variety of growth forms, including trees, grasses, and other herbaceous plants, and in regions that receive reliable summer rainfall that fosters growth of warm-season grasses (Romme et al. 2009). This type appears to be especially prevalent in the basins and foothills of northeastern New Mexico, where a large portion of annual precipitation comes in the summer via monsoon rains (Romme et al. 2009).

Key Processes and Interactions: *Juniperus monosperma* is a long-lived, slow-growing, drought-tolerant small tree (3-12 m in height) that also occurs as a tall shrub (Johnson 2002). It is more drought tolerant than *Pinus edulis* and often occurs without pinyon on more xeric, lower elevation sites (Johnson 2002). It is also non-sprouting and may be killed by fire (Wright et al. 1979). Juniper stands at cooler, higher elevation sites typically occur on xeric microsites that are too arid for pinyon or on post-disturbance sites such as where extended drought or ips beetle (*Ips confusus*) epidemics have eliminated pinyon from mixed pinyon-juniper stands. In this situation junipers and shrubs may act a nurse plants providing shade for pinyon germination and re-establishment, converting a juniper woodland to pinyon-juniper woodland.

Within a given region, the density of trees, both historically and currently, is strongly related to topo-edaphic gradients. Less steep sites, especially those with finer-textured soils, are where savannas, grasslands, and shrub-steppes have occurred in the past. Juniper stands on these gentler slopes may have been larger but more savanna-like, with very open upper canopy and high grass production. Expansion of juniper into previously non-wooded areas occurred prior to European settlement on some sites, although this expansion may have been more extensive in the 20th century versus the previous. However, loss of juniper from marginal sites also occurred historically and recently in some areas (Romme et al. 2009). Especially in areas in which trees were historically rare or absent, there have been type conversions such that the historical condition is unidentifiable/replaced today. An important result of expansion into formerly non-wooded areas in many regions is that formerly heterogeneous mosaics of small patches of woodland, shrubland, and grassland are becoming more homogeneous as trees become established in the shrubland and grassland patches (Romme et al. 2009).

Past fire regimes in southwestern juniper woodlands were mixed, having both surface and crown fires, reflecting variable intensity and frequency depending on site productivity. "Productive sites" could sustain patchy fires at intervals of 10-50 years and could have attained densities sufficient to carry crown fires at intervals of 200-300 years. In open stands, where grass cover was continuous, fire intervals might have been 10 years or less, and probably maintained grasslands and savannas (Gottfried et al. 1999). Romme et al. (2009) state that low-severity fires were probably uncommon except in savannas and in small patches in persistent woodlands.

Soil texture drives the fire regime. Sites with higher potential for graminoid understory will have higher fine-fuel loading and create the spread component for more frequent and lower intensity fires. Sites with shallow, gravelly soils produce less grass and more shrub components, less fire frequency, more lethal when wind-driven events occur (LANDFIRE 2007a).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2711190). The model was reviewed and reference to pinyon were removed then summarized as:
A) Early Development 1 All Structures (10% of type in this stage): Grass/forb/shrub/seedling - usually post-fire. Cover is 0-30%. Shrub height is 0-5 m. This class succeeds to B, a mid-open stage after approximately 70 years; however, it could be much longer depending on size of burn. Recruitment is even more episodic in response to optimal climate conditions than in ponderosa. An alternate successional pathway could take this class to class C, a mid-development closed stage, with a probability of 0.015. Replacement fire occurs infrequently, every 400 years. Competition/maintenance can maintain this stage, with a probability of 0.01.

B) Mid Development 1 Open (10% of type in this stage): Tree cover is 11-40%. Tree height is 5.1-10 m. Mid-development, open (<40% cover) juniper stand with mixed shrub/herbaceous community in understory. Review for MZ27 suggested this might even be lower canopy cover to 20%. This class succeeds to class E, a late-open stage after approximately 170 years. An alternate successional pathway could take this class to class D, a late closed stage, with a low probability of 0.002. Replacement fire occurs infrequently, every 500 years. Surface fire occurs every 25 years. Mixed fire occurs every 300 years. Competition/maintenance can maintain this class in class B, with a probability of 0.007.

C) Mid Development 1 Closed (10% of type in this stage): Tree cover is 41-70%. Tree height is 5 m. Mid-development, dense (>40% cover) pinyon-juniper woodland; understory being lost. Review for Map zone 27 suggested this might even be lower canopy cover to 30%. This class succeeds to D, a late-closed stage after 100 years. Mixed fire in this stage either causes no transition (every 1000 years) or brings it to an open mid stage (every 200 years). Surface fire occurs infrequently (every 1000 years) and causes no transition. Replacement fire also occurs infrequently (every 500 years).

D) Late Development 1 Closed (5% of type in this stage): Tree cover is 41-70%. Tree height is 10.1-25 m. Dense, old-growth stands with multiple layers. Late-development, closed pinyon-juniper forest. May have all-aged, multi-storied structure. Moderate mortality within stand. Occasional shrubs with few grasses and forbs and often much rock. Review for MZ27 suggested this might even be lower canopy cover to 11-35%. This class can persist. Mixed fire can cause this class to move to a late open stage, class E, but very infrequently - every 200 years. Replacement fire occurs very rarely (6-700 years), and surface fire also occurs very, very rarely. Insect/disease can also open this class and cause a transition to the late-open stage, class E, every 200 years. This interval may be even longer. Also, drought likely plays a major role, but it was not modeled here.

E) Late Development 1 Open (conifer-dominated - 65% of type in this stage): Tree cover is 11-40%. Tree height is 10-25 m. Late-development, open juniper-pinyon stand with "savannah-like" appearance; mixed grass/shrub/herbaceous community. This class persists. Replacement fire occurs infrequently - every 500 years. Mixed fire also occurs infrequently - every 200 years, and surface fire every 25 years, but neither cause a transition. Insect/disease occurs every 200 years but causes no transition. This interval may be even longer. Also, drought likely plays a major role, but it was not modeled here.

Other important ecological processes include drought, insect infestations, pathogens, herbivory and seed dispersal by birds and mammals. Juniper berries crops are primarily utilized by birds and small mammals (Johnsen 1962, McCulloch 1969, Short et al. 1977, Salomonson 1978). The most important dispersers of juniper seeds are birds, although many mammals also feed on them. These animals consume juniper berries and excrete viable scarified juniper seeds, which germinate faster than uneaten seeds, over extensive areas (Johnsen 1962, Meeuwig and Bassett 1983). Primary juniper seed dispersers are Bohemian waxwing (*Bombycilla garrulus*), but cedar waxwing (*Bombycilla cedrorum*), American robin (*Turdus migratorius*), turkey (*Meleagris gallopavo*), and several species of jays are also dispersers (Johnson 2002, Scher 2002).

There are several insects, pathogens, and plant parasites that attack juniper trees (Meeuwig and Bassett 1983, Gottfried et al. 1995, Rogers 1995, Weber et al. 1999). For juniper, there are several insects, plus the fungus blackstain root-rot (*Leptographium wageneri*) and juniper mistletoe (*Phoradendron juniperinum*). Mistletoe reduces vigor and causes occasional dieback but rarely causes mortality (Meeuwig and Bassett 1983). The insects are normally present in these woodland stands, and during drought-induced water-stress periods, outbreaks may cause local to regional mortality (Gottfried et al. 1995)

Many juniper savannas and woodlands in the Southwest have high soil erosion potential (Baker et al. 1995). Several studies have measured present-day erosion rates in juniper woodlands, highlighting the importance of herbaceous cover and cryptogamic soil crusts (Baker et al. 1995, Belnap et al. 2001) in minimizing precipitation runoff and soil loss in juniper woodlands.

Threats/Stressors: Although juniper woodlands and savannas are expected to occur naturally on the landscape, the extent and quality of this system have been severely altered since the early 1900s. Numerous studies have shown that juniper has encroached on shrublands and grasslands (e.g., West 1999b). Processes that influence the formation and persistence of juniper savannas include climate, livestock grazing, altered fire regime, tree harvest (fence posts), and insect-pathogen outbreaks (West 1999b, Romme et al. 2009).

The altered fire regime (intensity and frequency) in this savanna system in the form of fire exclusion has also allowed for juniper infill in some stands as well as expansion of juniper trees into the surrounding grasslands (West 1999b, Romme et al. 2009). Heavy grazing by livestock reduces fine fuels and indirectly decreases fire frequency, favoring fire sensitive woody species such as *Juniperus monosperma*. This may result in uncharacteristically high cover of trees (infilling) that shade out the grassy understory as it transitions from savanna to woodland, as well as tree invasion into adjacent grasslands. Some people confuse these younger juniper woodlands with true woodlands dependent on naturally fire-protected features such as rock outcrops. Lacking understory to carry fire, these woodlands only burn under extreme fire conditions resulting in high-intensity, high-severity stand-replacing fires. With loss of perennial grass cover with tree shading, these stands may have difficulty re-establishing the native perennial grass-dominated juniper savanna. Additionally, these stands are vulnerable to invasion by non-native annual grasses such as *Bromus arvensis* that can increase fire frequency beyond the natural fire regime.

Juniper savanna is typically invasive in lower valleys, mesas and rolling plains if deep soils, but natural if medium (~shallow) depth soils, e.g., low rises between drainages typically with large seemingly old junipers (LANDFIRE 2007a).

In addition, many stands within this system have been impacted by past range practices of chaining, tilling, and reseeding with exotic forage grasses and prescribed burning to reduce juniper and increase forage production, which have had mixed results. Although the dominant trees appear to regenerate after such disturbances, the effects on understory and soil crust species are poorly known. More study is needed to understand and manage these woodlands ecologically.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from catastrophic fire, stand-replacing fire and invasion and conversion to non-native, annual species. Extended fire suppression results in uncharacteristically dense tree canopy and loss of perennial grass understory (Romme et al. 2009). Under extreme fire conditions the stand burns severely causing mortality of juniper and leaving soil bare and exposed to erosion. After stand-replacing fire severe soil loss may occur where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion. Surface disturbances may allow invasive non-native species to become established and outcompete and replace the dominant native perennial species. Non-native species such as *Bromus japonicus* may provide fine fuels that increase fire frequency, mortality of juniper trees and reduce or eliminate tree regeneration, resulting in the conversion of savanna to invasive annual grassland or shrublands adapted to frequent fire. With loss of ecosystem structure many of the animals that depend on juniper berries will also be gone.

High-severity environmental degradation appears where occurrences tend to be relatively small (<1,000 acres) and subject to edge effects (CNHP 2010). Occurrence is surrounded primarily by urban or agricultural landscape, with <25% landscape cover of natural or semi-natural vegetation (CNHP 2010). The fire regime has high departure (VCC 3) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval to over 100 years and allowed high woody fuel load buildup. Surficial disturbances occur on more than 50% of the area (e.g., mines or ranch activities and buildings; off-road vehicle use). Up to 50% of the stand may have been "chained" and re-seeded (CNHP 2010). Microbiotic crusts are >75% removed, occurring only in small pockets naturally protected from livestock and off-road vehicle use. Soil erosion may be severe in places.

Moderate-severity environmental degradation appears where occurrences are moderate (1,000-2,000 acres) in size for this large-patch type (CNHP 2010). Landscape is a mosaic of agricultural or semi-developed areas and natural or semi-natural vegetation, the latter composing 25-80% of the landscape (CNHP 2010). The fire regime has moderate departure (VCC 2) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval to between 50-100 years and allowed moderate woody fuel load buildup. Surficial disturbances occur on more than 20% of the area. Up to 50% of the stand may have been "chained" and re-seeded. There are more than a few roads found within the occurrence (CNHP 2010). Microbiotic crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence. Soil erosion and gullying may be observed in patches (up to 30%) within the stand (CNHP 2010).

High-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) present and abundant throughout much of the stand. Tree density is very high (>800 tree/ha) (CNHP 2010). Connectivity is highly hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Herbaceous layer is sparse or absent and will not carry fire (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) may be present and even dominant in spots, but not throughout the stand. Tree density is high (>600 tree/ha on poor sites, >40 trees /ha on favorable sites) (CNHP 2010). Connectivity is moderately hampered by fragmentation from roads and/or agriculture that restrict natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Herbaceous cover is low and is not sufficient to carry fire (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES306.835 Southern Rocky Mountain Pinyon-Juniper Woodland

CES306.835 CLASSIFICATION

Concept Summary: This southern Rocky Mountain ecological system occurs on dry mountains and foothills in southern Colorado east of the Continental Divide, in mountains and plateaus of north-central New Mexico, and extends out onto limestone breaks in the southeastern Great Plains. These woodlands occur on warm, dry sites on mountain slopes, mesas, plateaus, and ridges. Soils supporting this system vary in texture ranging from stony, cobbly, gravelly sandy loams to clay loam or clay. *Pinus edulis* and/or *Juniperus monosperma* dominate the tree canopy. *Juniperus scopulorum* may codominate or replace *Juniperus monosperma* at higher elevations. Stands with *Juniperus osteosperma* are representative of the Colorado Plateau and are not included in this system. In southern transitional areas between ~Madrean Pinyon-Juniper Woodland (CES305.797)$$ and ~Southern Rocky Mountain Pinyon-

Juniper Woodland (CES306.835)$$ in central New Mexico, *Juniperus deppeana* may be present. Understory layers are variable and may be dominated by shrubs, graminoids, or be absent. Associated species are more typical of southern Rocky Mountains than the Colorado Plateau and include *Artemisia bigelovii, Cercocarpus montanus, Quercus gambelii, Achnatherum scribneri, Bouteloua gracilis, Festuca arizonica*, or *Pleuraphis jamesii*.
Related Concepts:
- Juniper - Pinyon Pine Woodland (504) (Shiflet 1994) **>**
- Pinyon - Juniper: 239 (Eyre 1980) **>**

Distribution: This system occurs on dry mountains and foothills east of the Continental Divide in southern Colorado, in mountains and plateaus of northern New Mexico and Arizona, and extends out onto breaks in the Great Plains. It extends south to the Sacramento Mountains, especially the eastern side. The western side of the Sacramento Mountains has Madrean elements (*Quercus grisea*) and may be classified as Madrean woodland.
Nations: US

Description Author: K.A. Schulz

CES306.835 CONCEPTUAL MODEL

Environment: This southern Rocky Mountain ecological system occurs on dry mountains and foothills in southern Colorado east of the Continental Divide, in mountains and plateaus of north-central New Mexico, and extends out onto limestone breaks in the southeastern Great Plains. Elevations range from near 1500 to 2900 m with high-elevation stands restricted to relatively warm, dry ridges and south and west aspects. Lower-elevation stands are often restricted to cooler north- and east-facing slopes.

Climate: Climate is cool-temperate, continental, and semi-arid. Precipitation ranges from approximately 33-46 cm (13-18 inches) annually. Most of the precipitation occurs during the summer growing season. Severe climatic events occurring during the growing season, such as frosts and drought, are thought to limit the distribution of pinyon-juniper woodlands to relatively narrow altitudinal belts on mountainsides.

Physiography/landform: These woodlands occur on warm, dry sites on mountain slopes, mesas, plateaus, and ridges.

Soil/substrate/hydrology: Soils supporting this system vary in texture ranging from stony, cobbly, gravelly sandy loams to clay loam or clay.

Key Processes and Interactions: Both *Pinus edulis* and *Juniperus monosperma* are relatively short (generally <15 m tall), shade-intolerant, drought-tolerant, slow-growing, long-lived trees (Meeuwig and Bassett 1983, Little 1987, Anderson 2002, Johnson 2002, Romme et al. 2003). Both tree species are also non-sprouting and may be killed by fire (Wright et al. 1979).

Pinyon-juniper woodlands are influenced by drought, fires, grazing, and insect-pathogen outbreaks (West 1999b). Stands vary considerably in appearance and composition, both elevationally and geographically. Juniper tends to be more abundant at the warmer/drier lower elevations, pinyon tends to be more abundant at the higher elevations, and the two species share dominance within a broad middle-elevation zone (Woodin and Lindsey 1954).

The effect of fire on a stand is largely dependent on the tree height and density, fine-fuel load on the ground, weather conditions, and season (Dwyer and Pieper 1967, Wright et al. 1979). Some large trees may survive unless the fire gets into the crown due to heavy fuel loads in the understory or extreme fire conditions.

Site conditions affects the successional pathway following a disturbance. Succession on a site is influenced by the severity and size of the disturbance, and by the composition, longevity, and density of any surviving plants and propagules within the disturbed area and the characteristics of plant communities in adjacent undisturbed areas. According to Gottfried et al. (1999) junipers are the first to return in secondary succession but are often followed and replaced by pinyon.

Site conditions influence the stand density. Sites with fewer trees typically have relatively deep soils and support a dense herbaceous level; those with more trees have shallow, rocky soils and often occur on steeper slopes. Stands may range from even-aged to uneven-aged stands. Some stands may have closed canopies with little or no understory, but many stands are open with widely scattered trees with a wide variety of understory vegetation (Rondeau 2001).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has four classes in total (LANDFIRE 2007a, BpS 2710590). These classes are summarized as:

A) Early Development 1 Open (10% of type in this stage): Total cover is 0-20% (grass cover <20%, shrub cover <15%, tree cover <10%). Shrub height 0-0.5 m. There would be very little of this class historically. Initial post-fire community grass- and shrub-dominated, consisting of mountain-mahogany with Gambel oak sprouts, perennial grass and various forbs. Pinyon and juniper seedlings and saplings will be in low density. Evidence of past fires may be observed, including charcoal and resprouting woody plants. Duration 50 years with succession to class B, mid-development stand of small trees. Trees exert very little influence until about 50 years in this system. Replacement fire occurs every few centuries. Drought occurs every 30 years and maintains the class but does not set it back to the beginning.

B) Mid Development 1 Open (20% of type in this stage): Tree cover is 0-40%. Tree height <3 m. Young juniper saplings are increasing and growing. Grass and shrubs are still dominant. Grass species that would be present are: blue grama, little bluestem, western wheatgrass, and needlegrass. Pinyon seedlings delayed until shade occurs for better growth. Mixed-severity fire also occurs because sometimes grass density is sufficient to result in pinyon and juniper scorch as well as mortality. Mixed fire occurs every 100-

200 years. Replacement fires every several hundred years. This class probably lasts approximately 100 years, i.e., 50 to 150 years. Might remain in class until 10-20-year heavy moisture cycle; this increases seedling production, and juveniles mature. Drought occurs every 30 years but does not cause a transition.

C) Mid Development 1 Closed (45% of type in this stage): Tree cover is 21-70%. Tree height 5.1-10 m. Junipers reaching pole-size, and pinyon pine seedlings and saplings are growing dependent on rainfall patterns and shade. Pinyon having rapid growth in this stage. Gambel oak is also forming stand patches. Thinning effect for mountain-mahogany due to space/nutrient competition. Very little recruitment of junipers in this stage. This class lasts from approximately 150-250 years of age, so spending 50-100 years in this class. For the model, this class will last 75 years. Replacement fire unlikely in this class due to open canopy. Mixed fire also modeled infrequently. Drought occurs every 30 years, also maintaining this class.

D) Late Development 1 Closed (25% of type in this stage): Tree cover is 10-40%. Tree height 5-10 m. Mature juniper mixed with maturing pinyon. Understory declining due to canopy closing. Small amount of fine fuels. There is a shift in dominance from juniper to pinyon. This class can persist. Pinyon would be susceptible to drought mortality, disease, and insects. Drought creates conditions for insect disturbance to occur in pinyon pine. Drought itself, however, can impact the understory separate from the insect component. Optional 1 is drought plus insect effect. This takes it back to class C, because pinyon lost but still have mature junipers. Modeled at every 50 years, or 2% of the class each year. Regular drought modeled as every 30 years, as in other classes, not causing a transition. Mistletoe might also be influenced by the drought but not being modeled due to lack of information.

Other important ecological processes include drought, insect infestations, pathogens, herbivory, and seed dispersal by birds and mammals. Juniper berry and pinyon nut crops are primarily utilized by birds and small mammals (Johnsen 1962, McCulloch 1969, Short et al. 1977, Salomonson 1978, Balda 1987, Gottfried et al. 1995). Large mammals, such as mule deer (*Odocoileus hemionus*), white-tailed deer (*Odocoileus virginianus*) and elk (*Cervus elaphus*), eat leaves and seeds of both species and they browse woodland grasses, forbs and shrubs, including *Artemisia tridentata, Cercocarpus montanus, Quercus gambelii*, and *Purshia stansburiana* (Short and McCulloch 1977).

The most important dispersers of juniper and pinyon seeds are birds, although many mammals also feed on them. These animals consume juniper berries and excrete viable scarified juniper seeds over extensive areas, which germinate faster than uneaten seeds (Johnsen 1962, Meeuwig and Bassett 1983). Primary juniper seed dispersers are Bohemian waxwing (*Bombycilla garrulus*), cedar waxwing (*Bombycilla cedrorum*), American robin (*Turdus migratorius*), turkey (*Meleagris gallopavo*), and several species of jays (Anderson 2002, Johnson 2002, Scher 2002). Pinyon seeds are a critically important food source for western scrub jay (*Aphelocoma californica*), pinyon jay (*Gymnorhinus cyanocephalus*), Steller's jay (*Cyanocitta stelleri*) and Clark's nutcracker (*Nucifraga columbiana*). These birds are the primary dispersers of pinyon seeds and, during mast crop years, cache hundreds of thousands of pinyon seeds, many of which are never recovered (Balda and Bateman 1971, Vander Wall and Balda 1977, Ligon 1978, Evans 1988, Hall and Balda 1988, Ronco 1990). Many mammals are also known to eat pinyon seeds, such as several species of mice (*Peromyscus* spp.), woodrats (*Neotoma* spp.), squirrels (*Sciurus* spp.), chipmunks (*Neotamias* spp.), deer, black bear (*Ursus americanus*), and desert bighorn sheep (*Ovis canadensis nelsoni*) (Anderson 2002). Because pinyon seeds are heavy and totally wingless, seed dispersal is dependent on vertebrate dispersers that store seeds in food caches, where unconsumed seeds may germinate. This dispersal mechanism is a good example of a co-evolved, mutualistic, plant-vertebrate relationship (Vander Wall et al. 1981, Evans 1988, Lanner 1996) and would be at risk with loss of trees or dispersers.

There are many insects, pathogens, and plant parasites that attack pinyon and juniper trees (Meeuwig and Bassett 1983, Gottfried et al. 1995, Rogers 1995, Weber et al. 1999). For pinyon and juniper, there are at least seven insects, plus fungus blackstain root-rot (*Leptographium wageneri*), juniper mistletoe (*Phoradendron juniperinum*) and pinyon dwarf mistletoe (*Arceuthobium divaricatum*). Both mistletoes reduce vigor and cause occasional dieback but rarely cause mortality (Meeuwig and Bassett 1983). The insects are normally present in these woodland stands, and during drought-induced water-stress periods, outbreaks may cause local to regional mortality (Wilson and Tkacz 1992, Gottfried et al. 1995, Rogers 1995). Most insect-related pinyon mortality in the West is caused by pinyon ips beetle (*Ips confusus*) (Rogers 1993). Pinyons cannot repel pinyon ips beetles when weakened by drought and many are killed. During the drought of 2002-2003, populations of ips beetles increased to epidemic levels that killed millions of pinyon trees in the southwestern U.S.

Most pinyon-juniper woodlands in the Southwest have high soil erosion potential (Baker et al. 1995). Several studies have measured present-day erosion rates in pinyon-juniper woodlands, highlighting the importance of herbaceous cover and biological soil crusts (Baker et al. 1995, Belnap et al. 2001) in minimizing precipitation runoff and soil loss in pinyon-juniper woodlands.

Threats/Stressors: Before 1900, this system was mostly open woodland restricted to fire-safe areas on rocky ridges and outcrops where the low cover fine fuels reduced the spread of fires. Since then the distribution and density of pinyon and juniper and accompanying native understory have been significantly altered (Stevens 1999, West 1999b, Romme et al. 2009). Altered fire regimes, overgrazing, and tree cutting can all affect stand quality and fire behavior (Anderson 2002, Johnson 2002). These factors can also disturb microbiotic soil crusts and lead to increased soil erosion and habitat/species loss.

Conversion of this type has resulted from catastrophic crown fires and "chaining" or mechanical removal of trees by land management agencies to convert woodlands to grasslands for livestock (Stevens 1999, Tausch 1999, Tausch and Hood 2007). If exotic species are present, post-crown fire and post-treatment outcomes may result in conversion to exotic species.

Fire regimes were altered by fire suppression and grazing by livestock, which reduces the amount of fine fuels (grasses) that carry fire thus reducing fire frequency (Pieper and Witte 1990, Swetnam and Baisan 1996a, Miller and Tausch 2001). Currently, much of this system's distribution has a more closed canopy than historically. Fire suppression has led to a buildup of woody fuels that in turn increases the likelihood of high-intensity, stand-replacing fires. Long-term heavy grazing reduces perennial grass cover and tends to favor shrub and conifer species. Fire suppression combined with grazing creates conditions that support invasion by pinyon and juniper trees into adjacent shrublands and grasslands. Under most management regimes, typical tree size decreases and tree density increases in this habitat.

Other common stressors include invasive species, insect/disease outbreaks, fuel wood cutting, and increased soil erosion, all of which affect stand quality and fire behavior. Livestock are also vectors for invasive species and disturb biological soil crusts. In addition, many of these communities have been severely impacted by past range practices of chaining, tilling, and reseeding with exotic forage grasses.

Human development has impacted some locations throughout the distribution of this type. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Management actions such as chaining pinyon-juniper stands creates a large food source of injured pines for ips beetles (*Ips confusus*) to feed on that can quickly multiply creating epidemic outbreaks of beetles that attack and kill many healthy pinyons (Furniss and Carolin 2002). Drought stresses pinyon trees and makes them less able to survive ips beetle attacks (Furniss and Carolin 2002).

Ecosystem Collapse Thresholds: Ecosystem collapse can occur after repeated stand-replacing fires. The increased fire frequency is a consequence of cheatgrass invasion, which provides fine fuels that carry fire. Burning that causes mortality of pinyon and juniper trees and reduces pinyon and juniper regeneration will result in loss of trees and conversion of woodland to grasslands or shrublands that are adapted to frequent fire. With loss of ecosystem structure many of the animals that depend on pinyon seeds and juniper berries will also be affected. In addition, severe soil loss may occur where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion and surface disturbances may allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<30,000 acres) for this type (CNHP 2010). Occurrence is surrounded primarily by urban or agricultural landscape, with <25% landscape cover of natural or semi-natural vegetation. The fire regime has high departure (VCC 3) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed high woody fuel load buildup. Surficial disturbances occur on more than 50% of the area (e.g., mines or ranch activities and buildings; off-road vehicle use) (CNHP 2010). Up to 50% of the stand may have been "chained" and re-seeded (CNHP 2010). Microbiotic crusts are >75% removed, occurring only in small pockets naturally protected from livestock and off-road vehicle use (CNHP 2010). Soil erosion may be severe in places (CNHP 2010).

Moderate-severity environmental degradation appears where occurrences are moderate (30,000-50,000 acres) in size for this large-patch type (CNHP 2010). Landscape is a mosaic of agricultural or semi-developed areas and natural or semi-natural vegetation, the latter composing 25-80% of the landscape (CNHP 2010). The fire regime has moderate departure (VCC 2) from historic reference condition; ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval and allowed moderate woody fuel load buildup. Surficial disturbances occur on more than 20% of the area. Up to 50% of the stand may have been "chained" and re-seeded (CNHP 2010). There are more than a few roads found within the occurrence (CNHP 2010). Microbiotic crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence (CNHP 2010). Soil erosion and gullying may be observed in patches (up to 30%) within the stand (CNHP 2010).

High-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) present and abundant throughout much of the stand. Connectivity is severely hampered by fragmentation from roads and/or agriculture or urban land use that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations (CNHP 2010). At best occurrence is buffered on one side by natural communities. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Area around the occurrence is entirely, or almost entirely, surrounded by agricultural or urban land use (CNHP 2010).

Moderate-severity biotic disruption appears where occurrences have non-native species (annual grasses, e.g., *Bromus tectorum*) may be present and even dominant in spots, but not throughout the stand. Connectivity is moderately hampered by fragmentation from roads and/or agriculture that restrict natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations (CNHP 2010). Area around the occurrence is largely a combination of cultural and natural vegetation, with barriers between species interactions and natural processes across natural communities; occurrence is surrounded by a mix of intensive agriculture and adjacent forest lots (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.
