1.B.2.Nd. Vancouverian Forest & Woodland

M886. Southern Vancouverian Dry Foothill Forest & Woodland

CES204.085 East Cascades Oak-Ponderosa Pine Forest and Woodland

CES204.085 CLASSIFICATION

Concept Summary: This narrowly restricted ecological system appears at or near lower treeline in foothills of the eastern Cascades in Washington and Oregon within 65 km (40 miles) of the Columbia River Gorge. It also appears in the adjacent Columbia Plateau ecoregion. Elevations range from 460 to 1920 m. Most occurrences of this system are dominated by a mix of *Quercus garryana* and *Pinus ponderosa* or *Pseudotsuga menziesii*. Isolated, taller *Pinus ponderosa* or *Pseudotsuga menziesii* over *Quercus garryana* trees characterize parts of this system. Clonal *Quercus garryana* can create dense patches across a grassy landscape or can dominate open woodlands or savannas. The understory may include dense stands of shrubs or, more often, be dominated by grasses, sedges or forbs. Shrub-steppe shrubs may be prominent in some stands and create a distinct tree / shrub / sparse grassland habitat, including *Purshia tridentata, Artemisia tridentata, Artemisia nova*, and *Chrysothamnus viscidiflorus*. Understories are generally dominated by herbaceous species, especially graminoids. Mesic sites have an open to closed sodgrass understory dominated by *Calamagrostis rubescens, Carex geyeri, Carex rossii, Carex inops*, or *Elymus glaucus*. Drier savanna and woodland understories typically contain bunchgrass steppe species such as *Festuca idahoensis* or *Pseudoroegneria spicata*. Common exotic grasses that often appear in high abundance are *Bromus tectorum* and *Poa bulbosa*. These woodlands occur at the lower treeline/ecotone between *Artemisia* spp. or *Purshia tridentata* steppe or shrubland and *Pinus ponderosa* and/or *Pseudotsuga menziesii* forests or woodlands. In the Columbia River Gorge, this system appears as small to large patches in transitional areas in the Little White Salmon and White Salmon river drainages in Washington and Hood River, Rock Creek, Moiser Creek, Mill Creek, Threemile Creek, Fifteen Mile Creek, and White River drainages in Oregon. *Quercus garryana* can create dense patches often associated with grassland or shrubland balds within a closed *Pseudotsuga menziesii* forest landscape. Commonly the understory is shrubby and composed of *Ceanothus integerrimus, Holodiscus discolor, Symphoricarpos albus*, and *Toxicodendron diversilobum*. Fire plays an important role in creating vegetation structure and composition in this habitat. Decades of fire suppression have led to invasion by *Pinus ponderosa* along lower treeline and by *Pseudotsuga menziesii* in the gorge and other oak patches on xeric sites in the east Cascade foothills. In the past, most of the habitat experienced frequent low-severity fires that maintained woodland or savanna conditions. The mean fire-return interval is 20 years, although variable. Soil drought plays a role, maintaining an open tree canopy in part of this dry woodland habitat.

Related Concepts:

- Oregon White Oak: 233 (Eyre 1980) **>**

Distribution: This narrowly restricted ecological system appears at or near lower treeline in foothills of the eastern Cascades in Washington and Oregon within 65 km (40 miles) of the Columbia River Gorge. It also appears in the adjacent Columbia Plateau ecoregion. Disjunct occurrences in Klamath and Siskiyou counties, Oregon, have more sagebrush and bitterbrush in the understory, along with other shrubs.
Nations: CA, US

Description Author: G. Kittel, C. Chappell, M.S. Reid, K.A. Schulz

CES204.085 CONCEPTUAL MODEL

Environment: This narrowly restricted ecological system appears at or near lower treeline in foothills of the eastern Cascades in Washington and Oregon within 65 km (40 miles) of the Columbia River Gorge. It also appears in the adjacent Columbia Plateau ecoregion. Elevations range from 460 to 1920 m. In the Columbia River Gorge, this system appears as small to large patches in transitional areas in the Little White Salmon and White Salmon river drainages in Washington and Hood River, Rock Creek, Moiser Creek, Mill Creek, Threemile Creek, Fifteen Mile Creek, and White River drainages in Oregon. *Quercus garryana* can create dense patches often associated with grassland or shrubland balds within a closed *Pseudotsuga menziesii* forest landscape.
Key Processes and Interactions: Fire plays an important role in creating vegetation structure and composition in this habitat. Decades of fire suppression have led to invasion by *Pinus ponderosa* along lower treeline and by *Pseudotsuga menziesii* in the gorge and other oak patches on xeric sites in the east Cascade foothills. Most of the habitat experienced frequent low-severity fires that maintained woodland or savanna conditions. The mean fire-return interval is 20 years, although variable. LANDFIRE VDDT models: #R OAP1 Oregon White Oak-Ponderosa Pine model describes general successional pathways treating drier pine succession separate from more mesic Douglas-fir pathways.

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 0710600). These are summarized as:

A) Early Development 1 All Structures (tree-dominated - 10% of type in this stage): Shrub cover is 0-40%. The early stage is the initial post-disturbance community dominated by white oak sprouts from coppice origin. Bunchgrasses and associated forbs dominate understory with bare ground and rock/gravel abundant in interspaces. Native herbivory may maintain oak sprouts in "shrub" form for extended period. Early stage includes oak sprouts or seedling/saplings growth to 4-6 inches dbh. Occasional sites with ponderosa pine or Douglas-fir will have diameters up to 8 inches. Succeeds to class C (mid/open) after about 50 years. Herbivory and surface fires maintain the stand in class A. About a tenth of this area is wet enough to succeed to class B.

B) Mid Development 1 Closed (tree-dominated - 5% of type in this stage): Tree cover is 41-80%. The mid-seral, closed stage occurs at the more mesic end of the environmental gradient and supports a dense canopy of oak and ponderosa pine and/or Douglas-fir. Oak diameter ranges from 6-12 inches dbh with crown closure approaching 70%. Ponderosa pine and Douglas-fir may be 8-20 inches dbh. Sod-forming grasses and shade-tolerant shrubs will be prominent on the majority of sites. Species from more arid sites may be remnants of earlier, more open post-fire communities. Lasts up to 150 years in this class. Replacement fire about every few hundred years; mixed fire opens the stand (to class C).

C) Mid Development 1 Open (tree-dominated - 10% of type in this stage): Tree cover is 10-40%. The mid-seral, open stage occurs on arid slopes and benches and represents that portion of the environmental gradient where fire-tolerant communities develop as oak woodlands. Usually the dry site conditions limit tree density and canopy closure is relatively low (between 10-30%). Conifers may occur sporadically at low coverage. Oak diameter ranges from 6-10 inches dbh. Bunchgrasses and shade-intolerant shrubs, notably antelope bitterbrush, will be prominent on the majority of sites. Replacement fire is infrequent; surface fire maintains it in class C. Moist sites can fill in to late/closed conditions (class E).

D) Late Development 1 Open (tree-dominated - 65% of type in this stage): Tree cover is 10-40%. The late-seral, open stage is characterized by large, principally multi-stemmed (now, although historically wider spaced, giant-trunked trees were more common), white oaks in open stands with bunchgrass, forb, and shrub understories. These woodlands support crown closure between 10-30%. Diameters range from 10-18 inches dbh with ages over 350 years for those individuals surviving fires. Mature, large conifers may occur sporadically at low coverage. Bunchgrasses (*Pascopyrum smithii* and *Festuca idahoensis*) and shade-intolerant shrubs, notably antelope bitterbrush, will be prominent on the majority of sites. Surface fires maintain it in class D. Replacement fire resets to class A.

E) Late Development 1 Closed (tree-dominated - 10% of type in this stage): Tree cover is 41-80%. This stage has mature overstory ponderosa pine and/or Douglas-fir as emergents over a lower canopy layer of white oak. The conifers have survived a few burn cycles and may show fire scars; dbhs are 21+ inches. Oregon white oak may reach its largest diameters in eastside ecosystems in these river and stream terraces attaining a dbh of 18-20 inches. Canopy closure is high (60-80%) with a dense understory dominated by sod-forming grasses and shrubs. Mixed fire opens the stand.

Historical fire frequency is between 5-30 years in this type. Fire intensities were probably low in open stands but increased in severity as woodland vegetation transitioned to a denser, closed-canopy type along water courses. Canopy is fire-tolerant and therefore fire severity is low. The natural fire regime was a type I regime in the upland. In the more mesic river terraces and draws, fire frequency probably decreased with a fire interval of 50-60 years. With dense vegetation and the occurrence of fuel ladders, fire severity would become mixed. The fire regime may reflect a type III in this more mesic habitat (LANDFIRE 2007a, BpS 0710600).

Insects and disease may impact individual trees (either ponderosa pine or white oak) locally. Armillaria root rot, western pine beetle, western oak looper, western tent caterpillar, and the pine engraver have the greatest potential for damage (LANDFIRE 2007a, BpS 0710600).

Nutrient cycling, specifically carbon cycling, is an important ecological process within many ecological systems. However, biological decomposition in ponderosa pine forests is more limited than biological production, resulting in accumulation of organic materials, especially in the absence of fire (Harvey 1994, Graham and Jain 2005).

Threats/Stressors: Conversion of this type has commonly come from agriculture and rural and urban development including past homesteading (WNHP 2011). Ongoing threats since European settlement include fire suppression, timber and fuelwood harvest, improper livestock grazing, and introduced species (WNHP 2011). Road building and development increase fragmentation (WNHP 2011).

This system is characterized by frequent (5-30 year fire-return interval) low-intensity ground fires that maintain the open savanna structure that is characteristic of most of this system (LANDFIRE 2007a fire regime I). Direct fire suppression and removal of fine fuels by improper grazing has increased fire-return intervals resulting in higher density of understory shrubs and canopy trees and increased fire severity. Logging and grazing have created scrub-like stands of oak that are more susceptible to stand-replacement fires (WNHP 2011). Improper grazing can result in loss of herbaceous cover or the replacement of native bunchgrasses with non-native species such as *Bromus tectorum, Poa bulbosa*, or *Cynosurus echinatus*. In summary, composition, abundance, and structure of native species in this system are significantly threatened by fire suppression, grazing, homesteading and development, and logging (WNHP 2011).

CES204.845 North Pacific Dry Douglas-fir-(Madrone) Forest and Woodland

CES204.845 CLASSIFICATION

Concept Summary: This ecological system is most common in the Puget Trough - Willamette Valley ecoregion of Oregon and Washington but also occurs in adjacent ecoregions. It occupies small patches associated with dry sites or larger areas in prairie landscapes. This system historically had moderate- to low-severity fires moderately frequently. Historically, these communities were either part of larger forested landscapes or occupied sheltered topographic positions in prairie-dominated landscapes. They now also occur on some sites that formerly supported prairies or tall shrublands (*Corylus cornuta*) with scattered trees. In the mountains, this type occurs locally on dry sites within dry to mesic (for the coastal areas) climates up to about 1220 m (4000 feet) elevation. This is a forest or woodland primarily dominated by the long-lived conifer *Pseudotsuga menziesii*. The broadleaf evergreen *Arbutus menziesii*, the short-lived conifer *Pinus contorta*, the broadleaf deciduous *Acer macrophyllum*, and the shade-tolerant conifer *Abies grandis* are local dominant or codominant species. These sites are too dry and warm or have been too frequently and extensively burned for anything more than small amounts of *Tsuga heterophylla* or *Thuja plicata* to be present as regeneration. *Arbutus menziesii* dominance is favored by high-severity fires on sites where it occurs, and *Pseudotsuga menziesii* can be locally eliminated by logging and hot fire or repeated high-severity fires. *Calocedrus decurrens* is absent. *Abies grandis* can be an important subcanopy or sapling tree, especially in and around the Willamette Valley and in the driest portions of the Georgia Basin (Coastal Douglas-fir Zone).

CES204.852 North Pacific Oak Woodland

CES204.852 CLASSIFICATION

Concept Summary: This ecological system is limited to the southern portions of the North Pacific region. It occurs primarily in the Puget Trough and Willamette Valley but trickles down into the Klamath ecoregion and into California. This system is associated with dry, predominantly low-elevation sites and/or sites that experienced frequent presettlement fires. In the Willamette Valley, soils are mesic yet well-drained, and the type is clearly large patch in nature. In the Puget Lowland and Georgia Basin, this system is primarily found on dry sites, typically either shallow bedrock soils or deep gravelly glacial outwash soils. It occurs on various soils in the interior valleys of the Klamath Mountains, and on shallow soils of "bald hill" toward the coast. Even where more environmentally limited, the system is strongly associated with a pre-European settlement, low-severity fire regime. Succession in the absence of fire tends to favor increased shrub dominance in the understory, increased tree density, and increased importance of conifers, with the end result being conversion to a conifer forest. The vegetation ranges from savanna and woodland to forest dominated by deciduous broadleaf trees, mostly *Quercus garryana*. Codominance by the evergreen conifer *Pseudotsuga menziesii* is common, and *Pinus ponderosa* is important in some stands. In the south, common associates also include *Quercus kelloggii* and *Arbutus menziesii*. This system merges into ~Mediterranean California Lower Montane Black Oak-Conifer Forest and Woodland (CES206.923)$$ on sites that support more conifer cover, and into ~Mediterranean California Mixed Oak Woodland (CES206.909)$$ in the southern portion of its distribution. This system is borderline between small patch and large patch in its dynamics.

Related Concepts:
- Oregon White Oak: 233 (Eyre 1980) =

Distribution: This system occurs primarily in the Puget Trough and Willamette Valley and extends southward at low elevations in the Klamath Mountains on both sides of the Oregon/California stateline.

Nations: CA, US

Description Author: C. Chappell, G. Kittel and M.S. Reid

CES204.852 CONCEPTUAL MODEL

Environment: This type is associated with dry, predominantly low-elevation sites and/or sites that experienced frequent presettlement fires. In the Willamette Valley, soils are mesic yet well-drained, and the type is clearly large patch in nature. In the Puget Lowland and Georgia Basin, this system is primarily found on dry sites, typically either on shallow bedrock soils or deep gravelly glacial outwash soils. It occurs on various soils in the interior valleys of the Klamath Mountains, and on shallow soils of "bald hills" toward the coast.

Key Processes and Interactions: Even where more environmentally limited, the system is strongly associated with a pre-European settlement, low-severity fire regime. Succession in the absence of fire tends to favor increased shrub dominance in the understory, increased tree density, and increased importance of conifers, with the end result being conversion to a conifer forest. Landfire (2007a) model: Fire Regime I, primarily short-interval (e.g., <10 years) surface fires. Surface fires every 3-10 years maintained an open savanna-like structure. Fires can be mixed-severity especially when closed-canopy conditions or additional species such as conifers and shrubs are present. Native American burning was a significant factor in fire frequency of this type, but fire frequency may have decreased significantly with a little distance from native settlements and valley bottoms. Landfire VDDT models: #R OWOA Oregon White Oak applies to southern occurrences. Dissemination of acorns by squirrels and chipmunks is thought to be the most important long-distance dispersal mechanism for the oaks (WNHP 2011).

Threats/Stressors: Conversion of this type has commonly come from urbanization or conversion to agriculture, but also conversion to conifer-dominated woodlands or forest due to lack of fire. Ongoing threats include residential development, increase and spread of exotic species, and fire suppression effects. With the cessation of regular burning 100-130 years ago, many oak woodlands have been invaded by a greater density and cover of oak and conifer trees. Fire suppression has also increased shrub cover in many oak woodlands. Removal of *Quercus garryana* trees for firewood, fence posts, and other lumber products has and continues to occur in some area. Selective logging of *Pseudotsuga menziesii* in oak stands can prevent long-term loss of *Quercus garryana* dominance. Oaks typically resprout after logging. Moderate to heavy grazing can lead to an increase in non-native species, many of which are now abundant. *Cytisus scoparius* is invasive and persistent in many oak woodlands. *Prunus avium* and *Crataegus monogyna* have invaded and now dominate the subcanopy in Willamette Valley oak woodlands. *Poa pratensis* is a major non-native dominant in the understory.

In the Pacific Northwest, regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation, averaged over all models, are small (+1 to +2%), and some models project wetter autumns and winters and drier summers. Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models (Littell et al. 2009). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. This change will result in less winter snow accumulation, higher winter streamflows, earlier spring snowmelt, earlier peak spring streamflow and lower summer streamflows in rivers that depend on snowmelt (as do most rivers in the Pacific Northwest) (Littell et al. 2009). Potential climate change effects could include: reduction in freshwater inflows through the further reduction in summer flows (Littell et al. 2009); but models also predict increases in extreme high precipitation over the next half-century, particularly around Puget Sound (Littell et al. 2009), which may provide freshwater pulses that are intermittent, less predictable; drop in groundwater table; and increased fire frequency due to warmer temperatures resulting in drier fuels, the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from (adapted from Alverson 2009a, WNHP 2011): cessation of regular fire resulting in dominance of conifers and loss of the *Quercus garryana* trees or shrubs from the occurrence; heavy invasion of exotic plant species, displacing the native shrubs, grasses and forbs; occurrences are small in size (less than 5 acres/2 ha) and surrounded by non-natural land uses; logging activity has removed mature oaks, and remaining trees are of a single age class and younger than 100 years; connectivity between stands has been eliminated or reduced due to intervening areas of human land uses.

Environmental Degradation (from WNHP 2011): High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; fire is no longer occurring, there is severe departure from the historic regime (FRCC = 3). Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2).

Disruption of Biotic Processes (from WNHP 2011): High-severity disruption of biotic processes appears where greater than 30% absolute cover of exotic invasives; non-native species dominate understory with minor native component (native species cover in shrub and herb layers <50%); conifers have >50% relative cover of the trees; overall species richness has declined, with fewer than 4 of the expected native species occurring in the shrub or herb layers; mature oaks have been removed by logging or overtopped by conifers. Moderate-severity appears where exotic invasives prevalent with 5-30% absolute cover; native species have 50-90% of the cover, non-natives can be codominant; conifers present but have not overtopped the oaks; overall species richness has declined, but at least 4 to 9 of the expected native species occurring in the shrub or herb layers; some of the mature oaks have been removed by logging, most oaks are <100 years of age.

M023. Southern Vancouverian Montane-Foothill Forest

CES206.918 California Montane Jeffrey Pine-(Ponderosa Pine) Woodland

CES206.918 CLASSIFICATION

Concept Summary: These forests are found on relatively xeric sites in mountains and plateaus from southern Oregon (600-1830 m [1800-5000 feet] elevation) south into the Sierra Nevada, throughout the Transverse Ranges of California, and into northern Baja California (1200-2740 m [4000-8300 feet]), Mexico. While the two dominant pines tend to segregate by soil fertility and temperature regimes, they may co-occur in certain areas (e.g., Modoc Plateau). These stands are more common on the east side of the Sierra Nevada, although they do occur on the west side. Stands are pure *Pinus jeffreyi, Pinus ponderosa*, or a mix of the two. Ponderosa pine and/or Jeffrey pine on the west slope of the Sierras with other conifer species are part of ~Mediterranean California Dry-Mesic Mixed Conifer Forest and Woodland (CES206.916)$$. This system includes sites where *Pinus ponderosa* and/or *Pinus jeffreyi* are the predominant conifers and other tree species do not occur in high abundance, if at all. The exception to this is in southern California on the edges of the Mojave Desert where *Pinus monophylla* or *Juniperus californica* might occur in a subcanopy under *Pinus ponderosa* or *Pinus jeffreyi*. *Pinus jeffreyi* is more tolerant of colder, drier and poorer sites and replaces *Pinus ponderosa* as the dominant at higher elevations. In the north, *Pinus jeffreyi* may be replaced by *Pinus ponderosa var. washoensis* (Carson Range and Warner Mountains). Throughout California, pure stands of ponderosa pine are relatively uncommon. Only on the Modoc Plateau do these pines co-occur in mixed stands. *Juniperus grandis* [in the south] and *Juniperus occidentalis* can co-occur in these stands but typically are not dominant. On moister and cooler sites, *Abies lowiana* can be present in some stands. There can be well-developed shrub understories with strong Great Basin affinities; species can include *Artemisia tridentata, Purshia tridentata, Symphoricarpos rotundifolius var. parishii, Arctostaphylos patula, Ceanothus cordulatus, Ceanothus prostratus, Ceanothus integerrimus, Chrysolepis sempervirens, Eriogonum wrightii, Quercus vacciniifolia*, and *Lupinus elatus*. *Cercocarpus ledifolius* is common on steeper slopes throughout the range. Historically, frequent localized surface fires maintained these systems. Stands of ponderosa pine on the east side of the Cascades transition into ~East Cascades Oak-Ponderosa Pine Forest and Woodland (CES204.085)$$, or ~Northern Rocky Mountain Ponderosa Pine Woodland and Savanna (CES306.030)$$ north of the Warm Springs Reservation of central Oregon.

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel, K.A. Schulz

CES206.918 CONCEPTUAL MODEL

Environment: This system occupies xeric (mean annual rainfall 200-430 mm, as winter snow), cool (cold winters; January minimums range from -13° to -5°C), and nutrient-poor sites in mountains and plateaus (600-2740 m elevation), in the rainshadow of the Sierra Nevada. Frequent (8-10 years) low-intensity and moderately frequent (44 years) mixed-intensity fires maintain this system. Greater moisture increases tree diversity (*Abies lowiana* at higher altitudes).
Key Processes and Interactions: *Pinus jeffreyi* and *Pinus ponderosa* trees are structurally and physiologically fire-adapted (Habeck 1992a, d, Gucker 2007). Both species have thick, insulating bark, insulating bud scales that protect terminal buds, self-pruning branches, open crowns, and high moisture content of needles, which make them moderately fire-resistant as saplings and highly fire-resistant as mature trees (Habeck 1992a, d, Gucker 2007). Historically, frequent localized surface fires maintained open canopy woodland stands in this system.

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 1210310). These are summarized as:

A) Early Development 1 All Structures (shrub-dominated - 15% of type in this stage): Shrub cover is 0-100%. Fire-dependent shrubs such as greenleaf manzanita and mountain whitethorn resprout and germinate from seed vigorously after fire. Scattered Jeffery pine seedlings sprout but may take several years to dominate over the shrub community. Perennial bunchgrasses and some forbs cover small portions of the area.

B) Mid Development 1 Closed (tree-dominated - 5% of type in this stage): Tree cover is 51-90%. This class has developed after escaping significant fire and it is modeled as an alternative pathway when three fire cycles have been missed. In the absence of fire, a closed forest with a dense stand of multi-layered pole and medium-sized Jeffery pine and white fir trees (5-16 inches dbh) develops. This multi-layered forest is often dominated by Jeffery pine in the overstory with white fir dominant in the mid and regeneration layers. The understory vegetation is almost absent due to the lack of sunlight and heavy litter and woody debris accumulations. In some cases, on the east side of the Sierra Nevada, both white fir and Jeffrey pine are pretty equally stocked and have a number of older individuals present suggesting that there is not always a low cover of white fir of small size classes in such settings (e.g., Buckeye Creek and other drainages northeast of Yosemite National Park). The understory vegetation is generally sparse, but not always due to lack of sunlight. *Poa wheeleri* and *Elymus elymoides* can be main understory species.

C) Mid Development 1 Open (tree-dominated - 20% of type in this stage): Tree cover is 0-50%. This class has developed with frequent low-intensity surface fires. Pole to medium-sized (5-21 inches dbh) Jeffery pine has become dominant over the shrub layer. Several conifer species could also be present depending on location. Shrubs are prevalent in the understory with scattered forbs and perennial grasses. East of the Sierra crest (e.g., Truckee Basin north of Tahoe), this class can have substantial amounts of white fir, but usually exists where the shrubs are mostly *Purshia tridentata* and other Great Basin species.

D) Late Development 1 Open (conifer-dominated - 65% of type in this stage): Tree cover is 0-50%. This class is a continuation of class C which has developed with frequent low-intensity surface fires. Large to very large (>21 inches dbh) Jeffery pine is dominant with an open canopy. Scattered shrubs are found in the canopy openings, with a diversity of forbs such as lupines and woolly mule's-ears. Perennial grasses are also present.

E) Late Development 1 Open (conifer-dominated - 5% of type in this stage): Tree cover is 51-90%. This class has developed in time from class B or class D after escaping significant fire (>3 years fire-return intervals). In the absence of fire a closed forest structure continues to develop with a dense stand of multi-layered medium- to large-sized Jeffery pines and white fir trees (16+ inches dbh). The diameter remains smaller than in the open forest due competition. This overstory canopy is often codominated by Jeffery pine and white fir, with white fir dominating the understory. There is severe competition for sunlight and water. This stress combined with insect and disease infestation create a high level of tree mortality. The understory vegetation is almost absent due to the lack of sunlight and heavy litter and woody debris accumulations. Current conditions where there are large Jeffery pine trees along with multi-age classes of white fir suggest that historically there were low-intensity fires that maintained stands without killing white fir, but more recently white fir has become dominant in the understory.

Where stands are relatively dense and sufficient fuels are available, this type is dependent on relatively frequent low-intensity surface fire intervals of about 30 years (LANDFIRE 2007a, BpS 1210310). The mixed-intensity fire interval is about 130 years, and the stand-replacement fire interval is 250 years. The mean fire interval for all fires is 20 years with a range from 8-28 years. Intervals may be longer for relatively open stands with low understory fuels, as over shallow granitic soils in the Kern Plateau or over serpentine substrate in the Klamath Mountains. The fire regimes in this type are more variable and somewhat longer than the ponderosa pine types, due to slower fuel accumulation rates (LANDFIRE 2007a, BpS 1210310).

Threats/Stressors: This system is characterized by frequent (5-30 years fire-return interval) low-intensity ground fires that maintain the open structure. Fire suppression has increased fire-return intervals resulting in higher density of understory shrubs and canopy trees, increased presence of ladder fuels resulting in high-severity, stand-replacing fires. On a landscape scale, a mixed-severity fire regime occurs in Jeffery pine habitats (Habeck 1992a, d, Gucker 2007).

CES206.917 Klamath-Siskiyou Lower Montane Serpentine Mixed Conifer Woodland

CES206.917 CLASSIFICATION

Concept Summary: This system occurs throughout the Klamath-Siskiyou region below 1500 m (4550 feet) elevation on thin, rocky, ultramafic (gabbro, peridotite, serpentinite) soils below winter snow accumulations and typically experiences hot and dry summers. Soils are not always rocky; they can be loamy, up to 76 cm (30 inches) in depth, and can be heavy clay. Not all ultramafic outcrops support distinct vegetation; only those with very low Ca:Mg ratios impact biotic composition. These woodlands are highly variable and spotty in distribution. These sites are more productive and can support large-statured (dbh, height) trees, although they tend to be widely spaced. Common species include *Pseudotsuga menziesii, Pinus sabiniana, Pinus lambertiana, Pinus jeffreyi, Pinus attenuata, Notholithocarpus densiflorus var. echinoides, Calocedrus decurrens, Arctostaphylos* spp., *Quercus vacciniifolia*, and *Xerophyllum tenax*. Perennial grasses such as *Festuca idahoensis* may also be characteristic. *Chamaecyparis lawsoniana* communities can occur within occurrences of this system in mesic and linear riparian zones. Herbaceous-dominated serpentine fens (and bogs) are treated in ~Mediterranean California Serpentine Fen (CES206.953)$$.

CES206.917 CONCEPTUAL MODEL

Environment: This system occurs throughout the Klamath-Siskiyou region below 1500 m (4550 feet) elevation on thin, rocky, ultramafic (gabbro, peridotite, serpentinite) soils below winter snow accumulations and typically experiences hot and dry summers. Soils are not always rocky; they can be loamy, up to 76 cm (30 inches) in depth, and can be heavy clay. Not all ultramafic outcrops support distinct vegetation; only those with very low Ca:Mg ratios impact biotic composition. Soils on ultramafics are usually shallow and skeletal, with little profile development. Ultramafic soils impose the following stresses on plants: imbalance of calcium and magnesium, magnesium toxicity, low availability of molybdenum, toxic levels of heavy metals, sometime high alkalinity, low concentrations of some essential nutrients, and low soil water storage capacity (Kruckeberg 1984, Sanchez-Mata 2007). In some cases, the steepness of the slopes and general sparseness of the vegetation result in continual erosion.

Key Processes and Interactions: Sites are productive and can support large-statured trees, although they will generally be widely spaced. Trees tend to grow very slowly due to the soil chemistry and textural characteristics which limit available nutrients.

Several important trees in this systems are fire-adapted, but the system as a whole is an edaphically-controlled type. Fire regimes vary depending on the slope position, elevation, fire history, and successional stage. *Chamaecyparis lawsoniana*-dominated stands have a low frequency of stand-replacing fires with an age class distribution showing >50% of stands are more than 300 years old (Jimerson et al. 1995). Other forest types in this system have more frequent stand-replacing fires. *Pseudotsuga menziesii* woodlands age class distribution shows >80% of stands were older than 175 years. *Pinus jeffreyi* occurs on drier sites and has more frequent fires, age classes are evenly distributed from young to old; while *Pinus lambertiana* has highest age class frequency of stands <175 years. *Pinus lambertiana* stands burn more frequently due to upper slope positions (Jimerson et al. 1995). Native dwarf mistletoe (*Arceuthobium* spp.) infest many trees within this system; generally they do not cause mortality but weaken trees sufficiently for bark or engraver beetles or wood borers to successfully attack and kill the tree.

Parker (1990) suggests that species growing on serpentine sites may suffer greater mortality and poorer recruitment after a fire than the same species on adjacent sandstone soils. Landfire (2007a): This type has a very limited distribution and consequently limited information for fire occurrence history. Adjacent mixed conifer forest types have similar characteristics and are detailed below. Surface and mixed-severity fires occur at an average of about 10-15 years (Taylor and Skinner 1998, 2003, Sensenig 2002). Kilgore and Taylor (1979) reported a FRI=19-39 years (N/NE aspects), which may favor mixed fires. Replacement fires with longer (70-110 years) return intervals are possible (Frost and Sweeney 2000). With historic fire regimes, insect outbreaks may have been much reduced compared to current conditions. Snow breakage occurs in the mid-seral closed state about every 5 years. While model is aspatial, most medium- and high-severity fire may actually occur on mid and upper slope positions (Taylor and Skinner 1998, Taylor 2000, Bekker and Taylor 2001).

Threats/Stressors: Conversion of this type has commonly come from mining, geothermal power development, logging for various purposes (fenceposts, homes, small amount of commercial timbering, firewood) which has removed the trees, and minor amount of other development (Kruckeberg 1984). Once mature trees have been logged and removed, they are slow to be replaced (Kruckeberg 1984), often >150 years, due to the soils characteristics. Common stressors and threats include logging, fire suppression, and non-native pathogens which are infecting conifers throughout northwestern California and southwestern Oregon. From Jimerson et al. (1995): The Port Orford-cedar root disease (a fungus, *Phytophthora lateralis*) is fatal to any infected *Chamaecyparis lawsoniana*, and now infects most stands. Spores are spread by mud on wheels, boots, or other equipment. White pine blister rust (*Cronartium ribicola*), also a fungus, infests both *Pinus monticola* and *Pinus lambertiana*, which can be killed directly by the fungus, or weakened and made susceptible to insects. Regeneration-sized trees are more significantly and rapidly affected than larger trees, which is resulting in shifts in age class distribution and loss of the regeneration layers and hence changes in succession (Jimerson et al. 1995). Fire suppression has lead to increased cover of some shrub species, which will change the characteristics of a fire, including severity and spread (Jimerson et al. 1995). Due to fire exclusion, many of these stands currently exhibit higher density of understory species and young conifer and hardwoods.

In northwestern California, regional climate models project mean annual temperature increases of 1.7-1.9°C (3.06-3.42°F) by 2070 (PRBO Conservation Science 2011). And regional climate models project a decrease in mean annual rainfall of 101 to 387 mm by 2070. Currently, there is greater uncertainty about the precipitation projections than for temperature in northwestern California, but with some evidence for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Potential climate change effects could include: increase fire frequency with warmer temperatures, lower precipitation may result in drier, more flammable fuels, which may exacerbate the fire intensity; and less rainfall and higher temperatures may shift species composition to more drought-tolerant species, such as *Lithocarpus densiflorus*, and which may also favor non-native species.

In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from lack of fire; occurrences are small in size (less than 5 acres/2 ha) and surrounded by non-natural land uses; mining activities have impacted most of the occurrences; the dominant conifers have died or are infected with introduced fungal pathogens; or the largest trees have been removed by logging; fragmentation has occurred and connectivity between occurrences is gone; rare serpentine endemic forbs and grasses have been eliminated from the occurrence.

Environmental Degradation: High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; fire is infrequent affecting recruitment post-fire and changing the structural characteristics, there is severe departure from the historic regime (FRCC = 3); logging has occurred, removing much of the tree biomass. Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2); logging has occurred, removing some of the tree biomass.

Disruption of Biotic Processes: High-severity disruption of biotic processes appears where overall species richness has declined, with fewer than 4 of the expected native species occurring in the shrub or herb layers; rare serpentine endemic plant species have been lost from the occurrence; excessively frequent or complete lack of fire has affected recruitment of the shrubs or trees; introduced fungal pathogens have killed or infested most of the conifers; fragmentation of occurrences and proximity to human activities has lead to the introduction of fungal pathogens. Moderate-severity appears where overall species richness has declined, but at least 4 to 9 of the expected native species occurring in the shrub or herb layers; some conifers may be infested with fungal pathogens.

CES206.914 Klamath-Siskiyou Upper Montane Serpentine Mixed Conifer Woodland

CES206.914 CLASSIFICATION

Concept Summary: This system occurs throughout the Klamath-Siskiyou mountains region above 1500 m (4550 feet) elevation on thin, rocky, ultramafic (gabbro, peridotite, serpentinite) soils in dry-mesic conditions. Not all ultramafic outcrops support distinct vegetation; only those with very low Ca:Mg ratios impact biotic composition. Although ultramafics may be relatively dry and have a moderate to high grass component, they do not burn often where the serpentine syndrome is severe. The problem is not just the calcium:magnesium ratio, but heavy metals and sometimes high clay content limit biomass production. These systems are highly variable and spotty in distribution. Common species include *Pinus monticola, Pinus balfouriana, Quercus vacciniifolia, Pinus jeffreyi, Ceanothus pumilus, Arctostaphylos* spp., *Notholithocarpus densiflorus var. echinoides, Abies magnifica var. shastensis*, and *Callitropsis nootkatensis*. Stands of stunted (up to 12 m [40 feet]) but straight *Pinus contorta* are also possible. *Chamaecyparis lawsoniana* communities can occur in this system in mesic and linear riparian zones. Herbaceous-dominated serpentine fens (and bogs) are treated in ~Mediterranean California Serpentine Fen (CES206.953)$$.

CES206.916 Mediterranean California Dry-Mesic Mixed Conifer Forest and Woodland

CES206.916 CLASSIFICATION

Concept Summary: These mixed-conifer forests, always with at least two conifer species codominating, occur on all aspects in lower montane zones (600-1800 m elevation in northern California; 1200-2150 m in southern California). This system occurs in a variety of topo-edaphic positions, such as upper slopes at higher elevations, canyon sideslopes, ridgetops, and south- and west-facing slopes which burn relatively frequently. Often, several conifer species co-occur in individual stands. *Pseudotsuga menziesii, Pinus ponderosa*, and *Calocedrus decurrens* are the most common conifers. Other conifers that can occasionally be present include *Pinus jeffreyi, Pinus attenuata*, and *Pinus lambertiana* (not as common in this as in ~Mediterranean California Mesic Mixed Conifer Forest and Woodland (CES206.915)$$). Common subcanopy trees include *Quercus chrysolepis* and *Quercus kelloggii*. *Arbutus menziesii* and *Notholithocarpus densiflorus* may be common with the oaks in northern areas. *Pseudotsuga macrocarpa* and *Pinus coulteri* can be present but are not dominant species in this system in the Transverse Ranges of southern California. Codominant *Abies lowiana* - *Calocedrus decurrens* communities in southern California are also included in this system. In the Transverse Ranges, where Great Basin and Mojavean elements are transitioning into the montane zones, *Juniperus californica* and *Pinus monophylla* can be mixed with the other conifers. Understories are variable, except in the Sierra Nevada, where in some stands there can be dense understory mats of *Chamaebatia foliolosa* (and other low, spreading shrubs) which foster relatively high-frequency, low-intensity surface fires. In Oregon, shrubs such as *Holodiscus discolor, Toxicodendron rydbergii, Mahonia nervosa, Mahonia aquifolium*, and *Symphoricarpos mollis* are common in addition to graminoids such as *Festuca californica, Elymus glaucus*, and *Danthonia californica*. In the north, where *Calocedrus decurrens* and *Pinus ponderosa* drop out, this system shifts to ~North Pacific Dry Douglas-fir-(Madrone) Forest and Woodland (CES204.845)$$.

- Sierra Nevada Mixed Conifer: 243 (Eyre 1980) **><**
- White Fir: 211 (Eyre 1980) **><**

Distribution: This system occurs in lower montane zones (600-1800 m elevation in northern California; 1200-2150 m in southern California), including the eastern Klamath-Siskiyou, interior Coast Ranges, Transverse Ranges and Sierra Nevada.
Nations: US
Concept Source: P. Comer and T. Keeler-Wolf
Description Author: P. Comer, T. Keeler-Wolf, G. Kittel and M.S. Reid

CES206.916 CONCEPTUAL MODEL

Environment: In the lower montane of the Sierra Nevada, 33% of the annual precipitation falls as snow and nearly all of it occurs in the fall, winter and spring months. Throughout California, conifers have to contend with summer drought. Winter precipitation is stored as soil moisture, and available water is virtually depleted by the end of September. The dry-mixed conifer system occurs where there is plenty of moisture but not prolonged cold. Shade tolerance, drought tolerance and response to fire of dominant tree species seedlings are important factors governing the composition and successional patterns of this forest system. Ponderosa pine seedlings are intolerant of shade compared to Douglas-fir, white fir, incense-cedar and sugar pine. In fact, abundant evidence indicates that incense-cedar and white fir have increased in ponderosa pine forests since the turn of the twentieth century, with more significant changes seen on xeric locations relative to mesic sites (Barbour et al. 2007). Historically, surface fires occurred every 5-10 years and mixed-severity fires occur about every 50 years. Fire suppression has led to an increase in forest canopy coverage and tree density, but a decrease in trees with >60 cm dbh. In addition, species composition has shifted due to targeted logging of preferred species.
Key Processes and Interactions: Historically, frequent and low-intensity fires maintained these woodlands. Due to fire suppression, the majority of these forests now have closed canopies, whereas in the past, a moderately high fire frequency (every 20-30 years) formerly maintained an open forest of many conifers.
Threats/Stressors:
Ecosystem Collapse Thresholds:

CES206.915 Mediterranean California Mesic Mixed Conifer Forest and Woodland

CES206.915 CLASSIFICATION

Concept Summary: This ecological system occurs in cool ravines and north-facing slopes (typically with 100-150 cm annual precipitation; 50% as snow). It is found from 800-1000 m (2400-3000 feet) elevation in the Sierra Nevada and 1250-2200 m (3800-6700 feet) in the Klamath Mountains. The most characteristically co-occurring conifers are *Abies lowiana, Calocedrus decurrens*, and *Pinus lambertiana*. *Pinus jeffreyi, Pinus ponderosa*, and *Pseudotsuga menziesii* occur frequently but are not dominant. In limited locations in the central Sierra Nevada, *Sequoiadendron giganteum* dominates, usually with *Abies lowiana*, and at the highest elevations also with *Abies magnifica*. *Acer macrophyllum* is common in lower elevation mesic pockets; *Chrysolepis chrysophylla* also occurs in the western Klamaths. Common understory species include *Corylus cornuta, Cornus nuttallii*, and at higher elevations

Chrysolepis sempervirens. In areas of recent fire or other disturbance, *Arctostaphylos patula, Ceanothus integerrimus, Ceanothus cordulatus, Ceanothus parvifolius*, and *Ribes* spp. are more common. Fire of highly variable patch size and return interval maintains the structure of these woodlands

- White Fir: 211 (Eyre 1980) **><**

Distribution: This system is found from 800-1000 m (2400-3000 feet) elevation in the Sierra Nevada and 1250-2200 m (3800-6700 feet) in the Klamath Mountains.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.915 CONCEPTUAL MODEL

Environment: This ecological system occurs in cool ravines and north-facing slopes (typically with 100-150 cm annual precipitation; 50% as snow). It is found from 800-1000 m (2400-3000 feet) elevation in the Sierra Nevada and 1250-2200 m (3800-6700 feet) in the Klamath Mountains. Throughout California, conifers have to contend with summer drought. Winter precipitation is stored as soil moisture, and available water is virtually depleted by the end of September. The mesic-mixed conifer system occurs where there is plenty of moisture but not prolonged cold. Shade tolerance, drought tolerance and response to fire of dominant tree seedlings are important factors governing the composition and successional patterns of this forest system. Ponderosa pine seedlings are intolerant of shade compared to Douglas-fir, white fir, incense-cedar and sugar pine. In fact, abundant evidence indicates that incense-cedar and while fir have increased in ponderosa pine forests since the turn of the twentieth century, with more significant changes seen on xeric locations relative to mesic sites (Barbour et al. 2007). Historically, surface fires occurred every 10-20 years and mixed-severity fires occurs about every 19-39 years. Fire suppression has led to an increase in forest canopy coverage and tree density, but a decrease in trees >60 cm dbh. In addition, species composition has shifted due to targeted logging of preferred species.

Key Processes and Interactions: Fire of highly variable patch size and return interval maintains the structure of these woodlands

CES206.928 Mediterranean California Mesic Serpentine Woodland and Chaparral

CES206.928 CLASSIFICATION

Concept Summary: This ecological system occurs in Mediterranean California in the north and south Coast Ranges and the northern Sierra Nevada, on cool northerly and concave slopes and toeslopes with thin, rocky, ultramafic (gabbro, peridotite, serpentinite) soils. Not all ultramafic outcrops support distinct vegetation; only those with very low Ca:Mg ratios impact biotic composition. These systems are highly variable and spotty in distribution, and the composition of individual stands can be very diverse, especially the shrubs (often individual species have low cover). *Hesperocyparis sargentii, Pinus sabiniana, Garrya congdonii, Quercus durata, Umbellularia californica*, and *Frangula californica ssp. tomentella* are characteristic. Common associates include *Heteromeles arbutifolia, Adenostoma fasciculatum*, and the California endemics *Arctostaphylos viscida ssp. pulchella* and *Ceanothus jepsonii*. In some settings *Arctostaphylos glauca, Styrax redivivus*, or *Cercocarpus montanus var. glaber* can be common. Occasionally, *Chamaecyparis lawsoniana* may be present. Common grasses and forbs can include *Melica torreyana, Festuca idahoensis, Iris* spp., and locally endemic serpentine forbs (*Senecio* spp. and others). Structurally, this system is sometimes woodland in character, but it can also be an arborescent chaparral, depending on fire history. Herbaceous-dominated serpentine fens (and bogs) are treated in ~Mediterranean California Serpentine Fen (CES206.953)$$.

CES206.928 CONCEPTUAL MODEL

Environment: This ecological system occurs in Mediterranean California in the northern and southern Coast Ranges and the northern Sierra Nevada, on cool northerly and concave slopes and toeslopes with thin, rocky, ultramafic (gabbro, peridotite, serpentinite) soils. Not all ultramafic outcrops support distinct vegetation; only those with very low Ca:Mg ratios impact biotic composition. Soils on ultramafics are usually shallow and skeletal, with little profile development (Kruckeberg 1984). Ultramafic soils impose the following stresses on plants: imbalance of calcium and magnesium, magnesium toxicity, low availability of molybdenum, toxic levels of heavy metals, sometime high alkalinity, low concentrations of some essential nutrients, and low soil water storage capacity (Kruckeberg 1984, Sanchez-Mata 2007). In some cases, the steepness of the slopes and general sparseness of the vegetation result in continual erosion.

Key Processes and Interactions: Structurally, this system is sometimes woodland in character, but it can also be an arborescent chaparral, depending on fire history. Landfire (2007a): Stand-replacing fires occur mostly in the shrub-dominated stages. In the conifer-dominated late-seral closed stage, surface fire is also important. Mean FRI is generally greater than that of the surrounding forested landscape (including the lower elevation ~California Mesic Chaparral (CES206.926)$$ - perhaps double (Nagel and Taylor 2005) - due to the lack of flammability of many young shrub fields without a long history of fuel accumulation.

Within this system, *Hesperocyparis sargentii* dominates some occurrences as woodlands or as dense shrubby thickets (Griffin and Critchfield 1976). This tree begins bearing cones by 3-7 years of age, and abundant cone crops are produced that require 2 years to mature. The serotinous cones remain closed on the tree until opened by the heat of a fire or from desiccation due to age. Seeds establish best on bare mineral soil. Seedling mortality is high on shaded sites with abundant litter because of damping-off fungi (Esser 1994b, Barbour 2007). *Hesperocyparis sargentii* has serotinous cones. Burned trees usually release large quantities of seed after fire, and seedlings establish as dense thickets. No information was available on fire-return intervals. To maintain a stand, fire-return intervals of greater than 7 years will allow new cone crops to develop (Esser 1994b).

The mesic chaparral stage of this system generally burns in high-intensity, stand-replacing crown fires that may burn thousands of acres in a single event (Landfire 2007a). However, there is a considerable range in the flammability of shrub species (e.g., *Adenostoma fasciculatum* is "flashier" than *Arctostaphylos* spp.). Large, stand-replacement events can interact with seed availability and, hence, influence post-fire successional pathways differently than for smaller, less severe fires. Mean fire-return intervals are highly variable across the range of this system depending on species composition and other factors. Sediment cores taken from the Santa Barbara Channel in central California dating from the 16th and 17th centuries indicate that large fires burned the Santa Ynez and Santa Lucia mountains every 40-60 years. Season of burning plays a large part in species composition. Occasionally, frost affects mortality and increases fuel buildup.

Quercus durata is an important shrub in this system. Plants sprout from swollen root crowns and root suckers after damage to their trunks; they sprout rapidly following fire (Sawyer et al. 2009). Small mammals and jays cache acorns, which other wildlife also eat.

Threats/Stressors: Conversion of this type has commonly come from mining, geothermal power development, logging for various purposes (fenceposts, homes, small amount of commercial timbering, firewood) which has removed the trees, and minor amounts of other development (Kruckeberg 1984, Barbour 2007). Conversion to agriculture is not a factor as the soil types are not conducive to agricultural use. Invasive plant species that are often threats to other California ecosystems may be less of a threat in serpentine ecosystems; however, some invasives are finding their way into serpentine soils (Batten et al. 2006). In the last century the high frequency of human ignitions has reduced the mean fire-return interval to 30-35 years in southern California (Landfire 2007a).

In the west central coast regions of California, regional climate models project mean annual temperature increases of 1.6-1.9°C by 2070. The projected impacts will be warmer winter temperatures, earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 61-188 mm by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Potential climate change effects could include (PRBO Conservation Science 2011): deep-rooted or phreatophytic species under greater stress and death; drop in groundwater table; more and larger fires; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006); increases in the areal extent of grasslands and concomitant reductions in the extent of chaparral, sage scrub, and oak woodlands; and increased competition for water from all users, and stresses on the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from too frequent fires; occurrences are small in size (less than 5 acres/2 ha) and surrounded by non-natural land uses; mining activities have impacted much of the occurrences; or mining restoration has introduced undesirable shrubs; fragmentation has occurred and connectivity between occurrences is gone; rare serpentine endemic forbs and grasses have been eliminated from the occurrence.

Environmental Degradation: High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; fire is too frequent affecting recruitment post-fire, there is severe departure from the historic regime (FRCC = 3); clearing has occurred, removing much of the shrub or tree biomass. Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2); clearing has occurred, removing some of the shrub or tree biomass.

Disruption of Biotic Processes: High-severity disruption of biotic processes appears where overall species richness has declined, with fewer than 4 of the expected native species occurring in the shrub or herb layers; rare serpentine endemic plant species have been lost from the occurrence; excessively frequent or poorly timed fire has affected recruitment of the shrubs or trees; fragmentation of occurrences has lead to a loss of seed source for stands that burn. Moderate-severity appears where overall species richness has declined, but at least 4 to 9 of the expected native species occurring in the shrub or herb layers.

CES204.101 Sierran-Intermontane Desert Western White Pine-White Fir Woodland

CES204.101 CLASSIFICATION

Concept Summary: This interior Pacific Northwest ecological system occurs on the Modoc Plateau and Warner Mountains of California, north into the Fremont National Forest along the east slope of the southern Cascades in Oregon, and may also occur in isolated high-elevation ranges of northern Nevada. These forests and woodlands range from just above the zone of ponderosa pine in the montane zone, to the upper montane zone. Elevations range from 1370 m to over 2135 m (4500-7000 feet). Occurrences are found on all slopes and aspects, although more frequently on drier areas, including northwest- and southeast-facing slopes, but also occurs on northerly slopes and ridges. This ecological system generally occurs on basalts, andesite, glacial till, basaltic rubble, colluvium, or volcanic ash-derived soils, and sometimes on granitics (Carson Range). These soils have characteristic features of good aeration and drainage, coarse textures, circumneutral to slightly acidic pH, an abundance of mineral material, rockiness, and periods of drought during the growing season. Climatically, this system occurs somewhat in the rainshadow of the Sierras and Cascades and has a more continental regime, similar to the northern Great Basin. This system tends to be more woodland than forest in character, and the undergrowth is more open and drier, with little shrub or herbaceous cover. Tree regeneration is less prolific than in other mixed-montane conifer systems of the Cascades, Sierras and California Coast Ranges. *Pinus monticola* is the dominant conifer in most places, but *Abies lowiana (= Abies concolor var. lowiana)* is usually present, at least in the understory, and occasionally as the dominant in the canopy, replacing *Pinus monticola*, particularly at lower elevations, and *Pinus ponderosa* is also often present. In the Warner Mountains, the *Abies lowiana* stands range from 1675 to 2135 m (5500-7000 feet) in elevation, and the mixed *Pinus monticola - Abies lowiana* is usually above 2135 m (7000 feet). Mixed stands with *Pinus contorta*, in moister locations, as well as *Pinus jeffreyi* and sometimes *Populus tremuloides* occasionally occur. Southern stands (around Babbitt Peak and in the Carson Range) can sometime have *Abies magnifica* in them, sometimes replacing *Abies lowiana*. These forests and woodlands are marked by the absence of *Pseudotsuga menziesii, Pinus lambertiana*, and *Calocedrus decurrens*, and the generally drier, continental climatic conditions. In addition, the overall floristic affinities are with the Great Basin rather than Pacific Northwest. Understories are typically open, with moderately low shrub cover and diversity, and include *Arctostaphylos patula, Arctostaphylos nevadensis, Chrysolepis sempervirens, Ceanothus* sp., and *Ribes viscosissimum*. Common herbaceous taxa include *Arnica cordifolia, Festuca* sp., *Poa nervosa, Carex inops, Pyrola picta*, and *Hieracium albiflorum*. In openings, *Wyethia mollis* can be abundant.

- White Fir: 211 (Eyre 1980) **><**

Distribution: This ecological system is found in the transition zone from the northern Sierra Nevada of California and Oregon, east into the Modoc Plateau and Intermountain region of northwestern Nevada. It is found in the Fremont National Forest east of Lake View in Oregon, and in the Modoc Plateau and Warner Mountains of California. It continues farther south in California to the Diamond Mountains south of Honey Lake (a northeast extension of the Sierras), on Babbitt Peak between Lake Tahoe and Sierra Valley, and also in the Carson Range in Nevada east of Lake Tahoe Scattered stands may occur on Hart Mountain and Steens Mountain in Oregon and possibly a few isolated places in the northern Great Basin and the Jarbridge Mountains of Nevada.
Nations: US
Concept Source: M.S. Reid
Description Author: M.S. Reid

CES204.101 CONCEPTUAL MODEL

Environment:
Key Processes and Interactions: The open nature of the stands suggests regeneration and establishment is slow and sporadic. Stand-replacing events are not frequent; most fire is probably partial stand disturbance. These stands are relatively high elevation, and there are generally widely spaced large and somewhat fire-resistant individuals. Also the discontinuous understory and only patchy regeneration suggests non-stand-replacing fire as the norm., rather patchy burns with isolated trees surviving regularly. Local windthrow, insects, disease (blister rust), and individual lightning strikes probably make up most of the disturbances.
Threats/Stressors:
Ecosystem Collapse Thresholds:

CES206.921 California Coastal Redwood Forest

CES206.921 CLASSIFICATION

Concept Summary: This system occurs from the Klamath Mountains south to Monterey Bay, California. The coastal redwood forest generally can be found in areas of within the fog belt. In the northern portion, it occurs on upland slopes and in riparian zones and on riverine terraces that are flooded approximately every 50-100 years. In the southern portion of the range, annual precipitation may be as little as 500 mm, and the system is limited to coves and ravines. It is commonly found on moderately well-drained marine sediments (non-metamorphosed siltstones, sandstones, etc.). This system forms the tallest forests in North America, with individuals reaching 100 m high (tallest being 106-110 m [350-360 feet]). Typically, mature stands of *Sequoia sempervirens* produce a deep shade, so understories can be limited, but coarse woody debris from past disturbance can be quite large. *Pseudotsuga menziesii* is the common associate among the large trees. *Tsuga heterophylla* is found in old-growth stands in northern sections, and *Notholithocarpus densiflorus* occurs as a subcanopy in almost all stands (possibly as a result of fire suppression). *Sequoia sempervirens* mixes with *Arbutus menziesii, Notholithocarpus densiflorus, Pseudotsuga menziesii* and *Umbellularia californica*. The moist, coastal *Chamaecyparis lawsoniana* stands from southwestern Oregon and northwestern California, often mixed with *Sequoia sempervirens, Pseudotsuga menziesii*, or *Tsuga heterophylla*, are included in this system, as ecologically they function in the same way and have a similar overall floristic composition. Shade-tolerant understory species include *Rubus parviflorus, Oxalis oregana, Aralia californica, Mahonia nervosa, Gaultheria shallon*, and many ferns, such as *Blechnum spicant, Polystichum* spp., and *Polypodium* spp. Historically, surface fires likely exposed mineral soil for redwood seed germination. Less frequent disturbance can result in increases in *Tsuga heterophylla* in northern occurrences, as it is sensitive to fire and is a decreaser with fire and flood. Fire suppression has tended to result in increasing abundance of *Notholithocarpus densiflorus, Umbellularia californica, Alnus rubra, Arbutus menziesii*, and *Acer macrophyllum*; all respond favorably to fire, flood, wind and slides, becoming more abundant in areas of frequent disturbance.

Related Concepts:
- Port Orford-Cedar: 231 (Eyre 1980) **><**
- Redwood: 232 (Eyre 1980) **=**

Distribution: This system occurs from the Klamath Mountains south to Monterey Bay, California.
Nations: US
Concept Source: P. Comer and T. Keeler-Wolf
Description Author: P. Comer, T. Keeler-Wolf, M.S. Reid and G. Kittel

CES206.921 CONCEPTUAL MODEL

Environment: Climate is wet, mild maritime. Forests along the immediate coast experience uniformly wet and mild climate, where precipitation averages 2000-3000 mm/year (500 mm for some of the driest redwood occurrences) with frequent fog and low clouds during warmer months; additional moisture from fog-drip can be significant. The coastal redwood system generally can be found in areas of lower rainfall than other coastal rainforests in this macrogroup, but still within the fog belt. In the northern portion, it occurs on upland slopes and in riparian zones and on riverine terraces that are flooded approximately every 50-100 years. In the southern portion of the range, annual precipitation may be as little as 500 mm, and the system is limited to coves and ravines. It is commonly found on moderately well-drained marine sediments (non-metamorphosed siltstones, sandstones, etc.). Redwood forests are limited to the north by ultramafic soils of the Klamath Mountains (Sawyer 2007).

Key Processes and Interactions: Historically, surface fires likely exposed mineral soil for redwood seed germination. Less frequent disturbance can result in increases in *Tsuga heterophylla* in northern occurrences, as it is sensitive to fire and is a decreaser with fire and flood. Landfire (2007a) model: Redwood forests typically burned in the summer and early fall in low- to moderate-intensity surface fires that consumed irregular patches of surface fuel and understory vegetation. The great height of the canopy and separation of surface and crown fuels resulted in a pattern where fire rarely resulted in canopy tree mortality. Fire intervals ranged from less than 10 years in interior and upland locations to 100 years or more along the coast in the fog belt. More recent research funded by Save the Redwoods League suggests that fire has been historically quite variable with much lower frequencies in the extreme north coastal portion of redwood range (as low as 1 every 500 years) and very high in the southern end where ravine redwood stands occur adjacent to California chaparral and grasslands (T. Keeler-Wolf pers. comm. 2013). Native Americans are thought to have contributed to the ignitions (perhaps as much as every 5-8 years) since lightning is relatively infrequent in the area, especially in the fog belt. Flooding events that undermine trees may be a significant disturbance, but it's not known for certain this is the case.

Threats/Stressors: Conversion of this type has commonly come from logging and residential and commercial development. Logging and fire suppression have tended to result in increasing abundance of *Lithocarpus densiflorus, Umbellularia californica, Alnus rubra,* *Arbutus menziesii*, and *Acer macrophyllum*; all respond favorably to fire, flood, wind and slides, becoming more abundant in areas of frequent disturbance. Recent studies are finding that many coastal redwood occurrences now have multi-tiered structures with tall-shrub layers and subcanopies of a variety of other trees, creating fuel ladders which can result is severe fires and increased mortality of *Sequoia sempervirens* when fires occur. In addition, Sillett and Van Pelt (2000) and Sillett and Bailey (2003) report that canopies of *Sequoia sempervirens* support significant biomass of epiphytic ferns and shrubs that are also contributing to an altered crown structure in these forests, which is impacting the fire regime.

In northwestern California, regional climate models project mean annual temperature increases of 1.7-1.9°C (3.06-3.42°F) by 2070 (PRBO Conservation Science 2011). Regional climate models also project a decrease in mean annual rainfall of 101 to 387 mm by 2070. Currently, there is greater uncertainty about the precipitation projections than for temperature in northwestern California, but with some evidence for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Recent species distribution modeling and comparison of historic climate anomalies to projected climate change show that northern redwood stands appear stable while southern stands may experience the greatest changes toward a warmer and drier future, while it remains unknown how the forest may change (Save the Redwood League 2013).

Increased fire frequency with warmer temperatures and lower precipitation may result in drier, more flammable fuels, which may exacerbate the fire intensity given changes to redwood forest structure, as noted above. Forest structure does differ immensely from north to south in redwood's range and much of this has to do with fire history coupled with the gradient of warm-dry to cool-wet from south to north. Less rainfall and higher temperatures may shift species composition, to more drought-tolerant species, such as *Lithocarpus densiflorus*, and may also which may favor non-native species. On the other hand, *Lithocarpus* is likely to wink out of existence due to sudden oak death syndrome and the most likely benefactor from this in terms of the future stand composition will be California bay, which seems to be increasing relative to *Lithocarpus* in the central and southern portions of redwood range (T. Keeler-Wolf pers. comm. 2013). In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain (PRBO Conservation Science 2011). Other research on redwood ecosystems suggests that they are quite stable and persistent as long as the combination of effects of cool coastal fog and some rain persist. Climate change models have not been particularly effective in predicting the future occurrence of redwood forests since the spatial resolution of the models does not match the fine-scale topographic position of redwood stands throughout much of their range (T. Keeler-Wolf pers. comm. 2013). Redwoods have great capacity to adapt to obtaining sufficient moisture from fog-drip or from precipitation (T. Keeler-Wolf pers. comm. 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from continual logging of redwood from forests and changes to the fire regime. Environmental Degradation: The following is based on threats noted in literature cited above, applied through standard criteria of landscape condition, size and physical/biologic condition, as described in NatureServe's Ecological Integrity Assessment (Faber-Langendoen et al. 2008b) and Heritage Program Ecological Occurrences Specifications [see WNHP (2011) and CNRA (2009) for example criteria]. Suggested thresholds are by the author. Any of these conditions or combination of conditions rates as high-severity: Landscape fragmentation of forests into tiny patches that cannot accommodate prescribed fire in a practical way nor reproduction after forest fires. Reduction of stand/forest size to non-sustainable units. Soil disturbance and soil erosion evident, severe and abundant. Any of these conditions or combination of conditions rates as moderate-severity: Stands are large enough to just support forest fires, but surrounding landscape condition has fragmented the watershed somewhat. Some soil damage and erosion evident.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: No large old trees, multi-tiered canopy structure, species composition more complex and not like reference old growth sites. Sexual reproduction of redwood trees is extremely limited to nonexistent. Any of these conditions or combination of conditions rates as moderate-severity: Limited old growth trees, some multi-tiered canopy structure, but much of the stand lacks this. Species composition somewhat complex over that of historic old growth stands. Sexual reproduction of redwood trees in limited but at least evident.

CES204.846 North Pacific Broadleaf Landslide Forest and Shrubland

CES204.846 CLASSIFICATION

Concept Summary: These forests and shrublands occur throughout the northern Pacific mountains and lowlands, becoming less prominent in the northern half of this region. They occur on steep slopes and bluffs that are subject to mass movements on a periodic basis. They are found in patches of differing age associated with different landslide events. The vegetation is deciduous broadleaf forests, woodlands, or shrublands, sometimes with varying components of conifers. *Alnus rubra* and *Acer macrophyllum* are the major tree species. *Rubus spectabilis, Rubus parviflorus, Ribes bracteosum*, and *Oplopanax horridus* are some of the major shrub species. Shrublands tend to be smaller in extent than woodlands or forests. Small patches of sparsely vegetated areas or herbaceous-dominated vegetation (especially *Petasites frigidus*) also often occur as part of this system. On earthflows, once stable, vegetation may succeed to dominance by conifers.

Related Concepts:

CES204.098 North Pacific Dry-Mesic Silver Fir-Western Hemlock-Douglas-fir Forest

CES204.098 CLASSIFICATION

Concept Summary: This forested system occurs only in the Pacific Northwest mountains, primarily west of the Cascade Crest. It generally occurs in an elevational band between *Pseudotsuga menziesii - Tsuga heterophylla* forests and *Tsuga mertensiana* forests. It dominates mid-montane dry to mesic maritime and some submaritime climatic zones from northwestern British Columbia to northwestern Oregon. In British Columbia and in the Olympic Mountains, this system occurs on the leeward side of the mountains only. In the Washington Cascades, it occurs on both windward and leeward sides of the mountains (in other words, it laps over the Cascade Crest to the "eastside"). Stand-replacement fires are regular with mean return intervals of about 200-500 years. Fire frequency tends to decrease with increasing elevation and continentality but still remains within this typical range. A somewhat variable winter snowpack that typically lasts for 2-6 months is characteristic. The climatic zone within which it occurs is sometimes referred to as the "rain-on-snow" zone because of the common occurrence of major winter rainfall on an established snowpack. *Tsuga heterophylla* and/or *Abies amabilis* dominate the canopy of late-seral stands, though *Pseudotsuga menziesii* is usually also common because of its long lifespan, and *Callitropsis nootkatensis* can be codominant, especially at higher elevations. *Abies procera* forests (usually mixed with silver fir) are included in this system and occur in the Cascades from central Washington to central Oregon and rarely in the Coast Range of Oregon. *Pseudotsuga menziesii* is a common species (unlike the mesic western hemlock-silver fir forest system) that regenerates after fires and therefore is frequent as a codominant, except at the highest elevations; the prevalence of this species is an important indicator in relation to the related climatically wetter ~North Pacific Mesic Western Hemlock-Silver Fir Forest (CES204.097)$$. *Abies lasiocarpa* sometimes occurs as a codominant on the east side of the Cascades and in submaritime British Columbia. Understory species that tend to be more common or unique in this type compared to the wetter ~North Pacific Mesic Western Hemlock-Silver Fir Forest (CES204.097)$$ include *Achlys triphylla, Mahonia nervosa, Xerophyllum tenax, Vaccinium membranaceum, Rhododendron macrophyllum*, and *Rhododendron albiflorum*. *Vaccinium ovalifolium*, while still common, only dominates on more moist sites within this type, unlike in the related type where it is nearly ubiquitous.

- Pacific Ponderosa Pine - Douglas-fir: 244 (Eyre 1980) **<**
- Western Hemlock: 224 (Eyre 1980) **><**

Distribution: This system only occurs in the Pacific Northwest mountains, on the leeward side of coastal mountains in both British Columbia and in the Olympic Mountains of Washington. It occurs throughout most of the Washington Cascades on both west and east sides (sporadically on the east) and in the western Cascades of northern to central Oregon. It occurs very sporadically in the Willapa Hills of southwestern Washington and in the northern Oregon Coast Range. This type may also occur on the east side of the Oregon Cascades north of 45°N latitude (Mount Hood National Forest - Hood River and Barlow ranger districts, and possibly the northern edge of Warm Springs Reservation in part of the McQuinn Strip).

CES204.842 North Pacific Hypermaritime Western Red-cedar-Western Hemlock Forest

CES204.842 CLASSIFICATION

Concept Summary: These forests occupy the outer coastal portions of British Columbia, southeastern Alaska, and northwestern Washington. Their center of distribution is the central coast of British Columbia, as *Thuja plicata* approaches its northernmost limit in the southern half of southeastern Alaska. These forests occur mainly on islands but also fringe the mainland. They are generally less than 25 km from saltwater; elevation ranges from 0 to 600 m, and below 245 m in Alaska (above 200 m, *Callitropsis nootkatensis (= Chamaecyparis nootkatensis)* replaces *Thuja plicata*). The climate is hypermaritime, with cool summers, very wet winters, abundant fog, and without a major snowpack. Fire is absent from this system in Alaska and rare throughout the rest of the range. These forests are influenced by gap disturbance processes and intense windstorms and not much by fire. The terrain is mostly gentle to rolling, of low topographic relief, and often rocky. Soils typically have a distinct humus layer overlying mineral horizons or bedrock; where the system is best developed in central British Columbia, the humus layers are very thick (mean 17-35 cm). Soils are often imperfectly drained, but this is not a wetland system. *Thuja plicata* and *Tsuga heterophylla* are the dominant tree species throughout, and *Callitropsis nootkatensis* joins them from northern Vancouver Island north. Canopy cover of trees is typically over 60%. *Pinus contorta* and *Tsuga mertensiana* can be present in some locations in the central and northern portion of the range. *Abies amabilis* occurs in British Columbia and northern Washington stands but is not typically found in southeastern Alaska. In Washington, nearly pure stands of *Tsuga heterophylla* are common and seem to be associated with microsites most exposed to intense windstorms. A shrub layer of *Gaultheria shallon, Vaccinium ovalifolium*, and *Menziesia ferruginea* is usually well-developed. The fern *Blechnum spicant* in great abundance is typical of hypermaritime conditions. *Oxalis oregana* (absent in Alaska) is important in the understory of moist sites in Washington. *Polystichum munitum* occurs at the northern end of its range in southeastern Alaska on well-drained sites. The abundance of *Thuja plicata* in relation to other conifers is one of the diagnostic characters of these forests; the other is the low abundance of *Pseudotsuga menziesii* (absent in Alaska) and *Picea sitchensis*. Where these forests are best developed, they occur in a mosaic with forested wetlands, bogs, and Sitka spruce forests (the latter in riparian areas and on steep, more productive soils).

Concept Source: G. Kittel and C. Chappell
Description Author: G. Kittel, C. Chappell and M.S. Reid

CES204.842 CONCEPTUAL MODEL

Environment: These forests occur mainly on islands but also fringe the mainland and coastal fjords. They are generally less than 25 km from saltwater; elevation ranges from 0 to 600 m, and below 245 m in Alaska (above 200 m, *Callitropsis nootkatensis* replaces *Thuja plicata*). Climate is characterized by moist mild air from the Pacific. Frequent winter storms produce abundant precipitation as they encounter rising mountain slopes. In summer, large high-pressure areas off the coast produce prolonged spells of fine weather (Taylor 1997). The climate is classified as hypermaritime, with cool summers, very wet winters, abundant fog, and without a major snowpack (Meidinger and Pojar 1991). Rainfall is relatively high for the region at 254-380 cm (100-150 inches) rain annually, rarely as snow (Landfire 2007a). The terrain is mostly gentle to rolling, of low topographic relief, and often rocky. This type generally occurs on relatively old, acidic, humic soils with a distinct humus layer overlying mineral horizons or bedrock; where the system is best developed in central British Columbia, the humus layers are very thick (mean 17-35 cm) (Banner et al. 1993, Green and Klinka 1994, Steen and Coupe 1997). Soils are often imperfectly drained, but this is not a wetland system. Where these forests are best developed, they occur in a mosaic with forested wetlands, bogs, and Sitka spruce forests (the latter in riparian areas and on steep, more productive soils). This system represents the upper end of the productivity gradient within the Cedar-Hemlock Ecological Zone and the lower end of the Western Hemlock Ecological Zone (DeMeo et al. 1992).
Key Processes and Interactions: Fire is absent from this system in Alaska and rare throughout the rest of the range, e.g., British Columbia's north coast (Banner et al. 1993, Landfire 2007a). These forests are primarily influenced by gap disturbance processes (gaps created by the death of individual trees, or small patches due to disease, insect damage and treefall following mortality). On the most exposed areas of the coastline, occasional hurricane force winds and severe storms result in major windthrow events. Less severe winds may cause breakage or early blowdown of diseased trees. The ground surface often has pit-and-mound microtopography that is formed by windthrow events. Storms are generally from the southwest and sweep across the low country of southwestern Washington, and strike either the front range of the Cascades or the southwest face of the Olympics. Wind damage tends to repeat at certain locations either due to direct exposure or due to the funneling of winds around topographic features. Wind damage tends to be more significant on the coast than further inland. Studies by USFS in southeastern Alaska show lots of broken boles as cause of tree mortality (Hennon 2008).
Threats/Stressors: Conversion of this type has commonly come from clearcutting, selective logging and urban development (WNHP 2011). Timber harvest, tree plantations and introduced species and diseases have impacted forest structure, composition, landscape patch diversity, and tree regeneration. For essentially all but *Tsuga heterophylla*, the understory shrub and herb layers are severely degraded on the Queen Charlotte Islands by the browsing of coast blacktail deer (*Odocoileus hemionus*) introduced in the early 1900s. Other stressors limited in scope are development, road building and pipelines, hydroelectric operations, and tree plantations. Development has fragmented the landscape changing connectivity of this small-patch system particularly in lowlands Washington, while limited recreational development has more of an impact in British Columbia. Timber harvest operations change canopy structural complexity and abundance of large woody debris of individual stands and has altered whole landscape patch pattern, age and structural complexity (Van Pelt 2007, as cited in WNHP 2011). Restocking and plantation forestry (more in Washington than British Columbia) have changed local tree gene pools, horizontal arrangement of trees and homogenized the diversity of tree sizes. Other effects include loss of early-seral shrub species, advanced stand development, increased stand density, and increased tree mortality. Older logged areas can support dense, stagnating second growth with root rot (Arno 2000, as cited in WNHP 2011). Ohlman and Waddel (2002) (as cited in WNHP 2011) speculated that snag abundance more likely reflects recent disturbance and forest succession, whereas downed wood amounts more strongly reflect long-term stand history and site productivity (WNHP 2011).

In the Pacific Northwest, regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation, averaged over all models, are small (+1 to +2%), but some models project wetter autumns and winters and drier summers. In British Columbia's central and north coast, projections into the 2050s are 2.1° to 2.3°C annual increase that is 7-12% relative to 1961-1990 annual temperatures (Werner 2011). Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models and as much as 55% decline in coastal mountain snowpack in British Columbia (Littell et al. 2009, Rodenhuis et al. 2009). More intense wind storms are projected for Haida Gwaii, British Columbia North Coast and Alaska Panhandle (Haughian et al. 2012). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing (Littell et al. 2009).

In the southern extent of the range, a drier overall climate may drive this ecosystem to a drier Douglas-fir-dominated type with the loss of western red-cedar, as this species is limited to humid climate, and in subhumid regions with relatively dry growing seasons, although it can occur much farther inland than other coastal conifer species, so coastal stands may be able to tolerate warmer and drier climates (Minore 1990). Stands may also experience the loss of western hemlock, as this species is limited to humid climate, and in subhumid regions with relatively dry growing seasons, in the southern part of its distribution it is currently confined to northerly aspects or moist stream bottoms (Packee 1990). However, regional climate model simulations generally predict increases in extreme high precipitation over the next half-century for the Puget Sound (Littell et al. 2009) and British Columbia (Spittlehouse 2008, Rodenhuis et al. 2009). The frequency of intense windstorms will increase from the more common light storms historically occurring along British Columbia's west coast. Increased wind speeds are anticipated for the coast and coastal mountains of British Columbia, varying by locale from slight 2% increase to up to 14% increase (Haughian et al. 2012). In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current observed trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain (from PRBO Conservation Science 2011). Affect on coastal fog is not addressed in the Washington Climate Change Impacts Assessment (Littell et al. 2009). Summer time fog and its associated fog-drip and cooling effect may increase with warmer inland air temperatures (PRBO Conservation Science 2011), but this will depend on oceanic circulations and he complex interaction of the El Niño-Southern Oscillation and the Pacific Decadal Oscillation makes prediction of land/ocean interaction difficult and increases the uncertainty of regional climate modeling outcomes (Karl et al. 2009).

In the southern part of the range, an increased fire frequency due to warmer temperatures resulting in drier fuels the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009, Haughian et al. 2012), and this may certainly occur in neighboring drier ecosystems on ridge crests, upper southern exposures and on shallow soils (Dorner and Wong 2003) which could affect this moister system as well on a landscape scale. An important factor in changes in the coastal forests will be the frequency and intensity of fire. Fires will likely increase, especially with warmer drier summers. Under such conditions Douglas-fir could expand rapidly (Hebda 1997). Preliminary studies of coastal sites on south Vancouver Island reveal much more fire activity in the early Holocene warm, dry interval than currently (Hebda 1997). In addition, current disturbance of the substrate and opening of the canopy from recent logging practices may have the same result as increased fire frequency (Hebda 1997).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from continuous logging, diseases, lack of reproduction, and shifts to drier forested ecosystems. Environmental Degradation (following criteria and thresholds are from WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Occurrence is severely reduced from its original natural extent (<50% remains); Absolute size <260 ha (640 acres); landscape connectivity relictual: embedded in <20% natural or semi-natural habitat; connectivity is essentially absent. Any of these conditions or combination of conditions rates as moderate-severity: Occurrence is substantially reduced from its original natural extent (50-80% remains); absolute size of stand 1300-260 ha (3200-640 acres); landscape connectivity fragmented: embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: Stands proportion of mature and old-growth is <20%; cover of native species in shrub and herbaceous layers

CES204.073 North Pacific Lowland Mixed Hardwood-Conifer Forest

CES204.073 CLASSIFICATION

Concept Summary: This lowland mixed hardwood - conifer forest system occurs throughout the Pacific Northwest. It occurs on valley terraces, margins, and slopes at low elevations in the mountains of the Pacific Northwest Coast and interior valleys west of the high Cascade Range. These forests are composed of large conifers, including *Pseudotsuga menziesii, Thuja plicata, Abies grandis, Tsuga heterophylla*, and/or *Picea sitchensis*, with deciduous hardwood trees present and usually codominant. Major dominant broadleaf species are *Acer macrophyllum, Quercus garryana, Alnus rubra, Frangula purshiana*, and *Cornus nuttallii*. Conifers tend to increase with succession in the absence of major disturbance although the hardwoods, particularly *Acer macrophyllum*, persist in the overstory. The understory is characterized by deciduous shrubs such as *Acer circinatum, Corylus cornuta, Oemleria cerasiformis, Rubus ursinus, Symphoricarpos albus*, and *Toxicodendron diversilobum*, but evergreen shrubs, including *Gaultheria shallon* and *Mahonia nervosa* and forbs, such as *Polystichum munitum* and *Oxalis oregana*, can be dominant.

Related Concepts:

Distribution: This system occurs throughout the Pacific Northwest elevationally below the Silver Fir Zone.

Nations: CA, US

Concept Source: J. Kagan

Description Author: J. Kagan

CES204.073 CONCEPTUAL MODEL

Environment: In some places, hardwoods are truly only found in early-seral conditions. This is more true the farther north you get, so in Washington, there are a few places where hardwoods persist, outside of the dry Douglas fir - madrone forests around the Willamette Valley, Puget Trough and the western Oregon Interior Valleys. In the Coast Ranges and Cascades, there are hardwoods (mostly alder and bigleaf maple) found in most of the valley toeslopes. They also occur in areas with exposed talus, exposed rocks, and in dry places, and often with Oregon white oak and Oregon ash. This mix of deciduous hardwoods and conifers is a climax forest in many areas, while in others it is successional, with the conifers completely overtaking the hardwoods after 200 years or so without disturbance.

CES204.001 North Pacific Maritime Dry-Mesic Douglas-fir-Western Hemlock Forest

CES204.001 CLASSIFICATION

Concept Summary: This ecological system comprises much of the major lowland forests of western Washington, northwestern Oregon, eastern Vancouver Island, and the southern Coast Ranges in British Columbia. In southwestern Oregon, it becomes local and more small-patch in nature. It occurs throughout low-elevation western Washington, except on extremely dry or moist to very wet sites. In Oregon, it occurs on the western slopes of the Cascades, around the margins of the Willamette Valley, and in the Coast Ranges. These forests occur on the drier to intermediate moisture habitats and microhabitats within the Western Hemlock Zone of the Pacific Northwest. Climate is relatively mild and moist to wet. Mean annual precipitation is mostly 90-254 cm (35-100 inches) (but as low as 20 inches in the extreme rainshadow) falling predominantly as winter rain. Snowfall ranges from rare to regular, and summers are relatively dry. Elevation ranges from sea level to 610 m (2000 feet) in northern Washington to 1067 m (3500 feet) in Oregon. Topography ranges from relatively flat glacial tillplains to steep mountainous terrain. This is generally the most extensive forest in the lowlands on the west side of the Cascades and forms the matrix within which other systems occur as patches. Throughout its range it occurs in a mosaic with ~North Pacific Maritime Mesic-Wet Douglas-fir-Western Hemlock Forest

(CES204.002)$$; in dry areas it occurs adjacent to or in a mosaic with ~North Pacific Dry Douglas-fir-(Madrone) Forest and Woodland (CES204.845)$$, and at higher elevations it intermingles with either ~North Pacific Dry-Mesic Silver Fir-Western Hemlock-Douglas-fir Forest (CES204.098)$$ or ~North Pacific Mesic Western Hemlock-Silver Fir Forest (CES204.097)$$.

Overstory canopy is dominated by *Pseudotsuga menziesii*, with *Tsuga heterophylla* generally present in the subcanopy or as a canopy dominant in old-growth stands. *Abies grandis, Thuja plicata*, and *Acer macrophyllum* codominants are also represented. In the driest climatic areas, *Tsuga heterophylla* may be absent, and *Thuja plicata* takes its place as a late-seral or subcanopy tree species. *Gaultheria shallon, Mahonia nervosa, Rhododendron macrophyllum, Linnaea borealis, Achlys triphylla*, and *Vaccinium ovatum* typify the poorly to well-developed shrub layer. *Acer circinatum* is a common codominant with one or more of these other species. The fern *Polystichum munitum* can be codominant with one or more of the evergreen shrubs on sites with intermediate moisture availability (mesic). If *Polystichum munitum* is thoroughly dominant or greater than about 40-50% cover, then the stand is probably in the more moist ~North Pacific Maritime Mesic-Wet Douglas-fir-Western Hemlock Forest (CES204.002)$$. Young stands may lack *Tsuga heterophylla* or *Thuja plicata*, especially in the Puget Lowland. *Tsuga heterophylla* is generally the dominant regenerating tree species. Other common associates include *Acer macrophyllum, Abies grandis*, and *Pinus monticola*. In southwestern Oregon, *Pinus lambertiana, Calocedrus decurrens*, and occasionally *Pinus ponderosa* may occur in these forests. Soils are generally well-drained and are mesic to dry for much of the year. This is in contrast to ~North Pacific Maritime Mesic-Wet Douglas-fir-Western Hemlock Forest (CES204.002)$$, which occurs on sites where soils remain moist to subirrigated for much of the year and fires were less frequent. Fire is (or was) the major natural disturbance. In the past (pre-1880), fires were less commonly high-severity, typically mixed-severity or moderate-severity, with natural return intervals of 100 years or less in the driest areas, to a few hundred years in areas with more moderate to wet climates. In the drier climatic areas (central Oregon Cascades, Puget Lowlands, Georgia Basin), this system was typified by a (mixed) moderate-severity fire regime involving occasional stand-replacing fires and more frequent moderate-severity fires. This fire regime would create a complex mosaic of stand structures across the landscape.

Related Concepts:

- Western Hemlock: 224 (Eyre 1980) **>**

Distribution: This system comprises the major lowland and low montane forests of western Washington, northwestern Oregon, and southwestern British Columbia. In British Columbia and Washington, it is uncommon to absent on the windward side of the coastal mountains where fire is rare. It also occurs locally in far southwestern Oregon (Klamath ecoregion) as small to large patches.

CES204.001 CONCEPTUAL MODEL

Environment: This system occurs throughout low-elevation western Washington, except on extremely dry or moist to very wet sites. These forests occur on the drier to intermediate moisture habitats and microhabitats within the Western Hemlock Zone of the Pacific Northwest. Climate is relatively mild and moist to wet. Mean annual precipitation is mostly 90-254 cm (35-100 inches) (but as low as 50 cm [20 inches] in the extreme rainshadow) falling predominantly as winter rain. Snowfall ranges from rare to regular, and summers are relatively dry. Elevation ranges from sea level to 610 m (2000 feet) in northern Washington to 1067 m (3500 feet) in Oregon. Topography ranges from relatively flat glacial tillplains to steep mountainous terrain. This is generally the most extensive forest in the lowlands on the west side of the Cascades and forms the matrix within which other systems occur as patches.
Key Processes and Interactions: Fire is (or was) the major natural disturbance process. In the past (pre-1880), fires were high-severity or, less commonly, moderate-severity, with natural return intervals of 100 years or less in the driest areas, to a few hundred years in areas with more moderate to wet climates. In the drier climatic areas (central Oregon Cascades, Puget Lowlands, Georgia Basin), this system was typified by a (mixed) moderate-severity fire regime involving occasional stand-replacement fires and more frequent moderate-severity fires. This fire regime would create a complex mosaic of stand structures across the landscape. Landfire VDDT models: #RDFHEdry Douglas-fir Hemlock dry mesic describes general successional stage relationship with bias to OR (Landfire 2007a).
Threats/Stressors: Conversion of this type has commonly come from logging and urban development. Development, timber harvest, road building, fire suppression, tree plantations and introduced diseases have all impacted natural disturbance regimes, forest structure, composition, landscape patch diversity, and tree regeneration. Development has fragmented the landscape changing fire regime and connectivity of this small patch system particularly in lowlands. Timber harvest operations change canopy structural complexity and abundance of large woody debris of individual stands and has altered whole landscape patch pattern, age and structural complexity (Van Pelt 2007, as cited in WNHP 2011). Plantation forestry has changed local tree gene pools, horizontal arrangement of trees and homogenized the diversity of tree sizes. Other effects include loss of early-seral shrub species, advanced stand development, increased stand density, and increased tree mortality. Older logged areas can support dense, stagnating second

growth with root rot (Arno 2000, as cited in WNHP 2011). Ohlman and Waddel (2002) (as cited in WNHP 2011) speculated that snag abundance more likely reflect recent disturbance and forest succession, whereas down wood amounts more are strongly reflect long-term stand history and site productivity (WNHP 2011).

In the Pacific Northwest, regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation, averaged over all models, are small (+1 to +2%), but some models project wetter autumns and winters and drier summers. Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models (Littell et al. 2009). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing (Littell et al. 2009).

Drier overall climate may drive this ecosystem to a drier Douglas-fir-dominated type with the loss of western hemlock, as this species is limited to humid climate, and in subhumid regions with relatively dry growing seasons, and in the southern part of its range it is confined to northerly aspects or moist stream bottoms (Packee 1990). However, regional climate model simulations generally predict increases in extreme high precipitation over the next half-century, particularly around Puget Sound (Spittlehouse 2008, Littell et al. 2009, Werner 2011). In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain. (From PRBO Conservation Science 2011). However, affect on coastal fog is not addressed in the Washington Climate Change Impacts Assessment (Littell et al. 2009) nor is it currently a factor in Georgia Basin (C. Cadrin pers. comm. 2013). Summer-time fog and its associated fog-drip and cooling effect may increase with warmer inland air temperatures (PRBO Conservation Science 2011), but this will depend on oceanic circulations and he complex interaction of the El Niño-Southern Oscillation and the Pacific Decadal Oscillation makes prediction of land/ocean interaction difficult and increases the uncertainty of regional climate modeling outcomes (Karl et al. 2009). Increased fire frequency due to warmer temperatures resulting in drier fuels the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009). In the Georgia Depression, increases of up to 10% in fire severity are reported (Haughian et al. 2012).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from continuous logging, diseases, lack of reproduction, and shifts to drier forested ecosystems. Environmental Degradation (following criteria and thresholds are from WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Occurrence is severely reduced from its original natural extent (<50% remains); absolute size <260 ha (640 acres); landscape connectivity relictual: embedded in <20% natural or semi-natural habitat; connectivity is essentially absent. Any of these conditions or combination of conditions rates as moderate-severity: Occurrence is substantially reduced from its original natural extent (50-80% remains); absolute size of stand 1300-260 ha (3200-640 acres); landscape connectivity fragmented: embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: Stands proportion of mature and old-growth is <20%, cover of native species in shrub and herbaceous layers

CES204.002 North Pacific Maritime Mesic-Wet Douglas-fir-Western Hemlock Forest

CES204.002 CLASSIFICATION

Concept Summary: This ecological system is a significant component of the lowland and low montane forests of western Washington, northwestern Oregon, and southwestern British Columbia. It occurs throughout low-elevation western Washington, except on extremely dry sites and in the hypermaritime zone near the outer coast where it is rare. In Oregon, it occurs on the western slopes of the Cascades, around the margins of the Willamette Valley, and on the west side of the Coast Ranges, and is reduced to locally small patches in southwestern Oregon. In British Columbia, it occurs on the eastern (leeward) side of Vancouver Island, commonly and rarely on the windward side, and in the southern Coast Ranges. These forests occur on moist habitats and microhabitats, mainly lower slopes or valley landforms, within the Western Hemlock Zone of the Pacific Northwest. They differ from ~North Pacific Maritime Dry-Mesic Douglas-fir-Western Hemlock Forest (CES204.001)$$ primarily in having more hydrophilic undergrowth species, moist to subirrigated soils, high abundance of shade- and moisture-tolerant canopy trees, as well as higher stand productivity, due to higher soil moisture and lower fire frequency. Climate is relatively mild and moist to wet. Mean annual precipitation is mostly 90-254 cm (35-100 inches) (but as low as 20 inches in the extreme rainshadow) predominantly as winter rain. Snowfall ranges from rare to regular (but consistent winter snowpacks are absent or minimal), and summers are relatively dry. Elevation ranges from sea level to 610 m (2000 feet) in northern Washington to 1067 m (3500 feet) in Oregon. Topography ranges from relatively flat glacial tillplains to steep mountainous terrain. This is an extensive forest in the lowlands on the west side of the Cascades. In some wetter climatic areas, it forms the matrix within which other systems occur as patches, especially riparian wetlands. In many rather drier climatic areas, it occurs as small to large patches within a matrix of ~North Pacific Maritime Dry-Mesic Douglas-fir-Western Hemlock Forest (CES204.001)$$; in dry areas, it can occur adjacent to or in a mosaic with ~North Pacific Dry Douglas-fir-(Madrone) Forest and Woodland (CES204.845)$$, and at higher elevations it intermingles with either ~North Pacific Dry-Mesic Silver Fir-Western Hemlock-Douglas-fir Forest (CES204.098)$$ or ~North Pacific Mesic Western Hemlock-Silver Fir Forest (CES204.097)$$.

Overstory canopy is dominated by *Pseudotsuga menziesii, Tsuga heterophylla*, and/or *Thuja plicata*, as well as *Chamaecyparis lawsoniana* in western Oregon, away from the coast. *Pseudotsuga menziesii* is usually at least present to more typically codominant or dominant. *Acer macrophyllum* and *Alnus rubra* (the latter primarily where there has been historic logging disturbance) are commonly found as canopy or subcanopy codominants, especially at lower elevations. In a natural landscape, small patches can be dominated in the canopy by these broadleaf trees for several decades after a severe fire. *Polystichum munitum, Oxalis oregana, Rubus spectabilis*, and *Oplopanax horridus* typify the poorly to well-developed herb and shrub layers. *Gaultheria shallon, Mahonia nervosa, Rhododendron macrophyllum*, and *Vaccinium ovatum* are often present but are generally not as abundant as the aforementioned indicators; except where *Chamaecyparis lawsoniana* is a canopy codominant, they may be the dominant understory. *Acer circinatum* is a very common codominant as a tall shrub. Forested stands with abundant *Lysichiton americanus*, an indicator of seasonally flooded or saturated soils, belong in ~North Pacific Hardwood-Conifer Swamp (CES204.090)$$. Stands included are best represented on lower mountain slopes of the coastal ranges with high precipitation, long frost-free periods, and low fire frequencies. Young stands may lack *Tsuga heterophylla* or *Thuja plicata*, especially in the Puget Lowland. *Tsuga heterophylla* is generally the dominant regenerating tree species. Other common associates include *Abies grandis*, which can be a codominant especially in the Willamette Valley - Puget Trough - Georgia Basin ecoregion. Soils are moist to somewhat wet but not saturated for much of the year and are well-drained to somewhat poorly drained. Typical soils for *Polystichum* sites would be deep, fine- to moderately coarse-textured, and for *Oplopanax* sites, soils typically have an impermeable layer at a moderate depth. Both types of soils are well-watered from upslope sources, seeps, or hyperheic sources. This is in contrast to ~North Pacific Maritime Dry-Mesic Douglas-fir-Western Hemlock Forest (CES204.001)$$, which occurs on well-drained soils, south-facing slopes, and dry ridges and slopes where soils remain mesic to dry for much of the year. Fire is (or was) the major natural disturbance in all but the wettest climatic areas. In the past (pre-1880), fires were less commonly high-severity, typically mixed-severity or moderate-severity, with natural return intervals of a few hundred to several hundred years. This system was formerly supported by occasional, stand-replacing fires. More frequent moderate-severity fires would generally not burn these moister microsites.

CES204.097 North Pacific Mesic Western Hemlock-Silver Fir Forest

CES204.097 CLASSIFICATION

Concept Summary: This forested system occurs only in the Pacific Northwest mountains entirely west of the Cascade Crest from coastal British Columbia to Washington, and probably occurs in southeastern Alaska. It generally occurs in an elevational band between *Pseudotsuga menziesii - Tsuga heterophylla* or hypermaritime zone forests and *Tsuga mertensiana* forests. It dominates mid-montane maritime climatic zones on the windward side of Vancouver Island, the Olympic Peninsula, and the wettest portions of the North Cascades in Washington (north of Snoqualmie River). A somewhat variable winter snowpack that typically lasts for 2-6 months is characteristic. The climatic zone within which it occurs is sometimes referred to as the "rain-on-snow" zone because of the common occurrence of major winter rainfall on an established snowpack. *Tsuga heterophylla* and/or *Abies amabilis* dominate the canopy of late-seral stands, and *Callitropsis nootkatensis* can be codominant, especially at higher elevations. *Thuja plicata* is also common and sometimes codominates in British Columbia. In Alaska, *Abies amabilis* occurs in nearly pure stands and in mixture with *Picea sitchensis* and *Tsuga heterophylla*. *Pseudotsuga menziesii* is relatively rare to absent in this system, as opposed to the similar but drier ~North Pacific Dry-Mesic Silver Fir-Western Hemlock-Douglas-fir Forest (CES204.098)$$. The major understory dominant species is *Vaccinium ovalifolium*. Understory species that help distinguish this system from the drier silver fir system (they are much more common here) include *Oxalis oregana, Blechnum spicant*, and *Rubus pedatus*. Windthrow is a common small-scale disturbance in this system, and gap creation and succession are important processes.

Distribution: This system occurs only in the Pacific Northwest mountains (Coastal and westside Cascades). It occurs on the windward side of coastal mountains in both British Columbia and in the Olympic Mountains and north Cascade Range of Washington. It may also extend north to about 56°N latitude in southeastern Alaska. *Abies amabilis* has a limited distribution in Alaska, apparently confined to the extreme southern mainland and a few islands south of 56°N latitude.

Nations: CA, US

Concept Source: G. Kittel

Description Author: G. Kittel, C. Chappell and M.S. Reid

CES204.097 CONCEPTUAL MODEL

Environment:

Key Processes and Interactions: Stand-replacing fires are relatively infrequent to absent, with return intervals of several hundred or more years. More mixed-severity fires occur in the southern parts of this system, so that forest structure, patch size and proportions will be different from northern stands. Further north, stand-replacing fires are also infrequent but are a more common fire event.

Threats/Stressors:

Ecosystem Collapse Thresholds:

CES204.841 North Pacific Seasonal Sitka Spruce Forest

CES204.841 CLASSIFICATION

Concept Summary: This ecological system is restricted to the hypermaritime climatic areas near the Pacific Coast from Point Arena, California, north to northern Vancouver Island, British Columbia. These forests are typically dominated or codominated by *Picea sitchensis* and often have a mixture of other conifers present, such as *Tsuga heterophylla, Thuja plicata, Pseudotsuga menziesii*, or *Callitropsis nootkatensis*. *Tsuga heterophylla* is very often codominant. In the southern extent (in Oregon, but not in California), *Abies grandis, Acer circinatum, Alnus rubra, Acer macrophyllum, Chamaecyparis lawsoniana*, and *Frangula purshiana* can be associates, while *Callitropsis nootkatensis* is completely absent. Wet coastal environments that support stands of *Chamaecyparis lawsoniana* in the absence of *Picea sitchensis* are also part of this system. The understory is rich with shade-tolerant shrubs and ferns, including *Gaultheria shallon, Vaccinium ovatum, Polystichum munitum, Dryopteris* spp., and *Blechnum spicant*, as well as a high diversity of mosses and lichens. This ecological system is restricted to the hypermaritime climatic areas near the Pacific Coast from Point Arena, California, north to northern Vancouver Island and Smith Sound on the mainland coast of British Columbia. They are generally limited to areas within 25 km or so of saltwater and are most abundant along the coast of Vancouver Island, southern portions of coastal mainland British Columbia, and the Olympic Peninsula of Washington. This ecosystem is defined as the "Seasonal Rain Forest" by Wolf et al. (1995), as the climate has abundant rainfall in the winter months and very little in the summer months. At the northern boundary this Sitka spruce forest ecosystem merges into ~Alaskan Pacific Maritime Sitka Spruce Forest (CES204.151)$$ which has more continuous year-round rainfall and lacks Douglas-fir. ~North Pacific Seasonal Sitka Spruce Forest (CES204.841)$$ occurs on outermost coastal fringe where salt spray is prominent, riparian terraces and valley bottoms near the coast where there is major fog accumulation, and on steep, well-drained productive slopes not directly adjacent to the outer coast but within the hypermaritime zone. Annual precipitation ranges from 65 to 550 cm, with the majority falling as rain. Winter rains can be heavy. When summer drought occurs it is typically short in duration and ameliorated by frequent, dense coastal fog and cloud cover. In fact the fog belt becomes more and more important in the southern half of this ecosystem's distribution. In Washington and Oregon, it is found mostly below 300 m elevation. It also occurs as a very narrow strip or localized patches along the southern Oregon and northern California coasts. The disturbance regime is mostly small-scale windthrow or other gap mortality processes (though there are occasional widespread intense windstorms) and very few fires, the latter mainly in Oregon.

CES204.841 CONCEPTUAL MODEL

Environment: From Vancouver Island south, the forest is not confined to fjords, but a marked orographic effect from the Coast and Cascade ranges limits its interior extent. At its southern extent, the zone narrows again, confined to the fog belt not by mountains but by moisture. It is restricted to the hypermaritime climatic areas (Meidinger and Pojar 1991) near the Pacific Coast, along a fog belt from Point Arena, California, north to northern Vancouver Island, British Columbia. These forests are generally restricted to areas within 25 km of saltwater and are most abundant along the coast of Vancouver Island, southern portions of coastal British Columbia, and the Olympic Peninsula of Washington. Sites include the outermost coastal fringe where salt spray is prominent, riparian terraces and valley bottoms near the coast where there is major fog accumulation, and in the northern half of its range starting in central British Columbia, steep, well-drained productive slopes not directly adjacent to the outer coast but within the hypermaritime zone (Banner et al. 1993, Green and Klinka 1994, Steen and Coupe 1997). Annual precipitation ranges from 65 to 550 cm, with the majority falling as rain. Winter rains can be heavy. The climate has more seasonal rainfall than coastal areas to the north, with a pronounced drought in summer months. Summer drought does occur, but it is typically short in duration and ameliorated by frequent, dense coastal fog and cloud cover. This forest type also dominates lower elevations (to 350 m) on the leeward side of the Queen Charlotte Islands in British Columbia. In Washington and Oregon, it is found mostly below 300 m elevation. It also occurs as a very narrow strip or localized patches along the southern Washington, Oregon and northern California coasts.

Key Processes and Interactions: The disturbance regime is mostly small-scale windthrow or other gap mortality processes (though there are occasional widespread intense windstorms) and very few fires, the latter mainly in Oregon. Sitka spruce acts as an early colonizer of disturbed sites, such as land slumps, fluvial deposits, recently deglaciated areas. Seeds germinate best on bare mineral soil, a mixture of mineral soil and organic soil, and nurse-logs (Sawyer et al. 2009). Landfire (2007a) model: The disturbance regime is mostly small-scale windthrow or other gap mortality processes (though there are occasional widespread intense windstorms) and very few fires, the latter mainly in Oregon. Where fire does occur, it is usually stand-replacing, with a fire return interval of 300-1000 years or longer. In most of the range of the type, windthrow is a more significant catastrophic disturbance than wildfire. Windthrow "rotation" is estimated to be between 100-200 years, (but can be up to 1000 years due to patchiness). The effects of windthrow are strongly correlated with topography and adjacent land use (e.g., clearcuts). Landfire VDDT models: R#SSHE Sitka spruce - hemlock.

Threats/Stressors: Conversion of this type has commonly come from logging and residential and commercial development. Many, if not all, threats to Sitka spruce forest are the same as threats to western hemlock - Douglas-fir forests, well described by the Washington Natural Heritage Program. Those stressors and threats are repeated here: Logging, development, timber harvest, road building, tree plantations and introduced diseases have all impacted natural disturbance regimes, forest structure, composition, landscape patch diversity, and tree regeneration. Development has fragmented the landscape changing fire regimes and connectivity serious affecting this small patch system particularly in lowlands. Timber harvest operations change canopy structural complexity and abundance of large woody debris of individual stands and has altered whole landscape patch pattern, age and structural complexity (Van Pelt 2007, as cited in WNHP 2011). Plantation forestry has changed local tree gene pools, horizontal arrangement of trees and homogenized the diversity of tree sizes. Other effects include loss of early-seral shrub species, advanced stand development, increased stand density, and increased tree mortality. Older logged areas can support dense, stagnating second growth with root rot (Arno 2000, as cited in WNHP 2011). Ohlman and Waddel (2002) (as cited in WNHP 2011) speculated that snag abundance more likely reflect recent disturbance and forest succession, whereas down wood amounts more are strongly reflect long-term stand history and site productivity (WNHP 2011).

Across the range of this ecosystem, there is consistent projected warming and decrease in regional precipitation patterns. In the Pacific Northwest, regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation are small (+1-2%), but some models project wetter autumns and winters and drier summers. Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models (Littell et al. 2009). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. In BC's central and north coast projections into the 2050s are 2.1 to 2.3°C annual increase that is 7-12% relative to 1961-1990 annual temperatures (Werner 2011).

In northwestern California, regional climate models project mean annual temperature increases of 1.7-1.9°C (3.06-3.42°F) by 2070 (PRBO Conservation Science 2011). And regional climate models project a decrease in mean annual rainfall of 101 to 387 mm (4-15 inches) by 2070. Currently, there is greater uncertainty about the precipitation projections than for temperature in northwestern California, but with some evidence for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). With increased fire frequency due to warmer temperatures resulting in drier fuels, the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009). Less rainfall and higher temperatures may shift species composition, to more drought-tolerant species, and may also which may favor non-native species. In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain. Summer-time fog and its associated fog-drip and cooling effect may increase with warmer inland air temperatures (PRBO Conservation Science 2011), but this will depend on oceanic circulations and he complex interaction of the El Niño-Southern Oscillation and the Pacific Decadal Oscillation makes prediction of land/ocean interaction difficult and increases the uncertainty of regional climate modeling outcomes (Karl et al. 2009). Drier overall climate may drive this ecosystem to a drier Douglas-fir-dominated type with the loss of Sitka spruce, as this species is limited to maritime climate with abundant moisture throughout the year (Harris 1990), and in the southern extent of its range, summer fog and moist maritime air are important to maintain growth (Harris 1990). However, regional climate model simulations generally predict increases in extreme high precipitation over the next half-century, particularly around Puget Sound (Spittlehouse 2008, Littell et al. 2009).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from continuous logging, diseases, lack of reproduction, and shifts to drier forested ecosystems. Environmental Degradation (following criteria and thresholds are from WNHP 2011, as the criteria is very similar to the western hemlock - Douglas-fir forest ecosystem): Any of these conditions or combination of conditions rates as high-severity: Occurrence is severely reduced from its original natural extent (<50% remains); absolute size <260 ha (640 acres); landscape connectivity relictual: embedded in <20% natural or semi-natural habitat; connectivity is essentially absent. Any of these conditions or combination of conditions rates as moderate-severity: Occurrence is substantially reduced from its original natural extent (50-80% remains); absolute size of stand 1300-260 ha (3200-640 acres); landscape connectivity fragmented:

embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: Stands proportion of mature and old-growth is <20%, cover of native species in shrub and herbaceous layers

CES204.883 North Pacific Wooded Volcanic Flowage

CES204.883 CLASSIFICATION

Concept Summary: This ecological system is found from foothill to subalpine elevations and includes woodland to sparsely vegetated landscapes (generally >10% plant cover) on recent lava flows, excessively well-drained lahars, debris avalanches and pyroclastic flows. The characteristic feature of this system is the substrate limiting characteristic that creates an environment for a more open vegetation than the surrounding closed matrix forest. Examples are recent lava flows (3500-8200 years ago) on the north side of Mount Adams (andecite) and the big lava beds (basalt) south of Indian Heaven west of Mount Adams, Washington, and lahars (200-2000 years old) at Old Maid Flat west of Mount Hood, Oregon. These areas support open to sparse tree cover; characteristic species include *Pseudotsuga menziesii, Pinus contorta, Pinus monticola*, and *Abies lasiocarpa*. Tree cover can range from scattered (5%) up to 70% or occasionally even more. There may be scattered to dense shrubs present, such as *Acer circinatum, Vaccinium membranaceum, Arctostaphylos uva-ursi* (very characteristic), *Mahonia nervosa, Amelanchier alnifolia*, and *Xerophyllum tenax*. Soil development is limited, and mosses and lichens often cover the soil or rock surface.

Related Concepts:

- Lodgepole Pine: 218 (Eyre 1980) **><**

Distribution: This uncommon system is found in the east and west Cascades of Washington and Oregon, and may occur in small patches in northern California in the vicinity of Mount Lassen or Mount Shasta.

M025. Vancouverian Subalpine Forest

CES206.913 Mediterranean California Red Fir Forest

CES206.913 CLASSIFICATION

Concept Summary: This ecological system includes high-elevation (1600-2700 m [4850-9000 feet]) forests and woodlands dominated by *Abies magnifica var. magnifica, Abies magnifica var. shastensis*, and/or *Abies procera*. This system is typically found on deep, well-drained soils throughout this elevation zone from the central Sierra Nevada north and west into southern Oregon. Heavy snowpack is a major source of soil moisture throughout the growing season. The limiting factors can be either cold-air drainages or ponding, or coarser soils (pumice versus ash, for example). Other conifers that can occur in varying mixtures with *Abies magnifica* include *Pinus contorta var. murrayana, Pinus monticola, Tsuga mertensiana, Pinus jeffreyi*, and *Abies lowiana*. At warmer and lower sites of the North Coast Ranges and Sierra Nevada, *Abies lowiana* can codominate with *Abies magnifica*. *Pinus contorta* in Oregon indicates lower productivity where it intergrades with *Abies magnifica var. shastensis*. This system ranges from dry to moist, and some sites have mesic indicator species, such as *Ligusticum grayi* or *Thalictrum fendleri*. Common understory species include *Quercus vacciniifolia, Ribes viscosissimum, Chrysolepis sempervirens, Ceanothus cordulatus* (in seral stands), *Vaccinium membranaceum, Symphoricarpos mollis*, and *Symphoricarpos rotundifolius*. Characteristic forbs include *Eucephalus breweri, Pedicularis semibarbata*, and *Hieracium albiflorum*. This system commonly occurs above mixed conifer forests with *Abies lowiana* and overlaps in elevation with forests and woodlands of *Pinus contorta var. murrayana*. On volcanic sites of lower productivity, stands may be more open woodland in structure and with poor-site understory species such as *Wyethia mollis*. Driving ecological processes include occasional blowdown, insect outbreaks and stand-replacing fire.

Related Concepts:
- Red Fir: 207 (Eyre 1980) =

Distribution: This system is typically found on deep, well-drained soils throughout the high-elevation zone (1600-2700 m [4850-8200 feet]) from the central Sierra Nevada north and west into southern Oregon.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.913 CONCEPTUAL MODEL

Environment: Red fir forests occur at high elevations (1600-2700 m [4850-9000 feet]), and are typically found on deep, well-drained soils throughout this elevational zone from the central Sierra Nevada north and west into southern Oregon. Heavy snowpack is a major source of soil moisture throughout the growing season. Climate is relative mild for high-elevation forest with summer temperatures rarely exceeding 29°C (85°F) and winter temperatures rarely fall below -29°C (-20°F). Summers are dry (4-5 months). Between May (or April) and October summer thunderstorm precipitation is negligible, almost all precipitation occurs from October to March, 80% as snow. Snowpack can exceed 4 m (13 feet). Total ppt per year ranges 750-1500 mm (30-60 inches).

Key Processes and Interactions: Stand-replacing fire is important but so are moderately frequent (about once every 40 years) low- to moderate-severity fires. The whole system is characterized by a "moderate-severity fire regime" (Agee 1993), i.e., high variability in severity and moderate frequency of fires. See also Chappell and Agee (1996), Pitcher (1987), and Taylor and Halpern (1991) for documentation of fire regime in these forests. Windthrow causes tree-sized gaps that release already established individuals in the understory.

TNC model information: At higher elevations and in the southern Sierra Nevada, fuels are relatively more discontinuous than northern locations because the terrain is broken up by natural breaks such as rock outcrops, lava reefs, wet meadows, etc. Fuels may be more continuous at the northern end of the range, where this vegetation type is found at lower elevations. Primarily Fire Regime Group III, but because of slow fuel accumulation rates, it is possible to have 35- to 150-year frequency surface fire in some classes (lower frequency for these settings as a whole). The discontinuous nature of the fuels limits the extent of fires, and while fires may burn less often, they may burn at high severities. Larger and more frequent moderate-intensity fires occur on average every 60-70 years. High-intensity crown fires are rare, occurring every few hundred years; overall mean fire-return interval is approximately 35-50 years (Pitcher 1987, Skinner 2000, Taylor 2000, Bekker and Taylor 2001). Replacement fire likely varies with slope position (upper slope > midslope > lower slope), and landscapes with greater topographic variation are likely to experience more stand-replacement fires. A considerable range of values has been reported in the literature for mixed and surface fires (Taylor and Halpern 1991, Taylor 1993, Bekker and Taylor 2001, Taylor and Solem 2001).

CES206.910 Mediterranean California Subalpine Woodland

CES206.910 CLASSIFICATION

Concept Summary: This ecological system occurs on ridges and rocky slopes around timberline at 2900 m (9500 feet) elevation in the southern Sierra Nevada and Transverse and Peninsular ranges, up to 3500 m (11,500 feet) in the Sierra Nevada, and 2450 m (8000 feet) in the southern Cascades. Tree species often occur as krummholz growth forms with a wind-pruned, prostrate, and/or shrublike appearance, but in more protected sites they form true woodland physiognomy. Stands are dominated by *Pinus albicaulis* and/or *Pinus contorta var. murrayana*; other important conifers and locally dominant species include *Pinus balfouriana* (only in the Klamath Mountains and southern Sierra Nevada where it may replace *Pinus albicaulis*), *Pinus flexilis* (but only in small patches on the eastern flank of the Sierra Nevada escarpment when it does occur), *Pinus monticola* (not in Transverse or Peninsular ranges), and *Juniperus grandis* (mostly in the central and southern Sierra Nevada but not in the Klamath Mountains). Important shrubs include *Arctostaphylos nevadensis, Chrysolepis sempervirens*, and *Holodiscus discolor*. Grasses and forbs include *Carex rossii, Carex filifolia, Poa wheeleri, Eriogonum incanum, Penstemon newberryi*, and *Penstemon davidsonii*. Due to landscape position and very thin soils, these are harsh sites exposed to desiccating winds with ice and snow blasts, and rocky substrates. In addition, a short growing season limits plant growth. The highest tree diversity occurs in the Klamath Mountains, with sometimes five or more conifers sharing codominance in one stand.

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.910 CONCEPTUAL MODEL

Environment: Dry, thin soils and exposure to winds are key ecological environmental factors that drive the structure and appearance of this subalpine forest. These forests are at the limit of tree growth in terms of exposure to cold and desiccating winds in the winter (Arno and Huff 1990). Climate is predicted to get warmer in the Sierra Nevada (Fried et al. 2004, as cited in Barbour et al. 2007). This may lead to reduced growth and vigor of trees in this already stressed environment. However, it is the winter cold and desiccating

winds that keep trees in a krummholz form. If winter low temperatures increase, these woodlands may increase in growth and vigor, if adequate moisture continues to be available. Soils are thin and poorly developed, usually low in nitrogen-fixing bacteria which is apparently restricted by low soil temperature and high acidity of many sites. Increased temperatures may increase soil nitrogen availability (Arno and Huff 1990). However, this may result in increased competition from invading native tree species rather than an increase in those typically dominant on these sites.
Key Processes and Interactions: Due to landscape position and very thin soils, these are harsh sites exposed to desiccating winds with ice and snow blasts, and rocky substrates. In addition, a short growing season limits plant growth. The highest tree diversity occurs in the Klamath Mountains, with sometimes five or more conifers sharing codominance in one stand.

CES204.837 North Pacific Maritime Mesic Subalpine Parkland

CES204.837 CLASSIFICATION

Concept Summary: This ecological system occurs throughout the mountains of the Pacific Northwest, from the southern Cascades of Oregon to the mountains of southeastern Alaska bordering British Columbia. It occurs at the transition zone of forest to alpine, forming a subalpine forest-meadow ecotone. Mountain hemlock forests, as they approach treeline, become open patches of mature-height trees surrounded by mesic and wet meadows rich in dwarf-shrubs and forbs. Clumps of trees to small patches of forest interspersed with low shrublands and meadows characterize this system. Krummholz often occurs near the upper elevational limit of this system where it grades into alpine vegetation. Associations include woodlands, forested, and subalpine meadow types. It occurs on the west side of the Cascade Range and is a transitional open forest into the true alpine on the interior side of the Coast Mountains of British Columbia where deep, late-lying snowpack is the primary environmental factor. Major tree species are *Tsuga mertensiana, Abies amabilis, Callitropsis nootkatensis (= Chamaecyparis nootkatensis)*, and *Abies lasiocarpa*. This system includes British Columbia Hypermaritime and Maritime Parkland (*Tsuga mertensiana*). Dominant dwarf-shrubs include *Phyllodoce empetriformis, Cassiope mertensiana*, and *Vaccinium deliciosum*. Dominant herbaceous species include *Lupinus arcticus ssp. subalpinus, Valeriana sitchensis, Carex spectabilis*, and *Polygonum bistortoides*. There is very little disturbance, either windthrow or fire. The major process controlling vegetation is the very deep long-lasting snowpacks (deepest in the North Pacific region) limiting tree regeneration. Trees get established only in favorable microsites (mostly adjacent to existing trees) or during drought years with low snowpack. It is distinguished from more interior dry parkland primarily by the presence of *Tsuga mertensiana* or *Abies amabilis* and absence or paucity of *Pinus albicaulis* and *Larix lyallii*.

CES204.838 North Pacific Mountain Hemlock Forest

CES204.838 CLASSIFICATION

Concept Summary: This forested ecological system occurs throughout the mountains of the North Pacific, from the southern Cascades of Oregon north to southwestern British Columbia. It is the predominant forest of subalpine elevations in the coastal mountains of British Columbia, western Washington and western Oregon. It also occurs on mountain slopes on the outer coastal islands of British Columbia. It lies between the Western Hemlock, Pacific Silver Fir, or Shasta Red Fir zones and the Subalpine Parkland or Alpine Tundra Zone, at elevations ranging from 300 to 2300 m (1000-7500 feet). The lower and upper elevational limits decrease from south to north and from east to west. The climate is generally characterized by short, cool summers, rainy autumns and long, cool, wet winters with heavy snow cover for 5-9 months. The heavy snowpack is ubiquitous, but at least in southern Oregon and perhaps the eastern Cascades, summer drought is more significant. Fire is very rare or absent across the majority of the range of the system. *Tsuga mertensiana* is one of the dominant tree species throughout, and *Abies amabilis* becomes an important associated species in the southern portion of the range (British Columbia, Washington, and northwestern Oregon). *Tsuga heterophylla* often occurs at lower elevations in this system but is much less abundant than *Tsuga mertensiana*. *Callitropsis nootkatensis* occurs in the more coastal portions, while *Abies lasiocarpa* is found inland and becomes increasingly common near the transition to the Subalpine Fir-Engelmann Spruce Zone in the Cascades and British Columbia. On the leeward side of the Cascades, this is usually a dense canopy composed of *Abies lasiocarpa* and *Tsuga mertensiana*, with some *Picea engelmannii* or *Abies amabilis*. In the Cascades of central to southern Oregon, *Abies magnifica var. shastensis* is typically present and often codominant. *Picea sitchensis* and *Thuja plicata* are occasionally present. Deciduous trees are rare. Common understory species include *Vaccinium ovalifolium, Menziesia ferruginea, Elliottia pyroliflora*, and *Blechnum spicant*. Parklands (open woodlands or sparse trees with dwarf-shrub or herbaceous vegetation) are not part of this system but of ~North Pacific Maritime Mesic Subalpine Parkland (CES204.837)$$ or ~Alaskan Pacific Maritime Subalpine Mountain Hemlock Woodland (CES204.143)$$.

Nations: CA, US
Concept Source: G. Kittel and C. Chappell
Description Author: G. Kittel, C. Chappell and M.S. Reid

CES204.838 CONCEPTUAL MODEL

Environment:
Key Processes and Interactions: In the more summer-dry climatic areas (Cascades), occasional high-severity fires occur, with return intervals of 400-600 years (J. Kertis pers. comm. 2006, K. Kopper pers. comm. 2006). On drier sites, *Abies lasiocarpa* and *Pinus contorta* can be the first forests to develop after stand-replacing fire. These early-seral stages, with lodgepole pine dominant in the upper canopy, could be classified and mapped as ~Rocky Mountain Lodgepole Pine Forest (CES306.820)$$ but should be considered part of this system if other tree species listed above are present, as it will succeed as a mixed pine type, then mountain hemlock becomes characteristic. Landfire VDDT models: R#ABAMup.

CES206.911 Northern California Mesic Subalpine Woodland

CES206.911 CLASSIFICATION

Concept Summary: This ecological system occurs on ridges and rocky slopes around timberline at 2600 m (7900 feet) elevation in the central Sierra Nevada and 2450 m (8000 feet) in the southern Cascades. These woodlands are found on concave or mesic slopes in areas with long-lasting snowpack and better soil development than other drier and more exposed subalpine woodlands. The tree canopy is characterized by *Tsuga mertensiana* and may include *Abies magnifica, Abies procera, Pinus albicaulis*, and *Pinus monticola*. Mesic-site shrubs will include *Cassiope mertensiana, Phyllodoce breweri, Phyllodoce empetriformis, Vaccinium membranaceum*, and others. *Juniperus communis* is found in most stands of the northern Sierra Nevada. *Penstemon davidsonii*, as well as patches of grasses, sedges, and forbs grade into adjacent meadows.

CES206.912 Sierra Nevada Subalpine Lodgepole Pine Forest and Woodland

CES206.912 CLASSIFICATION

Concept Summary: This ecological system is widespread in glacial basins at upper montane to subalpine elevations of the central and northern Sierra Nevada and Transverse and Peninsular ranges where cold-dry conditions exist (1800-2450 m [6000-8000 feet] in the north and 2450-3600 m [8000-12,000 feet] in the south). It also occurs on extensive broad ridges and pumice plateaus of the southern Cascades in Oregon (the broad ridges that form the Cascade crest in southern Oregon tend to be dominated by extensive stands of lodgepole pine). Soils are often shallow and coarse-textured. These forests and woodlands are dominated by *Pinus* *contorta var. murrayana* with shrub, grass or barren understories. Avalanche as well as tree mortality from insect outbreak and disease, drought and associated wildfire are drivers of community structure and composition. Understories are open, with scattered shrubs and herbaceous species, which do not carry fire should one get started. Trees can be very large and old and can attain diameters of 1.2 m (4 feet). Associated plant species include *Arctostaphylos nevadensis, Ceanothus cordulatus, Cercocarpus ledifolius* (although not that common, just occasional in drier sites), *Chrysolepis sempervirens, Phyllodoce breweri*, and *Ribes montigenum*. Common graminoids include *Poa wheeleri, Carex filifolia, Carex rossii*, and *Carex exserta*. Fire-return intervals are many hundreds of years. This system occurs in less severe settings than ~Mediterranean California Subalpine Woodland (CES206.910)$$ and ~Northern California Mesic Subalpine Woodland (CES206.911)$$ and is made up of trees that are not usually krummholz. Avalanches are less of a factor except in association with the volcanic peaks. Low-elevation stands of *Pinus contorta* in the pumice zone of Oregon are included in ~Rocky Mountain Poor-Site Lodgepole Pine Forest (CES306.960)$$.

Related Concepts:
- Lodgepole Pine: 218 (Eyre 1980) **>**

Distribution: This system occurs in glacial basins at upper montane to subalpine elevations of the central and northern Sierra Nevada and Transverse and Peninsular ranges where cold-dry conditions exist (1800-2450 m [6000-8000 feet] in the north and 2450-3600 m [8000-12,000 feet] in the south). It also extends south into Baja California, Mexico, in the San Pedro Martir Mountains.

If present in Oregon, the most likely location is the southern Oregon Cascades. The broad ridges that form the Cascade Crest in southern Oregon tend to be dominated by extensive stands of lodgepole pine (south of Crater Lake and north maybe to Mount Bachelor). There are also relatively large areas of lodgepole pine along the broad crest from Mt. Jefferson to a little ways north of Olallie Butte that may also fit this type better than the Rocky Mountain lodgepole pine type, as these stands are more likely dominated by *Pinus contorta var. murrayana* than *Pinus contorta var. latifolia*. Understory species are probably different from those listed, however.

Nations: MX, US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, M.S. Reid, L. Evers and G. Kittel

CES206.912 CONCEPTUAL MODEL

Environment: Upper montane to subalpine elevations of the central and northern Sierra Nevada and Transverse and Peninsular ranges where relatively cold-dry conditions exist (1800-2450 m [6000-8000 feet] in the north and 2450-3600 m [8000-12,000 feet] in the south). It is often located on benches but also occurs on moderate slopes, and on extensive broad ridges and pumice plateaus of the southern Cascades in Oregon (the broad ridges that form the Cascade crest in southern Oregon tend to be dominated by extensive stands of lodgepole pine). The climate regime is Mediterranean with wet winters (November-April), with precipitation occurring as snow, and dry summers, although summer thunderstorms occur sporadically.

Key Processes and Interactions: LANDFIRE model information: Disturbance patterns have been poorly studied in Sierran lodgepole pine. Sierran lodgepole has been described as not being a fire type (Barbour and Minnich 2000) or as having long intervals between fires (Keeley 1980, Parker 1986, Potter 1998). Avalanche as well as tree mortality from insect outbreak and disease, drought and associated wildfire are the main drivers of community structure and composition. Somewhat similar wet lodgepole types in the Klamath Mountains and Oregon had a fire-return interval range of 70-100 years. Season of fire is generally late summer to early fall. Stand-replacement fire occurs at long interval, resulting in low stand complexity. Mixed-severity fire occurs when fuel conditions remain moist and result in mixed-age stands. Very infrequently, surface fires can occur. Forest understory is typically sparse with few shrubs and low to moderate herbaceous cover. Fuel is considered sparse (Parker 1986, van Wagtendonk 1991). Stands in the southern Sierra Nevada have been described as self-perpetuating (regeneration from treefall gaps) with long intervals between fires (Keeley 1980, Parker 1986, Potter 1998). Sparse fuels are believed to limit ignition and fire spread (Parker 1986). In contrast, fire history studies from dry subalpine lodgepole pine forest in the southern Sierra Nevada have found moderate fire-return intervals in some stands (Keifer 1991, Caprio 2008 and unpubl. data). Intervals ranged from 31-74 years (Chagoopa Plateau, Sequoia National Park and Palisades Canyon, Kings Canyon National Park). Fire severity was mixed and ranged from understory burns on areas up to 100s of ha to high-severity crown fires in patches up to 10s of ha (FRG of III). Season of fires was late summer or early fall. Seasonal fire scar positions on Chagoopa and Palisades (SEKI) was 40.7% and 15% latewood and 59.3% and 80% dormant, respectively (Caprio unpubl. data). Other important disturbance agents in this system include the lodgepole needle miner, windthrow and stress from extreme climatic events.

1.B.2.Ne. North American Great Plains Forest & Woodland

M151. Great Plains Forest & Woodland

CES205.688 Eastern Great Plains Tallgrass Aspen Parkland

CES205.688 CLASSIFICATION

Concept Summary: This system is found primarily on part of the Glacial Lake Agassiz plain in northwestern Minnesota, ranging into southern Canada. Calcareous glacial drift overlain with lacustrine soils ranging from loamy to gravelly is characteristic of the lakeplain within the range of this system. Historically this system included a mosaic of tallgrass prairie, wet prairie, brush prairie and aspen-oak woodlands. It is dominated by *Populus tremuloides* with scattered *Quercus macrocarpa* and *Betula papyrifera*. Shrubs such as willow (*Salix* spp.) and hazel (*Corylus* spp.) are also common. The dominant tallgrass species is *Andropogon gerardii* often associated with *Sorghastrum nutans, Calamagrostis* spp., and *Sporobolus heterolepis*. Fire is the most important natural dynamic in this system and helps maintain the open parkland or brush nature of this system. Wind and grazing are also important dynamics. Conversion to agriculture and fire suppression have decreased the range of this system and allowed more shrubs and trees to establish.

Related Concepts:
- Aspen: 16 (Eyre 1980) **<**
- Bur Oak: 42 (Eyre 1980) **<**
- Paper Birch: 18 (Eyre 1980) **<**

Distribution: This system is found primarily on part of the Glacial Lake Agassiz plain in northwestern Minnesota, ranging into southern Canada.

Nations: CA, US

Concept Source: S. Menard

Description Author: S. Menard and J. Drake

CES205.688 CONCEPTUAL MODEL

Environment: This system occurs largely on the lakeplain of Glacial Lake Agassiz. This landscape is very flat with soils ranging from fine to somewhat coarse. Drainage is moderate to poor at most sites.

Key Processes and Interactions: The interaction of fire and regional climate shaped this system. Aspen parklands occur on the margin of the northern prairies and northern forests. The climate will support tallgrass, tree and shrub species, and aspen parklands are a mix of these lifeforms. Frequent fires favor the spread of tallgrass species and reduce woody cover (Svedarsky et al. 1986). Sites not burned as often, due to a fire-protected position on the landscape or to a reduction in fire frequency across the entire landscape, tend to become dominated by trees and shrubs. An average fire-return interval of 10-15 years was estimated by Landfire modelers (Landfire 2007a), though individual areas would have burned less or more often. This system occurs on a very flat landscape and minor variations in topography can create wet prairie or wet shrub pockets within the parkland.

Threats/Stressors: Reduction in fire frequency and use of sites for agricultural purposes are the two main threats to this system. Reduction in fire frequency quickly results in shrubs and trees spreading into former prairie areas and in a closing of the canopy in former shrublands or woodlands. Many site of this system are on rich soil which can be used for sugar beets or other northern crops, resulting in destruction of the site. Overgrazing by livestock preferentially reduces cover of warm-season grasses in favor of forbs, cool-season grasses, shrubs and trees.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when fire is excluded from a site for several years, eliminating the mosaic of grassland, shrubland, and woodland in favor of dense shrubland and woodland. Collapse also occurs when sites are overgrazed, reducing native grasses and allowing the spread of woody species and non-native species.

CES303.680 Great Plains Wooded Draw and Ravine

CES303.680 CLASSIFICATION

Concept Summary: This ecological system is typically found associated with permanent or ephemeral streams though it may occur on steep northern slopes or within canyon bottoms that do not experience periodic flooding. Soil moisture and topography allow greater moisture conditions compared to the surrounding areas. Occurrences can be either tree-dominated or predominantly shrubland. *Fraxinus pennsylvanica* with *Ulmus rubra* or *Ulmus americana* typically dominate this system, although *Juniperus scopulorum* can dominate the canopy in the western Great Plains and *Juniperus virginiana* in the east. *Populus tremuloides, Betula papyrifera*, or *Acer negundo* are commonly present in portions of the northwestern Great Plains, for example in areas of central and eastern Montana. In south-central and east-central portions of the Great Plains, *Quercus macrocarpa* can also be present. Wetter areas within this system can have significant amounts of *Populus deltoides*. Component shrubs can include *Cornus sericea, Crataegus douglasii, Crataegus chrysocarpa, Crataegus succulenta, Elaeagnus commutata, Prunus virginiana, Rhus* spp., *Rosa woodsii, Shepherdia argentea, Symphoricarpos occidentalis*, or *Viburnum lentago*. Common grasses can include *Calamagrostis stricta, Carex* spp., *Pascopyrum smithii, Piptatheropsis micrantha, Pseudoroegneria spicata*, or *Schizachyrium scoparium*. This system was often subjected to heavy grazing and trampling by both domestic animals and wildlife and can be heavily degraded in some areas. In addition, exotic species such as *Ulmus pumila* and *Elaeagnus angustifolia* can invade these systems.

- Paper Birch: 18 (Eyre 1980) **<**
- Rocky Mountain Juniper: 220 (Eyre 1980) **><**

Distribution: This system is found throughout the Western Great Plains Division and east into the western tallgrass prairie zone of the central United States. In Wyoming, it occurs in the northeastern foothills of the Bighorns and across far-northeastern Wyoming into the northern fringes of the Black Hills. It has also been identified in the High Plains of Texas.

Nations: US
Concept Source: S. Menard and K. Kindscher
Description Author: S. Menard, K. Kindscher, M.S. Reid and J. Drake

CES303.680 CONCEPTUAL MODEL

Environment: This system is associated with permanent or ephemeral streams. It also can occur on steep northern slopes or within canyon bottoms that do not experience periodic flooding. Soils are primarily wet to mesic, and the more sheltered and lower landscape position allows for greater moisture conditions compared to the surrounding areas.
Key Processes and Interactions: Fire can influence this system; however, grazing is the most prevalent dynamic process influencing this system. Overgrazing can heavily degrade this system, particularly the understory, and allow for the invasion of exotic species.

CES303.681 Northwestern Great Plains Aspen Forest and Parkland

CES303.681 CLASSIFICATION

Concept Summary: This system ranges from the North Dakota/Manitoba border west to central Alberta and is considered part of the boreal-mixedgrass prairie grassland transition region. The climate in this region is mostly subhumid low boreal with short, warm summers and cold, long winters. Much of this region is covered with undulating to kettled glacial till. *Populus tremuloides* dominates this system. Common associates are *Betula papyrifera* and *Populus balsamifera* with an understory of mixedgrass species and tall shrubs. More poorly drained sites may contain willow (*Salix* spp.) and sedges (*Carex* spp.). Fire constitutes the most important dynamic in this system and prevents boreal conifer species such as *Picea glauca* and *Abies balsamea* from becoming too established in this system.

CES303.667 Western Great Plains Dry Bur Oak Forest and Woodland

CES303.667 CLASSIFICATION

Concept Summary: This system is dominated by *Quercus macrocarpa* and is found in upland areas in the northern part of the Western Great Plains. It often occurs as small to large patches on buttes, escarpments, and in foothill zones, usually on northerly-facing slopes. Other species, such as *Tilia americana* (not in the Dakotas), *Populus tremuloides, Juniperus virginiana*, and *Fraxinus* spp., may be present. The herbaceous layer can vary from sparsely to moderately vegetated and is composed of prairie grasses or woodland *Carex* spp. Shrub associates can include *Prunus virginiana, Corylus cornuta, Amelanchier alnifolia*, or *Symphoricarpos* spp. Historically, higher cover of grass species occurred as these stands were more open due to more frequent fires. Few good examples of this system likely remain because of past timber harvesting and heavy grazing. Where it occurs at elevations above 915 m (3000 feet), *Pinus ponderosa* woodlands are probably adjacent.

- Great Plains Dry Upland Bur Oak Woodland (Rolfsmeier and Steinauer 2010) **=**

Distribution: This system is found throughout the northern part of the Western Great Plains Division. In Wyoming, it occurs in the Bear Lodge Mountains and around Devils Tower National Monument. In North Dakota, it is found in the Killdeer Mountains, and it may occur in the Pine Ridge region of Nebraska.

Nations: US

Concept Source: S. Menard and K. Kindscher

Description Author: S. Menard, K. Kindscher, K.A. Schulz and J. Drake

CES303.667 CONCEPTUAL MODEL

Environment: This system is found in upland areas throughout the northern part of the Western Great Plains. Soils are predominately dry to mesic. It usually occurs on protected eastern or northern slopes of buttes or river valleys (Rolfsmeier and Steinauer 2010).

Key Processes and Interactions: This system is primarily driven by fire. This system occurs in a landscape where fire is common but the sites it occupies are somewhat sheltered so fire frequency is less than the surrounding prairie uplands. Fire-return intervals have been estimated at 15-25 years (Landfire 2007a). Fire reduces woody species regeneration and shrub cover and allows prairie grasses to grow under the open tree canopy.

Threats/Stressors: Grazing, conversion to agriculture, and timber harvesting can impact this system. Overgrazing can lead to a decrease in native understory species and an increase in exotic species. Timber harvesting can remove mature trees and impact the understory through the effects of logging equipment or can completely eliminate examples of this system. Reduction in fire frequency allows fire-sensitive species to spread and results in less cover by native grasses and fire-tolerant shrubs. The tree and shrub canopy will close in over time without fire, which will further impact the understory by reducing available light.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when sites are protected from fire or are used for pasture or selective logging for long periods. Significant reduction in fire frequency will allow the woody species to proliferate, causing a dense tree and/or shrub canopy to shade out shorter species. Overgrazing eliminates sensitive species, often beginning with native grasses, and opens up avenues for invasion by exotic species resistant to grazing.

1.B.3.Na. Eastern North American Flooded & Swamp Forest

M029. Central Hardwood Floodplain Forest

CES202.608 Central Appalachian River Floodplain

CES202.608 CLASSIFICATION

Concept Summary: This system encompasses floodplains of medium to large rivers in Atlantic drainages from southern New England to Virginia. This system can include a complex of wetland and upland vegetation on deep alluvial deposits and scoured vegetation on depositional bars and on bedrock where rivers cut through resistant geology. This complex includes floodplain forests in which *Acer saccharinum, Populus deltoides*, and *Platanus occidentalis* are characteristic, as well as herbaceous sloughs, shrub wetlands, riverside prairies and woodlands. Microtopography and soil texture determine how long the various habitats are inundated. Depositional and erosional features may both be present depending on the particular floodplain.

Distribution: Southern New England west to Lake Erie and south to Virginia. The James River in Virginia marks the southern extent of this system.

Nations: US

Concept Source: S.C. Gawler

Description Author: S.C. Gawler, J. Teague, L.A. Sneddon and M. Pyne

CES202.608 CONCEPTUAL MODEL

Environment: This system forms on broad, relatively flat floodplains along medium-sized to large rivers. Rivershores often exhibit development of one or more terraces formed in relation to hydroperiod and height from river channel. Backswamps may occur in poorly drained depressions behind the main river channel, where substrate is deep muck. Soils range from sandy and silty on point bars to deep muck in backswamps.

Key Processes and Interactions: Spring and summer flooding brings large amounts of sediment carried from tributaries, as well as other debris that is deposited on the floodplain as flood waters recede. Floodplain canopy trees often topple as a result of prolonged saturation of sediments; vegetation structure is highly variable and dynamic as a result. Dynamic disturbance regime and high fertility make this system highly susceptible to invasions of non-native plants.

Threats/Stressors: The high nutrient content of soils and the level topography of the floodplain have attracted a high degree of conversion to agriculture. Pesticides from crops and nutrients from fertilizer and farm animals often flow unimpeded into rivers, altering water quality and increasing the incidence of invasive species. Historic use of rivers as dumping areas of industrial waste leads to concentrations of toxic chemicals in the sediments. Dams convert natural flooding regimes, diminishing the dynamic quality of these systems as a result of controlled water releases. Dams also inhibit fish movement, altering movement of invertebrates such as freshwater mussels. Riprap or hardening of shorelines changes the flow regime. Vegetation on terraces and higher elevations above the river formerly maintained by flooding undergoes succession to other community types. Invasive plant species, easily spread by waterflow, inhibit growth of native plants.

Ecosystem Collapse Thresholds: Natural riverflow has been altered, either by damming or by bank stabilization; vegetated buffers are dominated by non-native plant cover (>50%) characterized by barren ground and highly compacted or otherwise disrupted soils, or there is no buffer present, with rivershore directly abutting development, agriculture, or transportation corridors; absence of woody vegetation on otherwise forested floodplains; absence or very low cover of characteristic species; >10% cover of exotic invasive plant cover; many physical patch types are lacking based on expected natural conditions (Faber-Langendoen et al. 2011).

CES202.609 Central Appalachian Stream and Riparian

CES202.609 CLASSIFICATION

Concept Summary: This riparian system ranges from southern New England to Virginia and West Virginia and occurs over a wide range of elevations. It develops on floodplains and shores along river channels that lack a broad flat floodplain due to steeper sideslopes, higher gradient, or both. It may include communities influenced by flooding, erosion, or groundwater seepage. The vegetation is often a mosaic of forest, woodland, shrubland, and herbaceous communities. Common trees include *Betula nigra* and *Platanus occidentalis*. Open, flood-scoured rivershore prairies feature *Panicum virgatum* and *Andropogon gerardii*, and *Carex torta* is typical of wetter areas near the channel.

Distribution: This system ranges from southern New England west to Lake Erie and south to Virginia and West Virginia. The James River in Virginia marks its southern extent.

Nations: US
Concept Source: S.C. Gawler
Description Author: S.C. Gawler, J. Teague and L.A. Sneddon

CES202.609 CONCEPTUAL MODEL

Environment: This alluvial system forms on the shores of rivers and streams influenced by flood scour and deposition. It includes vegetation on various substrates ranging from silty sediments low on the channel to rock outcrops, gorge walls, and cobbles.
Key Processes and Interactions: High-gradient waterflow causes scouring of rivershores, removing soils and depositing them in slower-moving portions of the river. High amounts of debris cause flood-battering of trees and shrubs, and removal of woody vegetation during extreme flooding events. Seepage from uplands may emerge from shores, and the often specialized flora of these environments is maintained by repeated removal, or prevention of establishment, of woody vegetation. Flood-battering of trees prevents succession; scouring by water, and sometimes ice, exposes substrate.
Threats/Stressors: Altered hydrologic regime and invasion by non-native species are two major threats to this system. Road and railroad corridors, as well as road crossings pinch the corridor and alter hydrologic regime.
Ecosystem Collapse Thresholds: Natural river flow has been altered, either by damming or by bank stabilization; vegetated buffers are dominated by non-native plant cover (>50%) characterized by barren ground and highly compacted or otherwise disrupted soils, or there is no buffer present, with rivershore directly abutting development, or transportation corridors; absence of woody vegetation on otherwise forested floodplains; absence or very low cover of characteristic species; >10% cover of exotic invasive plant cover; many physical patch types are lacking based on expected natural conditions (Faber-Langendoen et al. 2011).

CES202.694 North-Central Interior Floodplain

CES202.694 CLASSIFICATION

Concept Summary: This system is found along rivers across the glaciated Midwest. It occurs from river's edge across the floodplain or to where it meets a wet meadow system. It can have a variety of soil types found within the floodplain from very well-drained sandy substrates to very dense clays. It is this variety of substrates and flooding that creates the mix of vegetation that includes *Acer saccharinum, Populus deltoides*, willows, especially *Salix nigra* in the wettest areas, and *Fraxinus pennsylvanica, Ulmus americana*, and *Quercus macrocarpa* in more well-drained areas. Within this system are oxbows that may support *Nelumbo lutea* and *Typha* *latifolia*. Understory species are mixed, but include shrubs, such as *Cornus drummondii* and *Asimina triloba* (in Kansas), sedges and grasses, which sometimes help form savanna vegetation. Flooding is the primary dynamic process, but drought, grazing, and fire have all had historical influence on this system. Federal reservoirs have had a serious and negative effect on this system, along with agriculture that has converted much of this system to drained agricultural land.

Distribution: This system is found along medium and large river floodplains throughout the glaciated Midwest ranging from eastern Kansas and western Missouri to western Ohio and north along the Red River basin in Minnesota and the eastern Dakotas. This system is essentially restricted to USFS Provinces 251 and 222, though it may go further west in larger rivers in the Great Plains, notably the Missouri and Platte rivers.

Nations: US

Concept Source: S. Menard and K. Kindscher

Description Author: S. Menard, K. Kindscher, J. Drake

CES202.694 CONCEPTUAL MODEL

Environment: This ecological system occurs in floodplains of medium to large rivers. It is found on alluvial soils ranging from sandy to very dense clays. Soil texture reflects the upstream substrate through which the river and its tributaries flow and water velocity. Sandy sediments can be carried by faster-flowing water, while slow-moving rivers can only carry fine-textured sediment. Water velocity and volume change greatly during the year as rains and snowmelt deliver pulses of water and seasonal droughts (typically including winter in the northern portion of this system's range when most precipitation is frozen) result in low water. Within a short distance on a river floodplain, different soil textures can be found. Coarser-textured soils are typically adjacent to the main channel where they are deposited first by rising or falling floodwaters. Finer-textured soils are further away from the main channel, deposited when floodwaters have spread out and slowed down. Within the space of a few years, floods of differing magnitude can deposit sand over silt or vice versa, resulting in complex soil topology.

Key Processes and Interactions: This system is primarily controlled by moderate to frequent flooding. Flood frequency depends on precipitation patterns within the watershed and proximity to the main channel. Areas adjacent to the main channel or low islands within the channel can be flooded every year or even more than once per year. Those areas further from the channel on terraces or behind natural levees may only be flooded once every several years. Free-flowing rivers migrate across their floodplain, cutting new channels or eroding the bank on one side while building up the bank on the other, so the flooding regime of any one point in the floodplain will change over time. Flooding redeposits alluvium, eroding some areas and aggrading others, can bury or wash away small plants, and redistributes nutrients, especially in less frequently flooded zones where silt and clay tend to be deposited. These processes open up new areas for colonization. Where trees can grow (i.e., not in permanent or semi-permanent backwater wetlands), there is a common succession sequence of annual herbaceous species followed by shrub *Salix* spp., followed by *Populus deltoides, Salix nigra*, and *Acer saccharinum*, followed by a number of trees, including *Acer negundo, Carya illinoinensis, Celtis laevigata, Celtis occidentalis, Fraxinus pennsylvanica, Quercus macrocarpa*, and *Ulmus americana*. This sequence can be reset by major floods and erosion/deposition. Frequent minor to moderate flooding holds the system at the intermediate forest stage, and large areas of this floodplain system are dominated by *Populus deltoides, Salix nigra*, and *Acer saccharinum*.

Fire could impact parts of this system. Most of the forests in this system were not fire-prone due to the lack of litter, frequent flooding, and relatively protected landscape position in the river valley with wetlands often near, but forests on higher, coarser soils or wet-mesic prairies on the margins of the floodplain could become dry in late summer and burn, if an ignition source was present (Weaver 1960).

Threats/Stressors: This system has been heavily impacted by human activities. The flooding and channel migration that is important in maintaining this system have been affected by attempts to contain the channel in its current location through bank armoring (riprap or other bank stabilization techniques) and channelization (man-made levees, dredging, wing dams, closing dams). While these may not immediately affect large areas of this system, the changes to the flooding regime have longer term impacts. Dams, built for irrigation, recreation, hydropower, or navigation, have immediate impacts by flooding the reservoir area and increasing the amount of open water compared to floodplain. They have longer term effects by changing the flooding pattern, reducing the amplitude of low water in the upstream pool and of high water both upstream and downstream. Dams also trap much of the sediment being transported by the river and reduce the erosion and deposition rates downstream (Johnson 1992).

Agricultural and urban development has affected many examples of this system. Direct conversion to cropland or pastures, more common in the prairie regions, can destroy this system. Along the Missouri River in Missouri, an estimated 83% of the floodplain forests have been converted to agricultural use (Bragg and Tatschi 1977) and floodplain prairies have nearly been eliminated from the Mississippi River (Yin and Nelson 1996). Indirect effects of agricultural or urban development within or near the floodplain include increased sediment loads from erosion and chemical pollution from pesticides, herbicides, fertilizer, industrial activities, road maintenance, and other sources.

Grazing by native species was not likely an important factor shaping this system, but grazing or browsing by high white-tailed deer populations or domestic livestock can impact this system and lead to decreased cover of many graminoids and some sensitive forbs. Weedy invasives can dominate parts of the floodplain. Several herbaceous species are particularly aggressive and can dominate floodplain marshes, sometimes forming near monocultures. These include *Phragmites australis, Phalaris arundinacea, Typha x glauca*, and *Lythrum salicaria*. Other weedy species can become abundant in the understory of floodplain forests.

A serious threat to stands of this system that contain *Fraxinus* spp. is emerald ash borer (*Agrilus planipennis*). This exotic beetle has seriously affected *Fraxinus* spp. trees in southern Michigan and is projected to continue to spread throughout the range of *Fraxinus* spp. in the Midwest and Northeast by 2045 (DeSantis et al. 2012). After prolonged infestation, mortality of *Fraxinus* spp. is nearly 100% (Herms et al. 2010).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur over time when the flooding regime and channel migration are greatly altered, eliminating the processes required for maintenance of this system. Without direct conversion, this system will likely persist with these perturbations but over time the floodplain system will shrink or be eliminated. More immediate collapse tends to occur when sites are largely or wholly converted to agricultural or urban uses, resulting in a change to a non-natural system or to a significant change in structure and species composition. Invasive species can eliminate this system by choking out other species and eliminating the habitat necessary for native species.

CES202.705 South-Central Interior Large Floodplain

CES202.705 CLASSIFICATION

Concept Summary: This floodplain system is found in the Interior Highlands as far west as eastern Oklahoma, as well as throughout the Interior Low Plateau, Cumberlands, Southern Ridge and Valley, and Western Allegheny Plateau, and lower elevations of the Southern Blue Ridge. Examples occur along large rivers or streams where topography and alluvial processes have resulted in a well-developed floodplain. A single occurrence may extend from river's edge across the outermost extent of the floodplain or to where it meets a wet meadow or upland system. Many examples of this system will contain well-drained levees, terraces and stabilized bars, and some will include herbaceous sloughs and shrub wetlands resulting, in part, from beaver activity. A variety of soil types may be found within the floodplain from very well-drained sandy substrates to very dense clays. It is this variety of substrates in combination with different flooding regimes that creates the mix of vegetation. Most areas, except for the montane alluvial forests, are inundated at some point each spring; microtopography determines how long the various habitats are inundated. Although vegetation is quite variable in this broadly defined system, examples may include *Acer saccharinum, Platanus occidentalis, Liquidambar styraciflua, Populus deltoides*, and *Quercus* spp. Understory species are mixed, but include shrubs, such as *Cephalanthus occidentalis* and *Arundinaria gigantea*, and sedges (*Carex* spp.). This system likely floods at least once annually and can be altered by occasional severe floods. Impoundments and conversion to agriculture can also impact this system.

CES202.705 CONCEPTUAL MODEL

Environment: This system inhabits broad floodplains along large creeks and rivers that are usually inundated for at least part of each year. Flood frequency depends on precipitation patterns within the watershed and proximity to the main channel. Areas adjacent to the main channel or low islands within the channel can be flooded every year or even more than once per year. Those areas further from the channel on terraces or behind natural levees may only be flooded once every several years. Free-flowing rivers migrate across their floodplain, cutting new channels or eroding the bank on one side while building up the bank on the other, so the flooding regime of any one point in the floodplain will change over time. Flooding redeposits alluvium, eroding some areas and aggrading others, can bury or wash away small plants, and redistributes nutrients, especially in less frequently flooded zones where silt and clay tend to be deposited. These processes open up new areas for colonization.

Key Processes and Interactions: Flooding dynamics are an important factor in the development and maintenance of this system. Flood frequency depends on precipitation patterns within the watershed and proximity to the main channel. Areas adjacent to the main channel or low islands within the channel can be flooded every year or even more than once per year. Those areas further from the channel on terraces or behind natural levees may only be flooded once every several years. Free-flowing rivers migrate across their floodplain, cutting new channels or eroding the bank on one side while building up the bank on the other, so the flooding regime of any one point in the floodplain will change over time. Flooding redeposits alluvium, eroding some areas and aggrading others, can bury or wash away small plants, and redistributes nutrients, especially in less frequently flooded zones where silt and clay tend to be deposited. These processes open up new areas for colonization.

Threats/Stressors: This system has been heavily impacted by human activities. The flooding and channel migration that is important in maintaining this system has been affected by attempts to contain the channel in its current location through bank armoring (riprap or other bank stabilization techniques) and channelization (man-made levees, dredging, wing dams, closing dams). While these may not immediately affect large areas of this system the changes to the flooding regime have longer term impacts. Dams, built for irrigation, recreation, hydropower, or navigation, have immediate impacts by flooding the reservoir area and increasing the amount of open water compared to floodplain. They have longer term effects by changing the flooding pattern, reducing the amplitude of low water in the upstream pool and of high water both upstream and downstream. Dams also trap much of the sediment being transported by the river and reduce the erosion and deposition rates downstream (Johnson 1992).

Agricultural and urban development has affected many examples of this system. Direct conversion to cropland or pastures can destroy this system. Indirect effects of agricultural or urban development within or near the floodplain include increased sediment loads from erosion and chemical pollution from pesticides, herbicides, fertilizer, industrial activities, road maintenance, and other sources.

Grazing by native species was not likely an important factor shaping this system, but grazing or browsing by high white-tailed deer populations or domestic livestock can impact this system and lead to decreased cover of many graminoids and some sensitive forbs. Weedy invasives can dominate parts of the floodplain. Several herbaceous species are particularly aggressive and can dominate floodplain marshes, sometimes forming near mono-cultures. These include *Phragmites australis, Phalaris arundinacea, Typha x glauca*, and *Lythrum salicaria*. Other weedy species can become abundant in the understory of floodplain forests.

A serious threat to stands of this system that contain *Fraxinus* spp. is emerald ash borer (*Agrilus planipennis*). This exotic beetle has seriously affected *Fraxinus* spp. trees in southern Michigan and is projected to continue to spread throughout the range of *Fraxinus* spp. in the Midwest and Northeast by 2045 (DeSantis et al. 2012). After prolonged infestation, mortality of *Fraxinus* spp. is nearly 100% (Herms et al. 2010).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur over time when the flooding regime and channel migration are greatly altered, eliminating the processes required for maintenance of this system. Without direct conversion, this system will likely persist with these perturbations but over time the floodplain system will shrink or be eliminated. More immediate collapse tends to occur when sites are largely or wholly converted to agricultural or urban uses, resulting in a change to a non-natural system or to a significant change in structure and species composition. Invasive species can eliminate this system by choking out other species and eliminating the habitat necessary for native species.

CES202.706 South-Central Interior Small Stream and Riparian

CES202.706 CLASSIFICATION

Concept Summary: This system is found throughout the Interior Low Plateau, Southern Ridge and Valley and Cumberland Plateau, Western Allegheny Plateau, lower elevations of the Southern Blue Ridge, and parts of the Cumberlands. Examples occur along small streams and floodplains with low to moderately high gradients. There may be little to moderate floodplain development. Flooding and scouring both influence this system, and the nature of the landscape prevents the kind of floodplain development found on larger rivers. This system may contain cobble bars with adjacent wooded vegetation and rarely have any marsh development, except through occasional beaver impoundments. The vegetation is a mosaic of forests, woodlands, shrublands, and herbaceous communities. Canopy cover can vary within examples of this system, but typical tree species may include *Platanus occidentalis, Acer rubrum var. trilobum, Betula nigra, Liquidambar styraciflua*, and *Quercus* spp. Shrubs and herbaceous layers can vary in richness and cover. Some characteristic shrubs may include *Hypericum densiflorum, Salix* spp., and *Alnus* spp. Small seeps dominated by sedges (*Carex* spp.), cinnamon and royal ferns (*Osmunda* spp.), and other herbaceous species can often be found within this system, especially at the headwaters and terraces of streams.

Related Concepts:

Distribution: This system ranges from the Interior Low Plateau to the Southern Blue Ridge and north into the Western Allegheny Plateau and portions of the Cumberlands. There would be limited and peripheral presence in the Upper East Gulf Coastal Plain. It also is present on Crowley's Ridge, an anomalous and distinct upland topographic feature that is embedded within the Mississippi River Alluvial Plain.

Nations: US

Concept Source: S. Menard, M. Pyne, R. Evans, R. White, D. Faber-Langendoen

Description Author: S. Menard, M. Pyne, R. Evans, R. White, D. Faber-Langendoen, S.C. Gawler, J. Drake

CES202.706 CONCEPTUAL MODEL

Environment: This system is found along fairly high-energy streams and rivers with steep banks, this system is subject to frequent flooding and can be subject to scouring depending upon the substrate. Some associations do not flood but instead are saturated zones or patches near the streams.

Key Processes and Interactions: Flooding and seed propagule dispersal caused by flooding events are the two most important processes affecting this system. The two processes vary widely depending upon size of stream, upstream land use and topography, presence or absence of invasive exotics that may displace native community types, etc.

Threats/Stressors: Alteration of the hydrologic regime is one of the most common and serious threats to this system, whether through increased or decreased water input and timing of the input. Significantly increased water input can result from increased runoff from the watershed, typically due to parts of the watershed being covered with impervious surfaces, such as roads, parking lots, or other urban or infrastructure development, or from removal of natural vegetation. Increased water input leads to more frequent and heavier flooding which can increase scouring and channel down-cutting. More rapid runoff from the watershed also increases the "flashiness" of the hydrologic regime, with the stream rising more quickly and higher right after precipitation events or snowmelt and then falling to lower levels later because there is little water left to drain slowly into the stream. Significantly decreased water input can result from diversions within the watershed or lowering of the water table, for those streams that receive groundwater. Land-use changes in the watershed can affect this system. Conversion of nearby land for agriculture can lead to increased erosion and subsequent sedimentation within this system as well as runoff of pesticides, herbicides, and fertilizer (Stevens and Cummins 1999).

This system tends not to have broad floodplains and is often narrow and linear. Thus, it may be more accessible for logging along the margins or through entire stands than floodplains on larger rivers. Logging can destroy or alter the vegetation composition and structure of a site directly or, if done near this system, lead to increased sedimentation and less water retention within the watershed.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the watershed is converted to urban or agricultural use or logged, leading to faster runoff, higher flood volumes, increased sedimentation and chemical input, and lower between flood streamflow. Collapse can also occur due to direct alteration of sites by logging or use for livestock grazing, resulting in elimination of native species, changes in vegetation structure, and possibly introduction of invasive weedy species.

M503. Central Hardwood Swamp Forest

CES202.018 Central Interior Highlands and Appalachian Sinkhole and Depression Pond

CES202.018 CLASSIFICATION

Concept Summary: This system of ponds and wetlands is found in the Interior Highlands of the Ozark, Ouachita, and Interior Low Plateau regions, and ranges north from the Southern and Central Appalachians to the northern Piedmont regions. Stands occur in basins of sinkholes or other isolated depressions on uplands. Soils are very poorly drained, and surface water may be present for extended periods of time, rarely becoming dry. Water depth may vary greatly on a seasonal basis and may be a meter deep or more in the winter. Some examples become dry in the summer. Soils may be deep (100 cm or more), consisting of peat or muck, with parent material of peat, muck or alluvium. Ponds vary from open water to herb-, shrub-, or tree-dominated. Tree-dominated examples typically contain *Quercus* species, *Platanus occidentalis, Fraxinus pennsylvanica, Acer saccharinum*, or *Nyssa* species, or a combination of these. In addition, *Liquidambar styraciflua* may be present in southern examples. *Cephalanthus occidentalis* is a typical shrub component. The herbaceous layer is widely variable depending on geography.

- Water Tupelo - Swamp Tupelo: 103 (Eyre 1980) <

Distribution: This system is found from the Ozark and Ouachita mountains east to the Southern and Central Appalachians and the northern Piedmont regions (?), including the unglaciated Interior Low Plateau and Ridge and Valley. It ranges from Missouri, West Virginia, Pennsylvania, and Delaware south to Arkansas, Alabama and Georgia.

Nations: US

Concept Source: M. Pyne, S. Menard, D. Faber-Langendoen

Description Author: M. Pyne, S. Menard, D. Faber-Langendoen, J. Drake

CES202.018 CONCEPTUAL MODEL

Environment: Examples of this system occur in basins of sinkholes or other isolated depressions on uplands. Soils are very poorly drained, and surface water may be present for extended periods of time, rarely becoming dry. The watershed of these sites is typically small so water depth may vary greatly on a seasonal basis, and may be a meter deep or more in the winter (Homoya and Hedge 1985). Some examples become dry in the summer. The rate of water level rise and fall may also be related to whether these sites have internal drainage within the karst features or are essentially closed depressions (Wolfe 1996). Soils may be deep (100 cm or more), consisting of peat or muck, with parent material of peat, muck or alluvium. Many of these ponds have their geologic origin as a more-or-less complete karst collapse feature. Some of them may display this geologic origin in a more explicit manner, with definite walls and exposed limestone or dolomite at the surface ("sinkholes"). Others are more subtle and exist as more gentle depressions, with no exposed surface geology ("depression ponds").

Key Processes and Interactions: Water depth may vary greatly on a seasonal basis, and may be a meter deep or more in the winter. Some examples become dry in the summer.

Threats/Stressors: Logging, drainage, and use as stock ponds are threats to this system. Logging can eliminate the forested swamp aspect of this system, though it may be transformed to a shrub- or herbaceous-dominated community within the same system. Drainage will eliminate this system as the species found in it require the wetland setting. Use as a stock pond can degrade sites through physical trampling, consumption of certain plants, and introduction of invasive species. Of 14 sinkhole swamps identified in Indiana in the early 1980s, only 4 were still somewhat natural (Homoya and Hedge 1985).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when hydrologic alterations result in drying of this system or when physical damage occurs to the system through logging or use of the site as a stock pond. Invasive species can become abundant in some sites, especially where other disturbances have created openings for the exotics species. Severe environmental degradation occurs when the site has significantly increased or decreased water inputs; or when there is significant physical disturbance from logging or recreational use. Moderate environmental degradation occurs when the site has moderately increased surface water inputs or decreased groundwater flow; or when there is moderate physical disturbance from logging. Severe disruption of biotic processes occurs when invasive exotic species become abundant (>10% cover) (Faber-Langendoen et al. 2011); or when tree canopy is reduced to <25%. Moderate disruption of biotic processes occurs when invasive exotic species are common (3-10% cover) (Faber-Langendoen et al. 2011) or when tree canopy is reduced to <40%.

CES202.605 Central Interior and Appalachian Rich Swamp

CES202.605 CLASSIFICATION

Concept Summary: These forested wetlands are scattered throughout the north-central Midwest (south of the Laurentian region), the north-central Appalachians and southern New England at low to mid elevations. They are found in basins where higher pH and/or nutrient levels are associated with a rich flora. Species include *Acer rubrum, Fraxinus nigra*, as well as calciphilic herbs. Conifers include *Larix laricina*, but typically not *Thuja occidentalis*, which is characteristic of more northern wetland systems. There may be shrubby or herbaceous openings within the primarily wooded cover. The substrate is primarily mineral soil, but there may be some peat development.

Related Concepts:
- Black Ash - American Elm - Red Maple: 39 (Eyre 1980) **<**
- Tamarack: 38 (Eyre 1980) **<**

Distribution: This system is found from central New England to the southern Great Lakes and south-central Minnesota south to northern Illinois, Indiana, Ohio, and Pennsylvania. It is not known to extend south into the Southern Blue Ridge.

Nations: CA, US

Concept Source: S.C. Gawler

Description Author: S.C. Gawler and J. Drake

CES202.605 CONCEPTUAL MODEL

Environment: Water can come from nutrient-rich groundwater or surface runoff. Sites are basins or low areas in floodplains, usually near the edge of the floodplain in a localized basin or at the base of a bluff where groundwater emerges. Soils are muck or fine-textured mineral. Small hummocks and depressions, created from tree tip-ups, sluggish streams, or tree root build up, create drier and wetter microsites within the system. Sites are usually flooded in the spring, and low areas may remain wet for all or most of the growing season, but if stands remain under water for multiple years, the trees die (Kost et al. 2007). The microsite differences allow a mixture of wet-mesic upland species and wetland species to exist in the herbaceous layer of this system (WDNR 2015).

Key Processes and Interactions: The hydrologic regime is critical to maintenance of this system. Sites must be wet or flooded for part of the growing season but not completely saturated or under water for too long over a large portion of the site. Periodic sustained floods or droughts can kill canopy trees and allow the mostly shade-intolerant canopy trees (*Fraxinus nigra, Fraxinus pennsylvanica, Larix laricina*) to regenerate. Trees are shallowly rooted in this system so wind can blow canopy trees over relatively easily. This creates gaps in the canopy and allows smaller trees enough light to reach the canopy. Windthrow contributes to hummock-and-hollow microtopography, which generates small-scale gradients in soil moisture and chemistry, contributing to floristic diversity.

Threats/Stressors: Alterations in wetland hydrology, logging, invasive plants, and emerald ash borer (*Agrilus planipennis*) are the prime threats to this system. Hydrologic alterations can occur due to ditching, road construction, or quarrying/mining that affect groundwater or surface waterflows into sites. Both reductions and increases in groundwater or surface water input can negatively affect this system. Partial drainage of a site can allow upland species to colonize. Increased surface waterflow can flood these swamps, changing both the hydrologic regime and water chemistry. This would likely lead to tree death and the development of a herbaceous marsh or shrub swamp. The proximity of roads has been shown to be negatively correlated with black ash health in Minnesota (Ward et al. 2006). Increased flooding can also transport sediment and higher nutrient loads. Logging can negatively impact this system through removal of trees, compaction of the soil, and creation of ruts. A serious threat to stands of this system that contain *Fraxinus* spp. is emerald ash borer (*Agrilus planipennis*). This exotic beetle has seriously affected *Fraxinus* spp. trees in southern Michigan and is projected to continue to spread throughout the range of *Fraxinus* spp. in the Midwest and Northeast by 2045 (DeSantis et al. 2012). After prolonged infestation, mortality of *Fraxinus* spp. is nearly 100% (Herms et al. 2010). Invasive plant species that can reduce diversity and alter community structure of this system include *Elaeagnus umbellata, Frangula alnus (= Rhamnus frangula), Lythrum salicaria, Phalaris arundinacea, Phragmites australis, Rosa multiflora, Typha angustifolia*, and *Typha x glauca*. *Frangula alnus* is especially problematic because it is capable of completely dominating the shrub and ground layers and altering a sites hydrology and soil nutrient characteristics (Kost et al. 2007).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when hydrologic alterations result in excessive flooding or drying of this system or when physical damage occurs to the system through logging. Invasive species can become abundant in some sites, especially where other disturbances have created openings for the exotics species. Projected rates of infestation and mortality to *Fraxinus nigra* trees in this system would eliminate that species as a component of the system by 2045 (DeSantis et al. 2012). In stands that have a high proportion of *Fraxinus nigra*, this will result in change; whether the site would become another stand of this system dominated by other trees still characteristic of the system, another type of swamp forest, a shrub swamp, or allow invasive species to invade and create a ruderal system, depends on current composition of the stand, local seed sources, the relative proportion of *Fraxinus nigra* in the stand, and other site factors. Swamps in southern Michigan with heavy overstory mortality of black ash have been invaded by *Phragmites* and invasive *Frangula alnus (= Rhamnus frangula), Typha*, and *Rosa multiflora*. It also appears as though the hydrology has dramatically shifted with the loss of canopy trees; the formerly saturated sites are now inundated (J. Cohen pers. comm.).

Severe environmental degradation occurs when the site has significantly increased or decreased water input; or when there is significant physical disturbance from logging or recreational use; or when siltation or increased nutrient input allow invasive species to become abundant. Moderate environmental degradation occurs when the site has moderately increased surface water inputs or decreased groundwater flow; or when there is moderate physical disturbance from logging or recreational use; or when siltation or increased nutrient input allow invasive species to become common. Severe disruption of biotic processes occurs when exotic species become abundant (>10% cover) (Faber-Langendoen et al. 2011); or when tree canopy is reduced to <25%. Moderate disruption of biotic processes occurs when exotic species are common (3-10% cover) (Faber-Langendoen et al. 2011) or when tree canopy is reduced to <40%.

CES202.700 North-Central Interior Wet Flatwoods

CES202.700 CLASSIFICATION

Concept Summary: This small-patch system is found throughout the northern glaciated Midwest ranging east into Lower New England and the Champlain Valley. It usually occurs on somewhat poorly drained uplands or in depressions associated with glacial features such as tillplains, lakeplains or outwash plains. Soils often have an impermeable or nearly impermeable clay layer that can create a shallow, perched water table. Saturation can vary, with ponding common during wetter seasons, and drought possible during the summer and autumn months. Microtopography and fluctuating moisture levels can lead to complexes of forest upland and wetland species occurring within this system. *Quercus palustris* and/ or *Quercus bicolor* typically dominate the wetter portions and are often associated with *Acer rubrum*. *Quercus alba, Quercus rubra*, and *Fagus grandifolia* are common in the better-drained areas. *Carya ovata* is a characteristic tree in the Champlain Valley. *Liquidambar styraciflua, Nyssa sylvatica, Acer saccharinum, Fraxinus americana*, and *Fraxinus pennsylvanica* are also common associates, though their occurrence varies somewhat by region. Understory herbaceous and shrub species present in examples of this system can vary. Stands with more dense tree cover have less shrub and herbaceous cover, while those with moderate tree canopy cover tend to have a dense understory. Some common species in the wetter portions include *Carex* spp., *Osmunda cinnamomea, Cephalanthus occidentalis, Alnus* spp., and *Ilex* spp. Flooding, windthrow, drought, and fire can influence this system.

Distribution: This system is found in the northern Midwest, southern Ontario, and portions of the northeastern U.S.

Nations: CA, US

Concept Source: S. Menard

Description Author: S. Menard, J. Drake and S.C. Gawler

CES202.700 CONCEPTUAL MODEL

Environment: This system usually occurs on poorly drained uplands or in depressions associated with glacial features such as tillplains, lakeplains, or outwash plains. Soils often have an impermeable or nearly impermeable clay layer that impedes waterflow. This favors flooding or ponding in the spring or after heavy rains. It also restricts subsurface water movement into the system and slows the growth of roots through it. Both of these factors lead to water deficits for the vegetation in the late summer and fall. These fluctuating moisture levels can lead to complexes of forest upland and wetland species occurring within this system. Overall topographic relief is very flat in this system though small tip-up mounds and depressions can occur from windthrow and often create small pockets with vegetation more typical of upland or swamp forest, respectively.

Key Processes and Interactions: The large seasonal change in local available moisture is key to the development and maintenance of this system. Plants must be able to tolerate the excessive available moisture (surface flooding or saturation) and drought conditions that occur in most growing seasons. Fire can occur after the system dries, typically late in the growing season. Fires rarely start in this system but under favorable conditions can spread from nearby fire-prone systems (typically prairies, oak savannas, or oak woodlands). Under proper hydrologic conditions, this system can be self-maintaining (Tecic and McCain 2001). With the often shallowly-rooted trees, strong winds can create canopy openings. Small-scale windthrow is a characteristic disturbance in flatwoods that influences composition and structure by creating canopy gaps that are suitable for the colonization and growth of light-dependent tree seedlings and saplings, shrubs, and herbs. Windthrow also tips and uproots trees, creating pit-and-mound topography that provides suitable microhabitats for a diversity of plant species (Slaughter et al. 2010).

Threats/Stressors: Changes to the hydrologic regime and conversion to agricultural or urban uses are the most common threats to this system. Road building and urban development can cut off or increase waterflow; drainage systems for nearby agriculture can remove water from the system. *Fraxinus* spp. and *Ulmus* spp. can invade and become common if the flooding/drying regime is not maintained and fires do not move through the ground layer (Bowles et. al 2003). Invasive shrubs are a problem in some areas. Very few examples remain as almost all have been converted to agriculture. Those sites that do remain typically occur as isolated woodlots in agricultural or urban landscapes, degraded by landscape-scale fragmentation and hydrologic alteration. Additional disturbances that have reduced viability of remnant flatwoods over the past century include the introduction of non-native pests and pathogens (e.g., elm blight and emerald ash borer), invasive plants, and excessive deer herbivory, which have significantly altered community structure, species composition, and successional trajectory (Slaughter et al. 2010). Invasive plants that threaten diversity and structure include *Alliaria petiolata, Berberis thunbergii, Elaeagnus umbellata, Frangula alnus (= Rhamnus frangula), Ligustrum vulgare, Lonicera japonica, Lonicera maackii, Lonicera morrowii, Lonicera sempervirens, Lonicera tatarica, Lonicera x bella, Lonicera xylosteum, Rhamnus cathartica*, and *Rosa multiflora* (Kost et al. 2007).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from changes to the hydrology of the system. Excessive water can drown trees and prevent regeneration of canopy and understory species and will favor a shrub swamp or herbaceous marsh. More consistent flooding can favor more typical swamp trees. Prolonged lack of water will allow upland species to invade and will increase the risk of crown fires. Severe environmental degradation occurs when the site has significantly increased or decreased water input; or when there is significant physical disturbance from logging, development, or recreational use. Moderate environmental degradation occurs when the site has moderately increased or decreased water input; or when there is moderate physical disturbance from logging or recreational use. Severe disruption of biotic processes occurs when invasive exotic species become abundant (>10% cover) (Faber-Langendoen et al. 2011). Moderate disruption of biotic processes occurs when invasive exotic species are common (3-10% cover) (Faber-Langendoen et al. 2011).

CES202.336 Piedmont Upland Depression Swamp

CES202.336 CLASSIFICATION

Concept Summary: This system represents isolated wetlands primarily of the Piedmont in small, shallow basins in upland settings where water pools due to limited soil drainage. Most known examples occur over mafic bedrock. The typical hydrology is seasonally flooded. Most examples consist of forests of wetland oaks, but a few are treeless or open-canopied ponds. Vegetation in open ponds is typically zoned with an outer ring of trees, a more interior ring of shrubs, herbs and vines, and a central area with or without standing water year round depending on precipitation. This system also includes the wet hardwood forests ("Iredell Flatwoods" or "Gabbro Glades") which occur on gently sloping terrain or shallowly depressed upland flats over gabbro-derived clays in the Piedmont of Georgia and South Carolina. A few examples of this system occur in the adjacent Southern Blue Ridge; these are extremely rare and small-patch examples.

- Willow Oak - Water Oak - Diamondleaf (Laurel) Oak: 88 (Eyre 1980) **<**

Distribution: This system ranges throughout the Piedmont, from Virginia to Alabama. A few examples attributable to this system are found in the adjacent Southern Blue Ridge.

Nations: US

Concept Source: M. Schafale

Description Author: M.P. Schafale, M. Pyne and C. Nordman

CES202.336 CONCEPTUAL MODEL

Environment: This system occurs in small, shallow basins or gentle swales on flat to rolling upland sites, and occasionally in depressions on narrow, steeper ridgetops. Soils have a dense clay hardpan or occasionally bedrock which limits internal drainage. Rainwater accumulates in the basins and persists through the wet season, occasionally persisting all year. Only a few kinds of rock are known to form these depressions. Most examples occur on soils derived from mafic rocks such as gabbro or diabase, but a few occur over slates or mafic to felsic tuffs where a dense clay hardpan has formed, and a few occur over unfractured bedrock. Some sites in Georgia have soils with shrink-swell tendencies which allow for both wetness and extreme dryness and inhibit the survival of trees, promoting an open woodland structure (Edwards et al. 2013). Examples in North Carolina may lack trees in the deepest water parts of basins. A few occur over bedrock of other kinds. Rock chemistry affects soil chemistry and influences variation in vegetation, but hydroperiod is a more important influence.

Key Processes and Interactions: The dynamics of water levels are the most important factor in these systems, differentiating them from the surrounding uplands and differentiating the various communities within the system. These wetlands typically have very small watersheds, and input of water comes largely from rainfall. Variation in rainfall patterns will drive variation in duration of flooding, though most upland depression swamps have an outlet that limits water depth. Fire may be naturally rare in some examples of these systems, such as in North Carolina. Though they could naturally be exposed to fires occurring in the surrounding uplands, standing water and lack of continuous fuel would limit fires to the edges, expect perhaps very rarely in early fall. Other examples in South Carolina and Georgia are naturally prone to drying out and to fire, and have an open woodland structure with a grassy understory, typical of wet flatwoods which naturally burned (Edwards et al. 2013). Presumably important as a dynamic process is the migration of amphibians, which concentrate in these systems for breeding. Ecosystem dynamics may be strongly affected by the suitability of surrounding uplands for amphibian adult habitat.

Threats/Stressors: Threats include clearing, conversion and drainage for agriculture or intensive forestry. These threats to larger examples could leave the remaining sites small, isolated and degraded. Fragmentation is a threat. Invasive shrub *Ligustrum sinense*, vine *Lonicera japonica*, and grasses *Microstegium vimineum* and *Arthraxon hispidus* are threats. Logging of *Quercus* spp. and *Carya* spp. can lead to succession to wet forests dominated by ruderal trees, such as *Acer rubrum* and *Liquidambar styraciflua* and invasive exotic plants in the shrub and herbaceous vegetation layers. A more subtle threat comes from loss of the upland habitat used by adult amphibians which breed in these wetlands. Altered fire frequency is a threat or stressor to some upland depression swamps.

Ecosystem Collapse Thresholds: Ecological collapse in this ecosystem results from drainage, invasion or dominance by exotic shrubs and herbaceous plants, and especially the loss of the characteristic tree canopy of *Quercus* spp. The replacement of the *Quercus* spp. tree canopy by *Acer rubrum, Liquidambar styraciflua* or *Pinus taeda* indicates ecological decline, as does strong dominance of the herbaceous or low-shrub layer by exotic plant species. Collapse is also indicated if ditching eliminates seasonal standing water in the system. Ecological collapse is promoted by the destruction of adjacent upland vegetation, which leads to negative edge effects and exacerbates invasion of uncharacteristic or exotic plant species, and which can eliminate or degrade the breeding amphibian community. Edge effects have increased due to loss of habitat and fragmentation, sites are often isolated from each other and surrounded by anthropogenic or ruderal vegetation. Upland depression swamp systems that require periodic fire are negatively impacted by fire suppression or disruption of surrounding natural corridors of fire-prone vegetation.

CES203.479 South-Central Interior / Upper Coastal Plain Flatwoods

CES203.479 CLASSIFICATION

Concept Summary: This system represents mostly *Quercus stellata*-dominated "xerohydric flatwoods" of limited flat areas of the most inland portions of the East Gulf Coastal Plain in western Kentucky, as well as in the nearby Shawnee Hills in the western Interior Low Plateau. The core of the area is referred to as the Jackson Purchase or "Jackson Plain." There is some local variability in the expression of this system along a hydrologic/microtopographic gradient. The elevated areas are composed of somewhat coarser-textured soils and retain less moisture than do the lower areas, although both occur in a tight local mosaic. The soils appear to have well-developed subsurface hardpans. Thus, soil moisture fluctuates widely throughout the growing season, from saturated to very dry.

Related Concepts:

- Post Oak - Blackjack Oak: 40 (Eyre 1980) <

Distribution: This system occurs in limited areas of the most inland portions of the East Gulf Coastal Plain in western Kentucky and adjacent Tennessee (the "Jackson Purchase" or "Jackson Plain" region; 222Cb; 74b in part), as well as in the nearby "Shawnee Hills" of the Interior Low Plateau (222Dh, 222Di; 72c) of Kentucky and adjacent Indiana. The core of the area from which this system was initially described is referred to as the Jackson Purchase or "Jackson Plain," where these areas have long been recognized as a distinctive subdivision within this region (Davis 1923, Bryant and Martin 1988). It is known from the Clarks River National Wildlife Refuge (KSNPC 2009).

Nations: US

Concept Source: R. Evans and M. Evans

Description Author: R. Evans, M. Evans, M. Pyne and C. Nordman

CES203.479 CONCEPTUAL MODEL

Environment: The soils appear to have well-developed subsurface hardpans, the impermeability of which contributes to shallowly perched water tables during portions of the year when precipitation is greatest and evapotranspiration is lowest (not due to overbank flooding). Thus, soil moisture fluctuates widely throughout the growing season, from saturated to very dry, a condition sometimes referred to as xerohydric (M. Evans pers. comm. 2006). Examples of this system occur along the northeastern flank of the Upper East Gulf Coastal Plain ecoregion where loess deposits thin out and gravelly or sandy soils predominate. Examples occur on relatively high flat areas that are not directly affected by overbank flooding. These environments include ancient Quaternary or Tertiary post-glacial meltwater lakebeds and high terraces of the Upper Gulf Coastal Plain. The most typical soil is Okaw Silt Loam. The same system is found in the Shawnee Hills of Kentucky (M. Evans pers. comm. 2006). The lakes were originally formed by glacial damming of the Ohio River. It could also occur on upland plains and flat ridgetops (KSNPC 2009).

Key Processes and Interactions: Fire was an important natural process in this system, and well-burned examples tend to be relatively open-canopied with well-developed herbaceous layers (M. Evans pers. comm. 2006). The natural dynamics of wetness and drought and the patchy variation in soil wetness probably led to patchy fires in this habitat. Due to subsurface hardpans, tree rooting is restricted which makes trees more prone to windthrow. High wind and ice storms contribute to forest openings (Landfire 2007a).

Threats/Stressors: Threats include clearing, grazing pressure, invasion by woody plants, conversion to exotic cool-season grasses and lack of fire (Nelson 2005). Invasive shrubs *Ligustrum sinense, Lonicera maackii*, vine *Lonicera japonica*, and grasses *Microstegium vimineum* and *Arthraxon hispidus* are threats. Loss of habitat and fragmentation of the remaining flatwoods habitat have been pronounced. The small size of remaining flatwoods areas contributes to the lack of fire and invasion by invasive exotic plants from seed sources in surrounding ruderal habitat areas. Few areas remain of this flatwoods habitat.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of habitat, fragmentation of remaining habitat, drainage, lack of fire, canopy and midstory closure, loss of herbaceous ground cover, and invasion and then dominance by invasive exotic plants. Ecosystem collapse is characterized by the remaining habitat consisting of small, isolated and degraded habitat patches, in which drainage, lack of fire, and invasive exotic plants have resulted in a closed-canopy forest, lacking or with very sparse herbaceous ground cover, and with shrub and vine layers partially composed of invasive exotic plants.

CES203.480 South-Central Interior / Upper Coastal Plain Wet Flatwoods

CES203.480 CLASSIFICATION

Concept Summary: This system represents predominantly wet flatwoods of limited areas of the most inland portions of the East Gulf Coastal Plain in western Kentucky, as well as related broad, flat areas of the western Interior Low Plateau. This part of the Coastal Plain is referred to as the Jackson Purchase or "Jackson Plain." They tend to be confined to relatively small areas near the eastern flank of the region where loess deposits thin out. Unlike ~South-Central Interior / Upper Coastal Plain Flatwoods (CES203.479)$$ of the same general region (which is typified by complex microtopography), this system occupies broad flats underlain by fragipans. These fragipans impede the downward migration of water, resulting in wet conditions for portions of the year. Fire was important, probably maintaining relatively open-canopied stands. Stands are dominated by hardwood trees, including *Acer rubrum, Fagus grandifolia, Liquidambar styraciflua, Quercus falcata, Quercus pagoda*, and *Quercus palustris*.

Related Concepts:

- Pin Oak - Sweetgum: 65 (Eyre 1980) **<**
- Sweetgum - Willow Oak: 92 (Eyre 1980) **<**

Distribution: The primary range of this system is limited areas of the "Jackson Purchase" or "Jackson Plain" of Kentucky and possibly related areas in adjacent western Tennessee, as well as related broad, flat areas of the western Interior Low Plateau. Examples in the Pennyroyal Plain (of the western Interior Low Plateau) have been known for many years and referred to as "pondywoods" or "crawfishy land" (Chester et al. 1995). They are also known from the Shawnee Hills of Kentucky, on periglacial lakebeds (M. Evans pers. comm. 2006), and related wet flatwoods have been discerned from wetland modeling and confirmed in the Moulton Valley of Alabama (A. Schotz pers. comm. 2006) and are included here. It is assumed to cross the Ohio River into adjacent Indiana.

Nations: US

Concept Source: R. Evans and M. Evans

Description Author: R. Evans, M. Evans, M. Pyne and C. Nordman

CES203.480 CONCEPTUAL MODEL

Environment: These flatwoods have long been recognized as the primary vegetation type of a distinctive subdivision within the Upper East Gulf Coastal Plain region (Davis 1923, Bryant and Martin 1988), as well as related areas of the western Interior Low Plateau. Within the "Jackson Plain" portion of the Upper East Gulf Coastal Plain, these flatwoods tend to be confined to relatively small areas near the eastern flank of the "Jackson Plain" region where the loess deposits thin out. Like drier *Quercus stellata* flatwoods of these areas (which are typified by microtopographic variation), this system occupies broad flats underlain by fragipans. These fragipans impede the downward migration of water resulting in wet conditions for longer portions of the year. In the Jackson Plain area the soils include Henry silt loam, Routon silt loam (Bryant and Held 2001) and Calloway silt loam (Karathanasis et al. 2003). Fire is probably relatively infrequent in this system (M. Evans pers. comm.). In the Pennyroyal Plain, this system occurs on upland flats and depressions with poor drainage, underlain by limestone; soils include Robertsville silt loam (Chester et al. 1995) and Henry silt loam (M. Evans pers. comm.).

Key Processes and Interactions: Fire was an important but relatively infrequent natural process in this system, probably maintaining relatively open-canopied stands (M. Evans pers. comm.). Under such conditions *Andropogon gerardii* and *Chasmanthium* spp. may have dominated the herbaceous ground cover. Flooding and saturation are part of the natural dynamics. Due to the fragipan, deep rooting of trees is limited and the trees are particularly prone to windthrow during storms. This has helped maintain open woodland conditions.

Threats/Stressors: Threats include clearing, conversion and drainage for agriculture. Most historic occurrences have been cleared, drained and tiled, and remaining sites are small, isolated and degraded. Fragmentation and lack of fire are also threats. Invasive shrubs *Ligustrum sinense, Lonicera maackii*, vine *Lonicera japonica*, and grasses *Microstegium vimineum* and *Arthraxon hispidus* are threats. Tiling since the 1960s has contributed to the drainage of sites which previously were considered too wet to farm. Logging of oaks and hickories can lead to succession to wet forests dominated by ruderal trees, such as *Acer rubrum* and *Liquidambar styraciflua* and invasive exotic plants in the shrub and herbaceous vegetation layers.

Ecosystem Collapse Thresholds: Ecological collapse in this ecosystem results from invasion by exotic plant species, drainage, and dominance by invasive exotic shrubs and herbaceous plants. Decline in *Quercus* spp. and *Carya* spp. and their replacement by *Acer rubrum, Juniperus virginiana*, and *Liquidambar styraciflua* are indications of ecological decline. Ecological collapse is promoted by the fragmentation of the landscape, within the historic range of this ecological system. In the highly fragmented landscape of today, distances from other patches of this ecological system are large, with increased edge effects. These factors help promote the dominance by invasive exotic plants, which may be prolific seeders and easily dispersed across the fragmented landscape. Edge effects have increased due to loss of habitat and fragmentation. The drier parts of the overall landscape were converted to agriculture mainly prior to 1960, after that tiling was used to convert wetter areas to agriculture.

M028. Great Plains Flooded & Swamp Forest

CES303.676 Northwestern Great Plains Floodplain

CES303.676 CLASSIFICATION

Concept Summary: This ecological system is found in the floodplains of medium and large rivers of the northwestern Great Plains, ranging from the Dakotas Mixedgrass Prairie west through the Northern Great Plains Steppe and north into Canada. This system occurs in the upper Missouri River Basin and includes parts of the Niobrara, White, Cheyenne, Little Missouri, Yellowstone, Powder, Bighorn, Milk, and Musselshell rivers. Alluvial soils and periodic, intermediate flooding (every 5-25 years) typify this system. These are the perennial big rivers of the region with hydrologic dynamics largely driven by snowmelt in the mountains, rather than local precipitation events. Dominant communities within this system range from floodplain forests to wet meadows to gravel/sand flats, however, they are linked by underlying soils and flooding regime. Dominant species are *Populus balsamifera ssp. trichocarpa* or *Populus deltoides* and *Salix* spp. *Fraxinus pennsylvanica, Salix amygdaloides*, and *Ulmus americana* are common in some stands. If present, common shrub species include *Amorpha fruticosa, Cornus drummondii, Cornus sericea, Symphoricarpos occidentalis, Salix exigua, Salix interior*, and *Salix planifolia*. Grass cover underneath the trees is an important part of this system and is a mix of cool-season graminoid species, including *Carex pellita, Elymus lanceolatus, Pascopyrum smithii*, and *Schoenoplectus* spp., with warm-season species such as *Panicum virgatum, Schizachyrium scoparium*, and *Spartina pectinata*. This system is often subjected to heavy grazing and/or agriculture and can be heavily degraded. In Montana, most occurrences are now degraded to the point where the cottonwood overstory is the only remaining natural component; undergrowth is dominated by *Bromus inermis*, or a complex of pasture grasses. Another factor is that groundwater depletion and lack of fire have created additional species changes. In most cases, the majority of the wet meadow and prairie communities may be extremely degraded or extirpated from the system.

Distribution: This system is found in the northwestern Great Plains, north of the North Platte River through southern Canada. It is found in eastern Montana along the upper Missouri, Yellowstone, Bighorn, Milk, and Musselshell rivers; in northern Nebraska and the Dakotas on the Niobrara, upper Missouri, White, Cheyenne, and Little Missouri rivers; and in Canada on the Saskatchewan River.

CES303.677 Northwestern Great Plains Riparian

CES303.677 CLASSIFICATION

Concept Summary: This system is found in the riparian areas of medium and small rivers and streams throughout the northwestern Great Plains. It is likely most common in the Northern Great Plains Steppe. This system occurs in the Upper Missouri and tributaries starting at the Niobrara, White, Cheyenne, Belle Fourche, Moreau, Grand, Heart, Little Missouri, Yellowstone, Powder, Tongue, Bighorn, Wind, Milk, Musselshell, Marias, and Teton rivers; and in Canada, the Southern Saskatchewan, Red Deer and Old Man rivers to where they extend into ~Rocky Mountain Lower Montane-Foothill Riparian Woodland and Shrubland (CES306.821)$$ or ~Northern Rocky Mountain Lower Montane Riparian Woodland and Shrubland (CES306.804)$$. These are found on alluvial soils in highly variable landscape settings, from deep cut ravines to wide, braided streambeds. Hydrologically, these tend to be more flashy with less developed floodplain than on larger rivers, and typically dry down completely for some portion of the year. Dominant vegetation shares much with generally drier portions of larger floodplain systems downstream, but overall abundance of vegetation is generally lower. Communities within this system range from riparian forests and shrublands to gravel/sand flats. Dominant species include *Populus deltoides, Populus balsamifera ssp. trichocarpa, Salix* spp., *Artemisia cana ssp. cana*, and *Pascopyrum smithii*. These areas are often subjected to heavy grazing and/or agriculture and can be heavily degraded. Another factor is that groundwater depletion and lack of fire have created additional species changes.

CES303.678 Western Great Plains Floodplain

CES303.678 CLASSIFICATION

Concept Summary: This ecological system is found in the floodplains of medium and large rivers of the western Great Plains. It occurs on the lower reaches of the North and South Platte, Platte, Arkansas, and Canadian rivers, among others. Alluvial soils and periodic, intermediate flooding (every 5-25 years) typify this system. These are the perennial big rivers of the region with hydrologic dynamics largely driven by snowmelt in the mountains, instead of local precipitation events. Dominant communities within this system range from floodplain forests to wet meadows to gravel/sand flats; however, they are linked by underlying soils and the flooding regime. Dominant species include *Populus deltoides* and *Salix* spp. Grass cover underneath the trees is an important part of this system and is a mix of tallgrass species, including *Panicum virgatum* and *Andropogon gerardii*. Sometimes, *Tamarix* spp. and less desirable or exotic grasses and forbs can invade degraded areas within the floodplains, especially in the western portion of the province. These areas are often subjected to heavy grazing and/or agriculture and can be heavily degraded. Groundwater depletion and lack of fire have created additional alterations in species composition. In most cases, the majority of the wet meadow and prairie communities may be extremely degraded or extirpated from examples of this system.

Distribution: This system is found along major river floodplains in the southern and central portions of the Western Great Plains Division. This system occurs on the middle to lower reaches of the North and South Platte, Platte, Arkansas, and Canadian rivers, among others. Major river floodplains of eastern Wyoming and Montana are included in ~Northwestern Great Plains Floodplain (CES303.676)$$ and not this system.
Nations: US
Concept Source: S. Menard and K. Kindscher
Description Author: S. Menard, K. Kindscher, K.A. Schulz, L. Elliott and J. Drake

CES303.678 CONCEPTUAL MODEL

Environment: This system is found primarily in Quaternary alluvium along floodplains of medium and large rivers. Soils are primarily alluvial and range from sandy to dense clays. This system occurs on valley floors of large rivers and perennial streams where significant alluvial deposition occurs, and tends to occupy broad valley bottoms with deep alluvial deposits. In Texas, this system is found within the Clear Fork of the Middle Brazos watersheds and occurs on Loamy Bottomland, Clayey Bottomland, and Draw ecoclasses. Broad alluvial deposits commonly occur and are generally mapped as bottomland soils (Elliott 2011). Water velocity and volume change greatly during the year as rains and snowmelt deliver pulses of water and seasonal droughts (typically including winter in the northern portion of this system's range when most precipitation is frozen) result in low water. Within a short distance on a river floodplain, different soil textures can be found. Within the space of a few years, floods of differing magnitude can deposit sand over silt or vice versa, resulting in complex soil topology.

Key Processes and Interactions: Periodic and intermediate flooding (i.e., every 5-25 years) constitutes the major process influencing this system. Flood frequency depends on precipitation patterns within the watershed and proximity to the main channel. Areas adjacent to the main channel or low islands within the channel are flooded most often, while areas further from the channel or on terraces may only be flooded once every several years. Free-flowing rivers migrate across their floodplain, cutting new channels or eroding the bank on one side while building up the bank on the other, so the flooding regime of any one point in the floodplain will change over time. Flooding redeposits alluvium, eroding some areas and aggrading others, can bury or wash away small plants, and redistributes nutrients, especially in less frequently flooded zones where silt and clay tend to be deposited. These processes open up new areas for colonization. In the newly exposed or reworked areas, there is a common succession sequence of annual herbaceous species followed by shrub *Salix* spp., followed by *Populus deltoides* and *Salix amygdaloides*, followed by a number of trees, including *Acer negundo, Carya illinoinensis, Celtis laevigata, Celtis occidentalis, Fraxinus pennsylvanica*, and *Ulmus americana* (Bellah and Hulbert 1974). This sequence can be reset by major floods and erosion/deposition.

Fire could impact parts of this system. Most of the forests in this system were not fire-prone due to the lack of litter, frequent flooding, and relatively protected landscape position in the river valley with wetlands often near, but forests on higher, coarser soils or wet-mesic prairies on the margins of the floodplain could become dry in late summer and burn, if an ignition source was present.

Threats/Stressors: This system has been heavily impacted by human activities. Agricultural development has affected many examples of this system. Direct conversion to cropland or pastures can destroy this system. Irrigation has had a major effect both by removing water from some parts of the system and, conversely, by providing more consistent flow in the summer through the return flow of water used for irrigation. Other indirect effects of agricultural within or near the floodplain include increased sediment loads from erosion and chemical pollution from pesticides, herbicides, and fertilizer. The flooding and channel migration that is important in maintaining this system has been affected by attempts to contain the channel in its current location through bank armoring (riprap or other bank stabilization techniques) and channelization (man-made levees, dredging, wing dams, closing dams). While these may not immediately affect large areas of this system, the changes to the flooding regime have longer term impacts. Dams, typically built for irrigation or recreation, have immediate impacts by flooding the reservoir area and increasing the amount of open water compared to floodplain. They have longer term effects by changing the flooding pattern, reducing the amplitude low water in the upstream pool and of high water both upstream and downstream. Dams also trap much of the sediment being transported by the river and reduce the erosion and deposition rates downstream (Johnson 1992).

Grazing by native species was not likely an important factor shaping this system, but grazing domestic livestock can impact this system and lead to decreased cover of many graminoids and some sensitive forbs. Weedy invasives can dominate parts of the floodplain. Several herbaceous species are particularly aggressive and can dominate floodplain marshes, sometimes forming near monocultures. These include *Phragmites australis, Phalaris arundinacea*, and *Typha x glauca*. Other weedy species can become abundant in the understory of floodplain forests.

A serious threat to stands of this system that contain *Fraxinus pennsylvanica* is emerald ash borer (*Agrilus planipennis*). This exotic beetle has seriously affected *Fraxinus* spp. trees in southern Michigan and is projected to continue to spread throughout the range of *Fraxinus* spp. in the Midwest and Northeast by 2045 (DeSantis et al. 2012). After prolonged infestation, mortality of *Fraxinus* spp. is nearly 100% (Herms et al. 2010).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur over time when the flooding regime and channel migration are greatly altered, eliminating the processes required for maintenance of this system. Without direct conversion, this system will likely persist with these perturbations, but over time the floodplain system will shrink or be eliminated. More immediate collapse tends to occur when sites are largely or wholly converted to agricultural or urban uses, resulting in a change to a non-natural system or to a significant change in structure and species composition. Invasive species can eliminate this system by choking out other species and eliminating the habitat necessary for native species.

CES303.956 Western Great Plains Riparian

CES303.956 CLASSIFICATION

Concept Summary: This ecological system is found in the riparian areas of medium and small rivers and streams throughout the western Great Plains. It is most common in the Shortgrass Prairie and extends west as far as the Rio Grande in New Mexico, north into the Wyoming Basins and east into southwestern Nebraska, western Kansas and panhandles of Oklahoma and Texas. It includes primarily small, often narrow feeder streams that originate on the plains. However, it also includes reaches of major rivers, including the North and South Platte, portions of the Arkansas, Cimarron, Canadian and upper Pecos rivers, that have relatively narrow floodplains when compared to the Platte, for example. This system is found on alluvial soils in highly variable landscape settings, from deep cut ravines to wide, braided streambeds. The smaller streams hydrologically tend to be flashy and may dry down completely for some portion of the year. Main-stem larger rivers have a less well-developed floodplain than their downstream counterparts (e.g., the Platte and Missouri rivers), that are classified as floodplain systems. Water sources for this riparian system include snowmelt runoff, springs and summer rains. This system includes numerous smaller prairie rivers and streams that are often groundwater-fed, such as the Arikaree River and the Republican River. Dominant vegetation shares much with generally drier portions of larger floodplain systems downstream, but overall abundance of vegetation is generally lower. Communities within this system range from riparian forests and shrublands to herbaceous vegetation and gravel/sand bars. Dominant species include *Artemisia cana ssp. cana, Forestiera pubescens, Panicum obtusum, Panicum virgatum, Pascopyrum smithii, Populus deltoides, Salix amygdaloides, Salix exigua, Schizachyrium scoparium*, and *Sporobolus cryptandrus*. On the North Platte in southeastern Wyoming, *Fraxinus pennsylvanica* may be present to dominant. These areas are often subjected to heavy grazing and/or agriculture and can be heavily degraded. *Tamarix* spp., *Elaeagnus angustifolia*, and less desirable grasses and forbs can invade degraded examples up through central Colorado. Groundwater depletion and reduction in overbank flooding has resulted in additional species changes. In Texas, several cover types are represented within this system, including forest, woodland, shrubland, and herbaceous vegetation.

Forests and woodlands may have species such *Populus deltoides, Salix nigra, Celtis laevigata, Juniperus ashei*, and *Juniperus pinchotii*. *Quercus fusiformis* occurs here at the western edge of its range but may be locally dominant. Shrubland portions are frequently dominated by *Prosopis glandulosa* but may also contain species such as *Salix nigra* and *Sapindus saponaria var. drummondii*. Herbaceous vegetation may be represented by marshes associated with small drainages and dominated by *Schoenoplectus* spp., *Eleocharis* spp., and other sedges.

Distribution: This system is found in riparian areas of medium and small rivers and streams throughout the western Great Plains. It is most common in the Central Shortgrass Prairie and Southern Shortgrass Prairie, but extends west as far as the Rio Grande in New Mexico and into the Wyoming Basins. This system occurs on the North Platte, South Platte, Cache La Poudre, Arkansas, Purgatoire, middle Rio Grande, the upper reaches of the Cimarron, Canadian, and Pecos rivers, and smaller prairie rivers and streams, such as the Arikaree and Republican rivers. Its occurrence is confirmed for Texas (Elliott 2011).

Nations: US

Description Author: P. Comer, G. Kittel, K.A. Schulz, L. Elliott

CES303.956 CONCEPTUAL MODEL

Environment: This riparian system lacks a broad, well-developed floodplain. It includes primarily small, often narrow feeder streams that originate on the plains. However, it also includes reaches of major prairie rivers, including the North and South Platte, portions of the Arkansas, Cimarron, Canadian and upper Pecos rivers, that have relatively narrow, less well-developed floodplain when compared to their downstream counterparts (e.g., the Platte and Missouri rivers) that are classified as floodplain systems. Water sources for this riparian system include snowmelt runoff, springs and summer rains. The substrates are highly variable depending on landscape settings that range from deep-cut ravines to wide, braided streambeds, but tend to occur on relatively young alluvial substrates. In Texas this system occurs along headwater streams and generally occurs over upland soils that have developed in place over a variety of bedrock types, often limestone in parts of Texas (TPWD Phase 1). This system occurs along drainages that may be intermittent and tend to be dominated by erosional processes (as opposed to depositional processes) for example within the drainage of the Clear Fork of the Middle Brazos River of Texas (Elliott 2011). As this system is mapped by TPWD (Elliott 2011), it by definition occurs outside of areas mapped as bottomland soils. Soils are therefore mapped with soils of the surrounding uplands.

Key Processes and Interactions: Hydrologically, these sites tend to have a more flashy flood regime hydrology and narrow, less well-developed floodplains than those found on larger rivers, which are classified as floodplain systems. These streams may dry down completely for some portion of the year. Water sources for this riparian system are largely snowmelt runoff, springs and summer rains. This system includes numerous smaller prairie rivers and streams that are often also groundwater-fed, such as the Arikaree River and the Republican River.

From CNHP (2010b): Fluvial processes such as channel narrowing, meandering, and flood deposition play a key role in the dynamics of Western Great Plains streams (Friedman et al. 1996, Scott et al. 1996). Various combinations of these three factors may be acting at any particular site, depending on geologic and climate factors, including flow variability, sediment load, and gradient. Channel narrowing results when the stream abandons a portion of the former channel bed or when flow ceases in a channel. Narrowing happens when a period low flow prevents the reworking of the entire channel bed, and allows vegetation to establish. Newly established vegetation reduces erosion and promotes the deposition of fine sediment. On meandering streams, cutbanks on the outside bends gradually erode and the sediments are deposited downstream as point bars on the insides of bends. Vegetation is able to establish on these newly created moist surfaces. Flood deposition can produce bare, moist surfaces for tree establishment that are above the normal channel bed, and protected from normal flow-related disturbance.

Streamflows are highly variable in Western Great Plains streams. It is not known how much flows have changed since settlement, but a certain amount of intra- and inter-annual variation appears to be normal (Matthews 1988). Nearly all prairie steams are susceptible to lack of water during some years, if not annually. Although most streams receive groundwater inflow, recharge to groundwater is low due to limited precipitation, and water loss to evapotranspiration can be significant. The minimal to moderate groundwater inflow and the large loss of both groundwater and surface water to evapotranspiration resulted in many high plains streams having little to no flow under presettlement conditions, except during spring floods (Covich et al. 1997). Since settlement, variation in water flow is regulated by dams and diversions, groundwater levels have been reduced, agricultural activities have increased siltation rates and introduced both non-native species and chemical changes, and native grazers have been largely replaced by domestic cattle. Possible effects of altered fire regime in uplands are not known.

Additional factors affecting the dynamics of this system include drought and grazing. Riparian vegetation is affected by climatic drought that reduces soil moisture in the unsaturated zone and decreases streamflows, which reduces recharge and lowers the alluvial water table (Friedman et al. 1997). The elimination of beavers from most of the plains watersheds probably decreased water storage and increased variability in plains streams, although some of these changes were later reversed by dam construction (Friedman et al. 1997). The replacement of native grazers, especially bison, with fenced cattle has changed the regeneration patterns of cottonwood since settlement.

Threats/Stressors: These areas are often subjected to heavy grazing and/or agriculture and can be heavily degraded. Non-native *Tamarix* spp., *Elaeagnus angustifolia*, forage grasses (*Agrostis gigantea, Bromus inermis, Dactylis glomerata, Elymus repens, Poa pratensis, Phleum pratense*), and less desirable grasses and forbs such as *Polypogon monspeliensis, Cirsium arvense, Euphorbia esula* can invade degraded examples up through central Colorado (Kittel et al. 1999b, Muldavin et al. 2000a, Carsey et al. 2003a). Reduced annual flooding may cause channel down-cutting that can reduce the number of sandbars that provide seedbed for the characteristic tree species such as *Populus deltoides* (Scott et al. 1996). Groundwater depletion and stream diversion have frequently resulted in old gallery cottonwood riparian woodlands lacking cottonwood regeneration and encroachment of upland vegetation.

Other human impacts include highway, bridge, and pipeline construction; channel modifications for flood control; recreation; industrial and residential development; agriculture; irrigation; livestock grazing; and gravel mining. Offsite disturbances in the watershed that change watershed hydrology can also have adverse effects on the composition and productivity of riparian plants and corresponding animal associations (Manci 1989). Conversion of this type has commonly come from water developments/reservoirs and dryland wheat and irrigated agriculture especially hay meadows dominated by non-native forage grasses (CNHP 2010b). Severe alteration of hydrological regime such as major diversions can convert riparian areas to intermittent streams dominated by upland vegetation as wetland species are eliminated.

Common stressors and threats include altered hydrologic regime from water development, channel modifications for flood control, urban and industrial effluent discharge, and gravel mining. Excessive livestock use leads to a shift in plant species composition to more grazing- and disturbance-tolerant species including invasive non-native forage species. Potential climate change effects could include alterations to the hydrologic regime causing reductions of flows available for natural processes and plant and animal communities, if climate change has predicted the effect of less effective moisture with increasing mean temperature (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from groundwater pumping that lowers the base level, causing the stream to become a losing reach, which dries up the stream and lowers the groundwater table so it no longer supports phreatophytic vegetation such as cottonwoods (Stromberg and Tellman 2009).

High-severity environmental degradation appears where occurrences tend to be relatively small (<0.5 mile long) (CNHP 2010b). Natural hydrologic regime is severely altered and considered not restorable (system remains fundamentally compromised despite restoration of some processes) (CNHP 2010b). Large upstream dams and numerous water diversions may occur in watershed (CNHP 2010b). Streambank may be severely altered with riprap, or gravel mining in floodplain may be extensive. Flooding has been controlled so fresh gravel bars are not available for cottonwood regeneration. Adjacent uplands are mostly human-disturbed landscapes converted to urban or agricultural uses (<20% natural). Riparian occurrence may be reduced to narrow strip (buffer <30 m wide) with much edge effect. There may be evidence of excessive livestock grazing on streambank and/or disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Moderate-severity environmental degradation appears where occurrences are moderate (0.5-1 mile long) in size (CNHP 2010b). Natural hydrologic regime altered by upstream dams, local drainage, diking, filling, digging, or dredging. Alteration is extensive but potentially restorable over several decades (CNHP 2010b). Local or moderate human-caused alteration of hydrology may be present in watershed, for example small dams, irrigation ditches, and gravel mines. Groundwater pumping has produced noticeable changes from historic hydrologic patterns (CNHP 2010b). Streambanks are altered. Disturbance is significant enough to have notable impact on species composition and soil compaction, causing significant erosion. Uplands surrounding occurrence or upstream watershed are fragmented by urban or agricultural alteration (20-60% natural). Riparian occurrence may be reduced to narrow strip (buffer 30-60 m wide) with much edge effect. There may be evidence of heavy livestock grazing on streambank and/or disturbance from vehicles resulting in soil compaction and sheet and rill erosion.

High-severity disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species such as *Tamarix ramosissima* or *Elaeagnus angustifolia* may be dominant over significant portions of area, with little potential for control (CNHP 2010b). Connectivity is severely hampered and severely restricts or prevents natural ecological processes from occurring creating barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low (CNHP 2010b). Moderate-severity disruption appears where occurrences have moderate cover of native grassland species (30-60% relative cover). Non-native invasive species such as *Tamarix ramosissima* or *Elaeagnus angustifolia* may be widespread but potentially manageable with restoration of most natural processes

(CNHP 2010b). Connectivity is moderately hampered and severely restricts some natural ecological processes from occurring, creating some barriers to the natural movement of some animal and plant populations (CNHP 2010b).

M504. Laurentian-Acadian-North Atlantic Coastal Flooded & Swamp Forest

CES201.726 Great Lakes Wooded Dune and Swale

CES201.726 CLASSIFICATION

Concept Summary: This system is found in nearly 100 occurrences throughout the Great Lakes shorelines of the United States and Canada. It consists of a foredune, followed by a series of low to high dunes (uplands) and swales (wetlands). The system is often best developed where post-glacial streams entered an embayment and provide a dependable sand source. The combination of along-shore currents, waves, and winds form foredunes along the shoreline. The foredunes of most dune-and-swale complexes are commonly 1-2 m high, with *Ammophila breviligulata, Calamovilfa longifolia, Salix serissima, Salix cordata*, and *Populus balsamifera* most common. The swale immediately behind the foredune is influenced by short-term variation in lake levels and can be partially or occasionally completely filled by dune sands following major storm events. Species common to this first swale include *Juncus arcticus ssp. littoralis, Juncus pelocarpus, Juncus nodosus, Eleocharis acicularis*, and *Schoenoplectus americanus*. Occasionally, such swales may contain lake-influenced, calcareous sands and may contain moderately alkaline indicators.

A low dune field with more advanced plant succession often follows the first open dunes and swales. *Pinus banksiana, Pinus strobus*, and *Pinus resinosa* often form a scattered overstory canopy, while *Juniperus communis, Juniperus horizontalis, Arctostaphylos uva-ursi*, and *Koeleria macrantha* form a scattered ground layer. Following the dune-field zone, both dunes and swales are typically forested. Moist swales are often forested, and soil organic material has often begun to accumulate. *Thuja occidentalis, Alnus incana, Salix* spp., and *Acer rubrum* dominate the partial overstory canopy and understory. In contrast to the dry or moist swales, wetter swales (where standing water is present through most of the year) may be dominated by Carices, such as *Carex aquatilis* and *Carex stricta*. Forested beach ridges, with soils of medium to course sand, tend to be dominated by species common to dry-mesic and mesic northern forest. Complexes located in embayments protected from prevailing winds tend to be formed entirely of low, water-lain beach ridges. As a result, even the beach ridges within these complexes support wetland vegetation.

Six major subtypes of Great Lakes Dune and Swale were described for Michigan, including the Lake Superior high dune type, the Lake Superior low dune type, the North Lake Michigan high dune type, Northern Lake Huron-Lake Michigan low dune type, the Southern Lake Huron type, and the Northern Great Lakes low dune type. These subtypes represent patterns of floristic variation resulting from latitude and sand dune/beach ridge characteristics that constrain floristic and structural attributes. High dune types may support predominantly upland vegetation, while low dune types may support predominantly wetland vegetation.

Description Author: P. Comer and D. Albert

CES201.726 CONCEPTUAL MODEL

Environment: The system consists of a foredune, followed by a series of low to high dunes (uplands) and swales (wetlands). The system is often best developed where post-glacial streams entered an embayment and provide a dependable sand source. The combination of along-shore currents, waves, and winds form foredunes along the shoreline. With gradual long-term drops in water level, combined with post-glacial uplifting of the earth's crust, these low dunes gradually rise above the direct influence of the lakes, and new foredunes replace them. Over several thousand years, a series of ridges and swales is created. For most complexes, the flow of surface streams and groundwater maintain the wet conditions in the swales. With time, plant succession has proceeded to the point where the beach ridges are now forested while the wet swales are either forested or open wetlands. Along the Lake Superior shoreline, where post-glacial uplift is greatest, many of the complexes consist primarily of dry, forested swales. The dunes and swales differs depending on fetch and the amount of sediment available. The influence of Great Lakes water-level fluctuations is probably limited to the first few swales inland from the shoreline. For most of the complexes, the water occupying the swales comes from streams flowing from the adjacent uplands or from groundwater seepage.

Key Processes and Interactions: Foredune and immediate back dune areas are influenced by active dune processes of wind-caused "blowouts" and subsequent restabilization. Forested beach ridges may support fire regimes characteristic of similar upland forest systems outside of these complexes. Due to lakeshore proximity, heavy winds and resultant windthrow are common in forested ridges. Great Lakes water-level fluctuations likely influence water levels in swales closest to the shoreline, if at all. The hydrology of interdunal swales is driven largely by lateral flow through the porous beach ridges. Older swales (farthest from current lakeshores) in larger complexes support peat-forming bogs.

CES202.069 High Allegheny Wetland

CES202.069 CLASSIFICATION

Concept Summary: This system occurs along the high plateau of the Allegheny Mountains, immediately west of the Allegheny Front at elevations between 730 and 1430 m. Wetlands in this system are drained by low-gradient, meandering, intermittent to small headwater streams. Drainage is impounded in high, flat-lying basins by natural dams or "knickpoints" of resistant sandstone. In addition to poor moisture drainage, cold air drains from the surrounding uplands to pool in the flat basins, which function as frost pockets. Rainfall is plentiful, averaging about 1300 mm/year. Communities in this system may have substrates of shallow to deep peat or, less commonly, mineral soil. Soils are acidic to circumneutral. These high Allegheny wetlands form complex mosaics ranging in size from a few hectares to 6000 hectares. Forested swamps occupy the less disturbed margins or slightly higher "islands." This system has a distinctly northern character in its resemblance to bogs and swamps of New England. However, the striking absence of *Chamaedaphne calyculata* and *Picea mariana*, two abundant and common species of northern bogs and swamps, as well as the presence of species characteristic of the Southern Appalachians, such as *Hypericum densiflorum, Vaccinium erythrocarpum*, and *Rhododendron maximum*, distinguishes this system from its northern counterpart. Ombrotrophic bogs are rare but occur in undisturbed portions of a few of the larger wetlands. The more central, flood- or beaver-influenced portions contain shrub swamps, sedge fens, wet meadows, and open marshes. Forested swamps are dominated by *Picea rubens*, with varying cover by *Acer rubrum, Tsuga canadensis*, and *Betula alleghaniensis var. alleghaniensis*. It is likely that the role of *Pinus strobus* played a greater role in the structure and function of this system historically than it does today (Maryland Geological Survey and Curran 1902). Residual white pines in remote areas of this system in Cranesville Swamp in Maryland also suggest this possibility. Where limestone or calcareous shale influences seepage water, *Abies balsamea* and *Fraxinus nigra* are typical canopy dominants. Common shrub species are *Viburnum nudum var. cassinoides, Rhododendron maximum, Vaccinium myrtilloides, Alnus incana ssp. rugosa, Hypericum densiflorum, Ilex verticillata*, and *Aronia melanocarpa*. Herbaceous species frequently include *Rubus hispidus, Solidago uliginosa, Juncus effusus, Eriophorum virginicum, Osmunda cinnamomea var. cinnamomea, Polygonum sagittatum, Carex folliculata, Carex gynandra, Leersia oryzoides, Galium tinctorium, Solidago rugosa, Symplocarpus foetidus, Lycopus uniflorus var. uniflorus, Scirpus cyperinus, Carex scoparia var. scoparia*, and *Carex trisperma var. trisperma*. *Sphagnum* spp. and *Polytrichum* spp. dominate the bryophyte layer. This system is maintained by a spatially complex mix of seepage, low-energy flooding, beaver activity, and rainfall. Undisturbed examples exist (e.g., Cranberry Glades), where old-growth swamp buffers the central peatlands, which have been dated to 10,000 years. In presettlement time, some wetland mosaics in this system had significant forested components (e.g., Canaan Valley, Cranesville Swamp in West Virginia; Finzel Swamp, Hammel Glades in Maryland), while others (e.g., Cranberry Glades, Big Run Bog) were largely open peatlands with forested swamp only on the margins.

- Tamarack: 38 (Eyre 1980) **<**

Distribution: The system occurs in a southwest/northeast-trending band about 40 km wide and 200 km long along the high, flat plateau of the Allegheny Mountains. The eastern boundary is the Allegheny Front, and the western boundary is the heavily dissected, lower elevation Allegheny Plateau. Minimum elevations range from 730 m in the north to 940 m in the south (Droop Mountain, West Virginia). The maximum elevation is 1422 m on Mount Porte Crayon, West Virginia.

Nations: US

Description Author: E.A. Byers, S.C. Gawler, L.A. Sneddon

CES202.069 CONCEPTUAL MODEL

Environment: This system occurs along the high plateau of the Allegheny Mountains, immediately west of the Allegheny Front at elevations between 610 and 1430 m. Wetlands in this system are drained by low-gradient, meandering, intermittent to small streams that form the headwaters of larger (often high-gradient) mountain rivers. The system is underlain by gently folded sedimentary rocks of Carboniferous and Devonian age. Drainage is impounded in high, flat-lying basins by natural dams or "knickpoints" of resistant sandstone (Pottsville and Price formations). These sandstone layers come to the surface along the gently dipping axes of breached anticlines or synclines, or occasionally on the gently dipping limb of a fold. Cold air drains from the surrounding uplands to pool in the flat basins, which function as frost pockets. Rainfall is plentiful, averaging about 1300 mm/year. Communities in this system may have substrates of shallow to deep peat (a few centimeters to up to 3 m depth) or, less commonly, mineral soil. Soils are acidic to circumneutral, with pH ranging from 3.1 to 6.5. High values for soil organic matter, total exchange capacity, exchangeable nitrogen, soluble sulphur, and phosphorus are typical. Most soils are low in boron, copper, potassium, and manganese.

Key Processes and Interactions: This system is maintained by a spatially complex mix of seepage, low-energy flooding, beaver activity, and rainfall. Drainage in the flat headwater basins is partly impounded by resistant sandstone at the basin outlet. Low-gradient, meandering headwater streams provide regular low-energy inundation. Seepage from surrounding forests provides nutrients at the margins of the wetland mosaic, and where limestone or calcareous shale is present, circumneutral wetlands are maintained. Beaver activity encourages the cycling of early- to mid-successional types. In the rare ombrotrophic bogs, rainfall is the only source of moisture. Many of the forested swamps in this system were logged during 1880-1920, and some were subsequently burned and/or heavily grazed. Flat headwater basins function as frost pockets, catchment areas for cold air draining from surrounding uplands. Cool temperatures (mean annual temperature 6.7-9.4 degrees C) and high rainfall (1220-1680 mm/year) are characteristic. Floristic diversity is controlled by underlying sedimentary rocks that weather to form high diversity of nutrient, acidity, and drainage conditions (Byers et al. 2007).

Threats/Stressors: The logging boom of 1880-1920 resulted in profound alteration of the landscape, with 99% of forest harvested or burned. Denuded slopes resulted in sediment transport into the wetlands, and railroad beds were placed along most streambeds resulting in channelization and barriers. Upland forests have recovered to some degree, providing buffer to wetlands. Current threats include mining activities and home developments, grazing, fragmentation due to road construction and logging, excessive deer herbivory, and invasive species. *Frangula alnus* can be a major invasive species, particularly in the Allegheny National Forest. Additional threats here include clearcutting in the watershed, as well as activities associated with shale gas development, such as roads and pipelines. In Maryland and Virginia, communities in this system have been greatly impacted by ditching and draining for agriculture and silviculture. Climate change, natural gas development, and wind turbines also pose threats to this system.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the system is embedded in a largely unnatural habitat; average buffer width <10 m and/or in poor condition; characteristic species absent; 50% or more reduction in extent, >10% cover of invasive species; hydrologic regime altered by diversions, withdrawals, or source (Faber-Langendoen et al. 2011).

CES201.575 Laurentian-Acadian Alkaline Conifer-Hardwood Swamp

CES201.575 CLASSIFICATION

Concept Summary: These forested wetlands are found across northern New England and the upper Midwest and eastern to south-central Canada in basins or floodplains where higher pH and/or nutrient levels are associated with a rich flora. The substrate is typically mineral soil, but there may be some peat; often, there is an organic epipedon over mineral soil. *Thuja occidentalis* is a diagnostic canopy species and may dominate the canopy or be mixed with other conifers or with deciduous trees, most commonly *Acer rubrum* or *Fraxinus nigra* but also *Tsuga canadensis, Larix laricina*, and *Betula alleghaniensis*. Some examples can be almost entirely deciduous and dominated by *Fraxinus nigra*. *Cornus sericea* is a common shrub. The herb layer tends to be more diverse than in acidic swamps. Small open fenny areas may occur within the wetland. Seepage may influence parts of the wetland, but the hydrology is dominated by the basin setting.

Description Author: S.C. Gawler and J. Drake

CES201.575 CONCEPTUAL MODEL

Environment: This system is typically found in basins or in floodplains with higher pH and/or nutrient levels. Groundwater typically keeps these sites saturated or nearly so through most of the growing season. Surface water, either overland flow or from nearby lakes and streams, often contributes to the hydrologic regime, especially through flooding in the spring or after heavy rains. Some movement of groundwater is important in maintaining the dominant trees in this system (Schwintzer 1981, Johnson and Booker 1983). Soils are mineral or muck (well-decomposed peat) with sometimes a thin layer of peat over mineral soil. There is often pronounced microtopographic relief between hummock/mounds created by tree boles and roots and rotting fallen logs and small depressions. These provide different microhabitats and contribute to the diversity of the system.

Key Processes and Interactions: Cold, nutrient-rich and alkaline groundwater is important in maintaining this system. While water chemistry is similar to alkaline fens (~Laurentian-Acadian Alkaline Fen (CES201.585)$$), this is a treed conifer, conifer-hardwood, or hardwood swamp versus a shrub- or graminoid-dominated fen, implying other factors beyond just water chemistry are important in creating differing vegetation (Schwintzer and Tomberlin 1982). Other factors are likely hydrologic regime (length and degree of soil saturation), site history, and degree of water movement. Patchy windthrow creates small-scale canopy gaps. These swamps often occur on structurally weak organic soils where trees root shallowly due to anaerobic conditions and are thus particularly susceptible to windthrow (Slaughter et al. 2007). Fire was very infrequent in this system but could occur in very dry periods. If other factors remain the same, this system could regenerate after fire since *Thuja occidentalis* and many other dominants grow well on exposed mineral soil (Johnson and Booker 1983). Beaver (*Castor canadensis*) flooding can also shape conifer-hardwood swamp structure, species composition, and direct successional pathways.

Threats/Stressors: Alterations in wetland hydrology, logging, excessive deer browse, and physical destruction of sites are the prime threats to this system. Hydrologic alterations can occur due to ditching, road construction, or quarrying/mining that affect groundwater or surface waterflows into sites. Both reductions and increases in groundwater or surface water input can negatively affect this system. Partial drainage of a site can allow upland species to colonize. Increased surface waterflow can flood these swamps, changing both the hydrologic regime and water chemistry. This would likely lead to tree death and the development of an herbaceous marsh or shrub swamp. The proximity of roads has been shown to be negatively correlated with black ash health in Minnesota (Ward et al. 2006). Increased flooding can also transport sediment and higher nutrient loads. Deer prefer *Thuja occidentalis* stands as wintering yards and can have significant impacts on *Thuja occidentalis* and other species through over-browsing (Rooney 2001, Rooney et al. 2002). Logging can negatively impact this system through removal of trees, compaction of the

soil, and creation of ruts. This system is slow to recover from perturbation so disturbance can accumulate over time. A serious threat to stands of this system that contain *Fraxinus* spp. is emerald ash borer (*Agrilus planipennis*). This exotic beetle has seriously affected *Fraxinus* spp. trees in southern Michigan and is projected to continue to spread throughout the range of *Fraxinus* spp. in the Midwest and Northeast by 2045 (DeSantis et al. 2012). After prolonged infestation, mortality of *Fraxinus* spp. is nearly 100% (Herms et al. 2010). Invasive plant species that can reduce diversity and alter structure of conifer- hardwood swamps include *Elaeagnus umbellata, Frangula alnus (= Rhamnus frangula), Lythrum salicaria, Phalaris arundinacea*, and *Phragmites australis* (Kost et al. 2007).
Ecosystem Collapse Thresholds: Ecological collapse tends to occur when hydrologic alterations result in excessive flooding or drying of this system or when physical damage occurs to the system through logging or recreational use (off-road vehicles). Invasive species can become abundant in some sites, especially in more southern examples or where other disturbances have created openings for the exotics species. Projected rates of infestation and mortality to *Fraxinus nigra* trees in this system would eliminate that species as a component of the system by 2045 (DeSantis et al. 2012). In stands that have a high proportion of *Fraxinus nigra*, this will result in change. Whether the site would become another stand of this system dominated by other trees still characteristic of the system (*Acer rubrum, Thuja occidentalis*, etc.), another type of swamp forest, a shrub swamp, or allow invasive species to invade and create a ruderal system, depends on current composition of the stand, local seed sources, the relative proportion of *Fraxinus nigra* in the stand, and other site factors. Pressure from abundant deer can lead to collapse when browse pressure eliminates canopy regeneration and alters species composition and structure.

Severe environmental degradation occurs when the site has significantly increased or decreased water input water inputs; or when there is significant physical disturbance from logging or recreational use. Moderate environmental degradation occurs when the site has moderately increased surface water inputs or decreased groundwater flow; or when there is moderate physical disturbance from logging or recreational use. Severe disruption of biotic processes occurs when exotic species become abundant (>50% cover) (Faber-Langendoen et al. 2011). Moderate disruption of biotic processes occurs when exotic species are common (10-50% cover) (Faber-Langendoen et al. 2011).

CES201.587 Laurentian-Acadian Floodplain Forest

CES201.587 CLASSIFICATION

Concept Summary: This system encompasses north-temperate floodplains in the northeastern and north-central U.S. and adjacent Canada at the northern end of the range of silver maple. They occur along medium to large rivers where topography and process have resulted in the development of a complex of upland and wetland temperate alluvial vegetation on generally flat topography. This complex includes floodplain forests, with *Acer saccharinum* characteristic, as well as herbaceous sloughs and shrub wetlands. In areas subject to more scour, sparse non-wetland vegetation may develop on sandbars or exposed rock. Most areas are underwater each spring; microtopography determines how long the various habitats are inundated. Associated trees include *Acer rubrum* and *Carpinus caroliniana*, the latter frequent but never abundant. On terraces or in more calcareous areas, *Acer saccharum* or *Quercus rubra* may be locally prominent, with *Betula alleghaniensis* and *Fraxinus* spp. *Salix nigra* is characteristic of the levees adjacent to the channel. Common shrubs include *Cornus amomum* and *Viburnum* spp. The herb layer in the forested portions often features abundant spring ephemerals, giving way to a fern-dominated understory in many areas by mid-summer. Non-forested wetlands associated with these systems include shrub-dominated and graminoid-herbaceous vegetation.

CES202.604 North-Central Appalachian Acidic Swamp

CES202.604 CLASSIFICATION

Concept Summary: These swamps are distributed from central New England through the Central Appalachians south to Virginia and west to Ohio. They are found at low to mid elevations (generally <700 m) in basins or on gently sloping seepage lowlands. The acidic substrate is mineral soil, often with a component of organic muck; if peat is present, it usually forms an organic epipedon over the mineral soil rather than a true peat substrate (although peat layers up to 1 m deep have been found in some of these swamps). *Tsuga canadensis* is usually present and may be dominant. It is often mixed with deciduous wetland trees such as *Acer rubrum* or *Nyssa sylvatica*. *Sphagnum* is an important component of the bryoid layer. Basin swamps tend to be more nutrient-poor and less species-rich than seepage swamps; in some settings, the two occur adjacent to each other with the basin swamp vegetation surrounded by seepage swamp vegetation on its upland periphery.

CES201.574 Northern Appalachian-Acadian Conifer-Hardwood Acidic Swamp

CES201.574 CLASSIFICATION

Concept Summary: These forested wetlands are found in temperate northeastern and north-central U.S., primarily in glaciated regions in the eastern Laurentian-Acadian region. They occur on mineral soils that are nutrient-poor; there may be an organic epipedon, but the substrate is generally not deep peat. These basin wetlands remain saturated for all or nearly all of the growing season, and may have standing water seasonally. There may be some seepage influence, especially near the periphery. *Acer rubrum, Fraxinus* spp., *Picea rubens* (rarely *Picea mariana*), and *Abies balsamea* are the most typical trees. The herbaceous and shrub layers tend to be fairly species-poor. *Ilex mucronata (= Nemopanthus mucronatus)* and *Osmunda* spp. are typical shrub and herb species.

CES203.522 Northern Atlantic Coastal Plain Basin Peat Swamp

CES203.522 CLASSIFICATION

Concept Summary: This system comprises acidic peat swamps formed in basins of various sizes, predominantly Atlantic white-cedar swamps, occurring on the northern portion of the Atlantic Coastal Plain from Massachusetts south to Virginia. The hydrology is saturated, as evidenced by *Sphagnum*-dominated hummock-and-hollow microtopography. *Chamaecyparis thyoides* is characteristic and often dominant. *Acer rubrum* may also be an important species, especially after logging.

Related Concepts:
- Atlantic White-Cedar: 97 (Eyre 1980) <
- Red Maple: 108 (Eyre 1980) <

Distribution: This system occurs on the northern portion of the Atlantic Coastal Plain from Massachusetts south to Virginia, with sporadic occurrences north to mid-coast Maine, and occasional disjunct occurrences inland; it is historic in eastern Pennsylvania.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, S.C. Gawler and L.A. Sneddon

CES203.522 CONCEPTUAL MODEL

Environment: Topographic depression.
Key Processes and Interactions: Seasonal to saturated hydrology.
Threats/Stressors: Past logging was extensive.
Ecosystem Collapse Thresholds: Periodic fire stimulates regeneration.

CES203.520 Northern Atlantic Coastal Plain Basin Swamp and Wet Hardwood Forest

CES203.520 CLASSIFICATION

Concept Summary: This system comprises nonriverine hardwood swamps of seasonally flooded habitats, including relatively shallow groundwater-influenced depressions and Coastal Plain terraces. It ranges from the southern glaciated Atlantic Plain of Long Island, New York, south along the northern Coastal Plain to Virginia. Although supporting some seepage indicators, it is also affected by overland flow. The substrate is mineral soil overlain by a variable organic but non-peaty layer. Characteristic tree species include *Acer rubrum, Liquidambar styraciflua, Nyssa sylvatica, Quercus michauxii, Quercus pagoda, Quercus palustris*, and *Quercus phellos*. *Pinus taeda* is not uncommon south of Delaware Bay.

Related Concepts:
- Pin Oak - Sweetgum: 65 (Eyre 1980) <
- Pond Pine: 98 (Eyre 1980) <
- Red Maple: 108 (Eyre 1980) <
- Swamp Chestnut Oak - Cherrybark Oak: 91 (Eyre 1980) <

Distribution: It ranges from Long Island, New York, south to Virginia.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, J. Teague, M. Pyne and L.A. Sneddon

CES203.520 CONCEPTUAL MODEL

Environment: This system occurs in low-lying areas, such as stream headwaters or depressions, or along water courses.
Key Processes and Interactions: This system occurs on extensive, flat terraces and very wide, ancient floodplains that are no longer subject to alluvial processes. Its hydrology is seasonally to nearly permanently saturated, with occasional ponding or groundwater sheetflows, and is maintained by a high water table rather than riverine or estuarine flooding.
Threats/Stressors: Agricultural degradation in buffer causes nutrient input. Historical losses of this system likely resulted from mid-nineteenth century conversion to agriculture, altered hydrology caused by impoundments, and logging (NYNHP 2013c). There has been substantial loss of this system in southeastern New York (Stevens 1992, cited by NYNHP 2013c). Remaining examples in Pennsylvania are highly threatened by invasive species as a result of urbanization, as well as deer browse (Rhoads and Block 2011d).
Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the system is embedded in a largely unnatural habitat; average buffer width <10 m and/or in poor condition; characteristic species absent; 50% or more reduction in original extent, >10% cover of invasive species; hydrologic regime altered by diversions, withdrawals, or source (Faber-Langendoen et al. 2011).

CES203.374 Northern Atlantic Coastal Plain Pitch Pine Lowland

CES203.374 CLASSIFICATION

Concept Summary: This system comprises wetland pine barrens vegetation and coastal plain peatlands from the New Jersey Pine Barrens south into the Delmarva Peninsula and upper Chesapeake Bay. Although this system can be extensive, components often co-occur as a mosaic with upland pine barrens vegetation as well. The vegetation is characterized by associations having variable hydroperiods, occurring on a range of substrates from saturated deep peats to seasonally saturated mineral soils. Physiognomy of the component associations is similarly widely variable, ranging from wet grasslands dominated by *Calamovilfa brevipilis*, to boggy shrublands characterized by *Gaylussacia dumosa, Chamaedaphne calyculata, Eubotrys racemosa*, and others, to seasonally saturated pine forests characterized by mesic species such as *Clethra alnifolia*. Fire frequency, as well as hydrology, has a profound influence on the vegetation. Where fire frequency is high, woody vegetation is impeded, favoring the development of large wet grasslands.

Related Concepts:
- Pitch Pine: 45 (Eyre 1980) **?**

Distribution: This system is best developed in the New Jersey Pine Barrens, but occurrences are present south to the Inner Coastal Plain of Maryland.

Nations: US

Concept Source: R. Evans and L. Sneddon

Description Author: R. Evans, L.A. Sneddon, S.C. Gawler

CES203.374 CONCEPTUAL MODEL

Environment: This system occurs within the larger matrix of pitch pine - scrub oak barrens of the New Jersey Pinelands. Hydrology is primarily groundwater-controlled; vegetation composition is a reflection of depth to water table.

Key Processes and Interactions: This system and the composition and structure of its mosaic of patch types are influenced by depth to water table (Ehrenfeld 1986). Pitch pines are also structured by fires, but fire regime differs from uplands in that in the wet environment, fire frequency is lower, but the high shrub density often leads to crown fires. In high-intensity fires, pitch pines are killed, and even the organic layer may be consumed during periods of drought. Successional pathways following fire depend on depth of remaining organic layer and proximity of seed source (Little 1979c).

Threats/Stressors: Alteration of hydrology leading to drying of substrate.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the system is embedded in a largely unnatural habitat; average buffer width <10 m and/or in poor condition; characteristic species absent; 50% or more reduction in extent, >10% cover of invasive species; hydrologic regime altered by diversions, withdrawals, or source (Faber-Langendoen et al. 2011).

CES203.070 Northern Atlantic Coastal Plain Riverine Peat Swamp

CES203.070 CLASSIFICATION

Concept Summary: This ecological system is found throughout the northern Atlantic Coastal Plain, ranging from Virginia to New Jersey. Examples occur along low-gradient streams and rivers. Floodplain development varies from little to moderate according to stream size. This system is influenced by overbank flooding, groundwater seepage and occasional beaver impoundments. The vegetation is a mosaic of forests, woodlands, shrublands, and herbaceous communities. Canopy composition and cover can vary within and among examples of this system, but typical tree species may include *Quercus palustris, Quercus phellos, Chamaecyparis thyoides, Acer rubrum, Fraxinus pennsylvanica, Nyssa sylvatica, Betula nigra, Liquidambar styraciflua*, and *Platanus occidentalis*. Shrubs and herbaceous layers can vary in richness and cover. Some characteristic shrubs may include *Alnus maritima, Carpinus caroliniana, Lindera benzoin*, and *Viburnum nudum*. Seepage forests dominated by *Acer rubrum* and *Magnolia virginiana* can often be found within this system, especially at the headwaters and terraces of streams.

Distribution: This system occurs on the mid-Atlantic Coastal Plain from Virginia to New Jersey.
Nations: US
Concept Source: NCR Review Team
Description Author: J. Teague, S.C. Gawler and L.A. Sneddon

CES203.070 CONCEPTUAL MODEL

Environment: This system occurs on Coastal Plain flood terraces of streams and rivers, and is also influenced by groundwater seepage. In New Jersey, this system occurs in the Pine Barrens matrix.
Key Processes and Interactions: This system is hydrologically influenced primarily by groundwater seepage, but is also subjected to periodic overbank flooding. The system is maintained by a natural disturbance regime of flooding and periodic fires of varied intensity. High-intensity fires may consume peat and limit re-establishment of Atlantic white-cedar.
Threats/Stressors: Prior to the mid-nineteenth century, Pine Barrens savannas were exploited for iron and turf. Atlantic white-cedar of the associated riparian zones has been repeatedly logged (Wacker 1979), and cranberry production was practiced in these riparian zones and often converted from savannas (Walz et al. 2006c). Savannas have undergone a rapid decline in distribution, with a documented decrease of 71% of areal extent between 1940-2002, due to hydrological changes exacerbated by industrial dams, agriculture, and fire management that has altered historic frequency and intensity. (Smith 2012). Streamside Atlantic white-cedar swamps of the New Jersey Pinelands has decreased in extent to 21% of the original distribution (Laderman 1989, from Sipple 1971-1972). Threats to streamside Atlantic white-cedar wetlands on the Delmarva peninsula include millpond construction, riverbank stabilization, drainage, and channelization (Laderman 1989).
Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the system is embedded in a largely unnatural habitat; average buffer width <10 m and/or in poor condition; characteristic species absent; 50% or more reduction in extent, >10% cover of invasive species; hydrologic regime altered by diversions, withdrawals, or source (Faber-Langendoen et al. 2011).

CES203.245 Atlantic Coastal Plain Clay-Based Carolina Bay Wetland

CES203.245 CLASSIFICATION

Concept Summary: This system consists of wetlands associated with ovoid, shallow depressions with nearly flat bottoms in parts of the Atlantic Coastal Plain. Often called Carolina bays, these areas are most numerous and extensive in South Carolina but are also present in adjacent Georgia and the Inner Coastal Plain of North Carolina. These flat-bottomed depressions have mineral soils with clay hardpans, fragipans, or some other drainage-impeding mechanism that traps and retains water from a combination of rainfall and exposure of a high regional water table. Some examples are essentially permanently flooded, while others support water levels that vary substantially from year to year and over longer climatic cycles. Vegetation includes a series of primarily herbaceous and woodland associations. The wettest sites have open water and floating-leaved aquatic vegetation, or marsh vegetation of tall graminoids. Drier sites often have an open canopy of *Taxodium ascendens*, with a dense, often fairly species-rich herbaceous layer beneath. In a very few cases, *Taxodium ascendens* is replaced by *Taxodium distichum*. A few occurrences are shrubby, but none contain the dense shrub layers of characteristic pocosin species that occur in the bays with organic soils. Vegetational composition often varies substantially from year to year, in response to differences in water levels and drawdown times. Variation in hydroperiod is the most important dynamic, causing rapid major changes in the herbaceous vegetation. Unlike the steeper-sided solution depressions, where many different hydroperiods are present within a short distance and vegetation zones simply shift, the flat-bottomed Carolina bays experience drastic yearly changes in hydroperiod over most of their extent. Fire periodically spreads into the bays from adjacent uplands when conditions are dry, helps prevents invasion by less water-tolerant trees during dry periods, and interacts with flooding to affect vegetational composition. Where fire is removed, *Pinus taeda* often invades the bays. Fire may also be important in preventing buildup of organic matter on the soil surface.

Distribution: This system is found in the Inner to Middle Coastal Plain, from southern North Carolina, through South Carolina, and into adjacent Georgia. It is most numerous and extensive in South Carolina.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, M. Pyne and C.W. Nordman

CES203.245 CONCEPTUAL MODEL

Environment: Examples of this system occur in Carolina bays with mineral soils and with seasonal to permanent standing water. Carolina bays are oriented, oval, shallow depressions with nearly flat bottoms, which range from North Carolina through South Carolina, and into adjacent Georgia. The general thought has been that most of the Carolina bays in the Outer Coastal Plain occur in sandy sediments and are filled with peat, while most Carolina bays in the Inner Coastal Plain occur in loamy sediments and have mineral soils with clay hardpans, but the situation may be more complex than this. These depressions hold water, due to a combination of rainfall and exposure of a high regional water table. Some are essentially permanently flooded. Others contain water well into the growing season in most years, but water levels vary substantially from year to year and over longer climatic cycles. Fire is an important natural influence in dry times. The McColl soil series (a fine, kaolinitic, thermic Typic Fragiaquult) is the soil most consistently associated with Carolina bays which are not dominated by "pocosin-like" vegetation (M. Schafale pers. comm.). Its depth to fragic soil properties is 30-90 cm (12-36 inches); the depth to a fragipan is 38-100 cm (15-40 inches). Some pedons have few to common concretions of ironstone.

Key Processes and Interactions: Variation in hydroperiod is the most important dynamic, causing rapid major changes in the herbaceous vegetation. Unlike the steeper-sided solution depressions, where many different hydroperiods are present within a short distance and vegetation zones simply shift, the flat-bottomed Carolina bays experience drastic yearly changes in hydroperiod over most of their extent. Many plants persist in seed banks for periods of years when conditions are not suitable. Fire is also an important process, spreading into the bays from adjacent uplands when conditions are dry. Fire prevents invasion by less water-tolerant trees during dry periods, and interacts with flooding to affect vegetational composition. Where there is a lack of fire, *Pinus taeda* often invades the bays. Fire may also be important in preventing buildup of organic matter on the soil surface.

Threats/Stressors: Threats include logging of the *Taxodium* spp. canopy, lack of fire, alteration to the hydrology, and damage to the herbaceous ground cover from vehicles, feral hog (*Sus scrofa*) rooting, firebreak plowlines, and ditching. Many of these habitats that were forested with *Taxodium ascendens* have been cleared of trees which are used for cypress mulch. Invasion by trees or shrubs due to lack of fire has become a widespread threat. Mainly sites which are within an area managed for conservation (in conjunction with other resource management goals) have prescribed fires frequently enough to conserve the biological diversity of this open wetland habitat. The lack of fire can lead to shrub and tree encroachment, especially invasion by *Pinus taeda*, accompanied by increased shading and evapotranspiration, accumulation of leaf litter, and a drying out of the Carolina bay depression wetland during drier times of year. Since many of the herbaceous plants which grow in these predominantly herbaceous wetlands have corms, or starchy root structures, feral hogs are a real threat. Feral hogs will turn up the soil and eat the below-ground plant parts and amphibians and invertebrates that live in the wet soil. In doing this they disturb the soil and degrade the habitat. The areas with disturbed soil where feral hogs have rooted (or vehicles have rutted the wet soil) can provide habitat for weedy or invasive exotic plants. On lands managed as pine plantations, sometimes the depression pond habitat is bedded and planted in *Pinus elliottii* or *Pinus taeda*. Many Carolina bays have been ditched, resulting in lowered water levels and shortened hydroperiod. These wetlands are also potentially subject to eutrophication by nutrient input in runoff from surrounding developed or agricultural lands. In the 1950s, the number of Carolina bays was estimated at 500,000 (Prouty 1952). Only 10,000-20,000 remained by the early 1990s (Richardson and Gibbons 1993). In South Carolina, 97% of Carolina bays larger than 0.8 ha (2 acres) had been disturbed by agriculture or logging (Bennett and Nelson 1991).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur from long-term lack of fire (more than 15 years), increase of shading of the herbaceous vegetation, feral hog (*Sus scrofa*) rooting, invasive exotic plants, vehicle use in the wetland, or alteration of the hydrology, such as from drainage or from groundwater extraction lowering the water table. Prescribed fires even after 15 years can improve the habitat, but a schedule of at least one fire per decade is needed to maintain the high native species diversity of the Carolina bay rim and transition or ecotone edges of these wetland habitats. Many of these habitats that were forested with *Taxodium ascendens* have been cleared of trees which are used for cypress mulch.

Ecosystem collapse is characterized by a midstory tall-shrub or tree canopy, especially *Acer rubrum, Liquidambar styraciflua, Pinus taeda, Liriodendron tulipifera*, or invasive exotic species such as *Ligustrum sinense* or *Triadica sebifera*. The trees and tall shrubs shade the herbaceous ground cover plants. Contributors to ecological collapse are disturbance to the herbaceous plants from ditching, vehicle use in the wetland, feral hog rooting, plowlines, or a combination of these factors. Altered hydrology from ditching or from groundwater extraction lowering the water table can also be a characteristic of ecosystem collapse of this ecological system.

CES411.365 South Florida Cypress Dome

CES411.365 CLASSIFICATION

Concept Summary: This ecological system is found primarily in the Everglades and Big Cypress regions of Florida. This system consists of small forested wetlands in poorly drained depressions which are underlain by an impervious layer that impedes drainage and traps precipitation. *Taxodium ascendens* is the dominant tree, with the oldest and largest individuals characteristically occupying the center, and smaller and younger individuals around the margins. Pools of stagnant, highly acidic water may stand in the center of these depressions ranging from 0.3-1.2 m (1-4 feet) in depth, but becoming increasingly shallow along the margins. The understory flora is typified by species with tropical affinities. These ponds are important for many wildlife species.

Related Concepts:

- Pondcypress: 100 (Eyre 1980) **<**

Distribution: Endemic to south Florida.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and C.W. Nordman

CES411.365 CONCEPTUAL MODEL

Environment: This system occurs in areas of low relief, occupying poorly drained to permanently wet depressions. Pools of stagnant, highly acidic water may stand in the center of these depressions ranging from 0.3-1.2 m (1-4 feet) in depth, but becoming increasingly shallow along the margins.

Key Processes and Interactions: Cypress domes get their common name from the unique dome-shaped appearance in which trees in the center are higher than those around the sides (Monk and Brown 1965). The water draws down more frequently along the edges than in the deeper center. This allows for more frequent recruitment of *Taxodium ascendens* seedlings along the edges, which are also exposed to more frequent wildland fire than the center of the ponds which remain flooded for longer durations. These two factors are reflected in the presence of large trees in the center and smaller trees closer to the edges of the ponds.

Threats/Stressors: Lack of fire and invasive exotic plants such as *Melaleuca quinquenervia, Lygodium japonicum* and *Lygodium microphyllum* are threats (FNAI 2010a). Drainage is also a threat.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from the lack of fire and/or dominance of the wetland by invasive exotic plants (FNAI 2010a), such as *Melaleuca quinquenervia, Lygodium japonicum* and *Lygodium microphyllum*. Drainage can invoke an ecological collapse, when the wetland plant species no longer are able to thrive in the depression.

CES411.290 South Florida Dwarf Cypress Savanna

CES411.290 CLASSIFICATION

Concept Summary: The scrub or dwarf cypress system covers extensive areas of south Florida, especially in the Big Cypress Swamp region of southwest Florida. These stunted stands of *Taxodium ascendens* grow on shallow sands or marl soils above limestone bedrock. Individual trees are usually quite small and widely scattered, with canopy coverage ranging from 30-45%. The understory shares much overlap with wet prairies of the region and is dominated by the following genera: *Rhynchospora, Cyperus, Muhlenbergia*, and *Cladium*. The open, stunted aspect is maintained in part by stresses imposed by extreme seasonal water level changes and low-nutrient soils. This type has a hydroperiod of approximately 6 months.

Related Concepts:

CES203.251 Southern Coastal Plain Nonriverine Cypress Dome

CES203.251 CLASSIFICATION

Concept Summary: This system consists of small forested wetlands, typically dominated by *Taxodium ascendens*, often with a dome-shaped appearance in which trees in the center of the depression are taller than those around the exterior. Examples are known from the Southern Coastal Plain (Omernik Ecoregion 75 and adjacent 65) of Florida and Georgia, extending into Alabama, Mississippi and Louisiana. Examples occupy poorly drained depressions which are most often embedded in a matrix of pine flatwoods or mesic to dry pine woodlands. The oldest and largest individual trees typically occupy the center of these domed wetlands, with smaller and younger individuals around the margins. Pools of stagnant, highly acidic water may stand in the center of these depressions ranging from 30-120 cm (1-4 feet) in depth, but becoming increasingly shallow along the margins. These sites are underlain by an impervious clay pan which impedes drainage and perches precipitation. Depending on fire regime and hydroperiod, some examples may have thick (50-100 cm) organic layers. In addition to *Taxodium ascendens*, other woody species may include *Cephalanthus occidentalis, Clethra alnifolia, Hypericum chapmanii, Hypericum myrtifolium, Ilex myrtifolia, Eubotrys racemosa, Liquidambar styraciflua, Lyonia lucida, Morella cerifera, Nyssa biflora*, and *Styrax americanus*.

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and C. Nordman

CES203.251 CONCEPTUAL MODEL

Environment: This system occurs in areas of low relief, occupying poorly drained to permanently wet depressions in uplands such as pine flatwoods or mesic to dry pine woodlands. Pools of stagnant, highly acidic water may stand in the center of these depressions ranging from 30-120 cm (1-4 feet) in depth, but becoming increasingly shallow along the margins (Monk and Brown 1965). Some examples may have thick (50-100 cm) organic layers (Drew et al. 1998). Some of the depressions are fed by groundwater, while others are dependent on local precipitation.

Key Processes and Interactions: Cypress domes get their common name from the dome-shaped appearance in which trees in the center are taller than those around the sides (Monk and Brown 1965). The water draws down more frequently along the shallow margins than in the deeper center. This allows for more frequent recruitment of *Taxodium ascendens* seedlings along the edges, which are also exposed to more frequent wildland fire than the center of the ponds which remain flooded for longer durations. These two factors are reflected in the presence of large trees in the center and smaller trees closer to the edges of the ponds (FNAI 2010a), and greater amounts of herbaceous graminoid plants along the margins of the depression. Where fires are more frequent, open herbaceous vegetation is favored. Without periodic fires *Taxodium ascendens* may become less dominant as hardwood or bay canopy species increase and peat accumulates. *Taxodium ascendens* has fairly thick, fire-resistant bark and is tolerant of light surface fires; however, the seedlings and small *Taxodium ascendens* trees are vulnerable to fire (FNAI 2010a). When the forest canopy is harvested, the disturbed vegetation can transition to an herbaceous graminoid-dominated wetland, such as represented by the ecological systems ~East Gulf Coastal Plain Depression Pondshore (CES203.558)$$ or ~Southern Atlantic Coastal Plain Depression Pondshore (CES203.262)$$. Transitions like this can also occur in response to the natural disturbance dynamics of Coastal Plain depressions, in which the influences of flooding, hurricanes and occasional wildland fire (or lack of fire) can lead to vegetation transition from wooded to herbaceous, or without canopy disturbance, succession from herbaceous to wooded or wetland forest vegetation.

Threats/Stressors: Threats include lack of fire, alteration to the hydrology, and damage to the herbaceous ground cover from vehicles, feral hog (*Sus scrofa*) rooting, plowlines, and ditching. Lack of fire has been a widespread threat, and generally only sites which are within an area managed for conservation have prescribed fires frequently enough to conserve the biological diversity of this open wetland habitat, especially the rim or herbaceous ecotone transition to upland. The lack of fire can lead to shrub and hardwood tree encroachment, increased shading and evapotranspiration, accumulation of leaf litter, and a drying out of the depression wetland during drier times of year. Since many of the herbaceous plants which grow around the edge or rim of these wetlands have corms, or starchy root structures, feral hogs are a real threat. Feral hogs will turn up the soil and eat the below-ground plant parts and amphibians and invertebrates that live in the wet soil. In doing this they disturb the soil and degrade the habitat. The areas of disturbed soil where feral hogs have rooted (or vehicles have rutted the wet soil) can provide habitat for weedy or invasive exotic plants. Also these disturbed soil areas are favored by red imported fire ants (*Solenopsis invicta*), which threaten amphibians using the depressions. On lands managed as pine plantations, sometimes shallow parts of cypress domes are bedded and planted in *Pinus elliottii var. elliottii* or *Pinus taeda*.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur from intensive forestry practices, such as bedding for *Pinus elliottii var. elliottii* or *Pinus taeda* plantation establishment, feral hog (*Sus scrofa*) rooting, invasive exotic plants, off-road vehicle use in the wetland, or alteration of the hydrology, such as from drainage, or long-term drought. Prescribed fires even after 15 years can improve the depression margin ecotone habitat, but a schedule of at least one fire per decade is needed to maintain the high native species diversity of the herbaceous ecotone habitats. Many of these habitats that were forested with *Taxodium ascendens* have been cleared of trees which are used for cypress mulch. Logging can lead to a transition to an herbaceous depression ecological system, rather than ecosystem collapse, for instance ~East Gulf Coastal Plain Depression Pondshore (CES203.558)$$ or ~Southern Atlantic Coastal Plain Depression Pondshore (CES203.262)$$.

Ecosystem collapse is characterized by a tree canopy dominated by trees which are not obligate wetland plants, especially *Acer rubrum, Liquidambar styraciflua, Liriodendron tulipifera, Pinus taeda*, or invasive exotic species such as *Ligustrum sinense, Lonicera* *japonica, Lygodium japonicum, Lygodium microphyllum, Melia azedarach, Microstegium vimineum*, or *Triadica sebifera*. The trees and tall shrubs shade the native herbaceous ground cover plants, especially the graminoid plants. Contributors to ecological collapse are disturbance to the herbaceous plants from ditching, off-road vehicle use in the wetland, feral hog rooting, plowlines, or a combination of these factors. Altered hydrology from ditching, or long-term drought lowering the water level in the depression can also be a characteristic of ecosystem collapse of this ecological system, as the vegetation transitions to upland vegetation.

M033. Southern Coastal Plain Basin Swamp & Flatwoods

CES203.557 East Gulf Coastal Plain Southern Loblolly-Hardwood Flatwoods

CES203.557 CLASSIFICATION

Concept Summary: This forested system occurs on broad upland flats in the East Gulf Coastal Plain of Alabama and Mississippi, as well as western parts of the lower terraces of the East Gulf Coastal Plain ("Florida Parishes"; EPA Ecoregion 74d) of Louisiana, and likely occurs in other parts of the region as well. Its status and extent in this intervening terrain is unknown. Known examples in the Alabama/Mississippi parts of the range include a mosaic of open forests dominated by *Pinus taeda* interspersed with patches of *Quercus phellos* and sometimes other tree species. The ground surface displays an evident microtopography of alternating mounds and swales occurring in a tight local mosaic. These mounds are most likely "gilgai" resulting from vertic or shrink-swell properties of the Luinn soil series. Known examples display a range of moisture conditions from dry to wet. The wettest examples trap significant moisture from local rainfall events. These areas have ponded water for a minimum of several days at an interval and potentially for long periods of the year, especially when evapotranspiration is lowest. The vegetation of this system supports relatively low vascular plant diversity and thus may appear floristically similar to other pine-hardwood vegetation of the region. The dry portion of this vegetational mosaic is dominated by grassy ground cover (*Chasmanthium sessiliflorum*) with scattered emergent greenbriars (*Smilax* spp.) underneath a nearly pure *Pinus taeda* overstory. The historical composition of this type is unknown, but it seems likely that *Pinus taeda* was a natural and even dominant component of this system, as it is in related systems in the West Gulf Coastal Plain. Wetter areas are dominated by an overstory of *Quercus phellos* with an abundance of *Sabal minor* in the understory. Although the specific role of fire in this system is unknown, low-intensity surface fires may have been ecologically important. Such fires could have originated in the surrounding ~East Gulf Coastal Plain Interior Shortleaf Pine-Oak Forest (CES203.506)$$.

In the western parts of the lower terraces of the East Gulf Coastal Plain ("Florida Parishes") of Louisiana (EPA Ecoregion 74d and adjacent 75a), the flatwoods vegetation tends to be dominated primarily by hardwoods in the most western portion, and a mixture of *Pinus glabra* and *Pinus taeda* in the intermediate portion to the east of this (Smith 1996b). In this "Louisiana Florida Parishes Spruce Pine Flatwoods Forest" some characteristic species include *Pinus glabra, Quercus laurifolia, Quercus michauxii, Quercus nigra, Quercus pagoda, Quercus virginiana, Pinus taeda*, and *Magnolia grandiflora*. Some important understory trees and shrubs include *Crataegus opaca, Sabal minor* (which may often be very abundant or dominant), and *Arundinaria tecta*.

Distribution: This forested system occurs on broad upland flats in the East Gulf Coastal Plain of Alabama and Mississippi, as well as western parts of the lower terraces of the East Gulf Coastal Plain ("Florida Parishes") in Louisiana. The complete and detailed range of this system is being developed and is not completely understood. It is not thought to extend into the Mississippi River Alluvial Plain of Louisiana (P. Faulkner pers. comm.).

Description Author: R. Evans, M. Pyne and C. Nordman

CES203.557 CONCEPTUAL MODEL

Environment: In the Alabama/Mississippi parts of this system's range, the ground surface displays an evident microtopography of alternating mounds and swales occurring in a tight local mosaic. In Louisiana, the soils are described as Hydric, acidic silt loams (including the Encrow, Gilbert, and Springfield series). The setting is broad, low flats, in small to large depressions, and along small, ill-defined drainages locally known as "slashes" (Smith 1996b).

CES203.193 Lower Mississippi River Flatwoods

CES203.193 CLASSIFICATION

Concept Summary: This system encompasses forests, prairies and woodlands on Pleistocene terraces in the Mississippi Alluvial Plain of Arkansas, Missouri and Louisiana. It occurs primarily west of Crowley's Ridge on Pleistocene glacial outwash deposits in Arkansas and Missouri, and on Macon Ridge in Louisiana and adjacent Arkansas. The sites are above modern floodplains, but have poor internal drainage and are flat with poor runoff, leading to very wet conditions in winter and spring. They also often have a claypan that restricts both internal drainage and, later in the year, water availability. Therefore, they are very wet in the winter/spring and very dry in the summer, a moisture regime termed hydroxeric. Because of this moisture regime, the communities are variable, ranging from willow oak flats to post oak flats to prairies. In the 1940s, the Arkansas Game and Fish Commission produced a wildlife habitat map of Arkansas in which these sites were classified as "terrace hardwood forests." These communities have a large variety of upland and lowland tree species, ranging from post oak to overcup oak in a small area. Such species diversity may be explained by regeneration of species with dramatically different moisture tolerances on the same site in dry and wet years on these hydroxeric sites. Because the sites are above current floodplains and susceptible to being drained, they have been cleared at an even greater rate than nearby floodplain forests.
Related Concepts:
Distribution: This system is found in the Mississippi Alluvial Plain from the Missouri "bootheel" south to Louisiana. It occurs primarily west of Crowley's Ridge on Pleistocene glacial outwash deposits in Arkansas and Missouri. In southeastern Arkansas and northeastern Louisiana it is found on Macon Ridge (Ecoregion 73j (EPA 2004, LNHP 2009)). It is not reported from Kentucky, Tennessee, or Mississippi.
Nations: US
Concept Source: T. Foti and M. Pyne
Description Author: T. Foti, M. Pyne, C. Nordman

CES203.193 CONCEPTUAL MODEL

Environment: The sites where this system is found are above modern floodplains, but have poor internal drainage and are flat with poor runoff, leading to very wet conditions in winter and spring. They also often have a claypan that restricts both internal drainage and, later in the year, water availability. Therefore, they are very wet in the winter/spring and very dry in the summer, a moisture regime termed hydroxeric. In Louisiana, distinct mesic and wet community variants are recognized (LNHP 2004, 2009).
Key Processes and Interactions:
Threats/Stressors: Threats include clearing, grazing pressure, invasion by woody plants, conversion to exotic cool-season grasses and lack of fire (Nelson 2005). Loss of habitat and fragmentation of the remaining flatwoods habitat have been pronounced. The small size of remaining flatwoods areas contributes to the lack of fire and invasion by invasive exotic plants from seed sources in surrounding ruderal habitat areas.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of habitat, fragmentation of remaining habitat, drainage, lack of fire, canopy and midstory closure, loss of herbaceous ground cover, invasion and then dominance by invasive exotic

plants. Areas that have been deep plowed to break the fragipan and enable better cultivation would not be restorable to flatwoods, as the fragipan is an important natural characteristic of the soil which influences the vegetation and natural dynamics. Ecosystem collapse is characterized by the remaining habitat consisting of small, isolated and degraded habitat patches, in which drainage, lack of fire, and invasive exotic plants have resulted in a closed-canopy forest, lacking or with very sparse native herbaceous ground cover, and with shrub and vine layers partially composed of invasive exotic plants.

CES203.304 Southern Atlantic Coastal Plain Nonriverine Swamp and Wet Hardwood Forest

CES203.304 CLASSIFICATION

Concept Summary: This system consists of poorly drained, organic or mineral soil flats of the Atlantic Outer Coastal Plain. These areas are saturated by rainfall and seasonal high water tables without influence of river or tidal flooding. Fire is generally infrequent but may be important for some associations. Vegetation consists of hardwood or mixed forests of *Taxodium distichum, Nyssa* spp., bottomland oaks, *Acer rubrum*, or other wetland trees of similar tolerance. The lower strata have affinities with pocosin or baygall systems rather than the river floodplain systems that have affinities with the canopy. The combination of hardwood/deciduous canopy dominants and nonriverine, non-seepage hydrology distinguishes this system from other Coastal Plain systems. Stands with a high cover of *Chamaecyparis thyoides* formerly occupied much of the acreage of this system. This phase is presently only present in high-quality examples, and it helps distinguish this system from other Coastal Plain systems. Disturbed and fire-disrupted examples (those dominated by *Nyssa* spp., bottomland oaks, *Acer rubrum*) may be hard to distinguish from other wetland forests based purely on canopy composition.

Distribution: This system ranges from Maryland to Georgia. This system is most abundant in the Embayed Region of northeastern North Carolina and southeastern Virginia (south of the James River), where it covers large expanses.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, M. Pyne and C. Nordman

CES203.304 CONCEPTUAL MODEL

Environment: This system occurs on flat areas of the Atlantic Outer Coastal Plain from Maryland to Georgia, where soils are seasonally to nearly semipermanently saturated because of low relief, poor soil drainage, and seasonal high water table. The largest areas are on broad interfluvial flats, but substantial areas occur on organic deposits in drowned river valleys in the Embayed Region of North Carolina and Virginia, beyond the reach of the influence of wind tides. Hydrology is dominated by rainfall and sheetflow, and overbank flooding, tidal flooding, and seepage are a secondary influence, if at all. Soils may be loamy to clayey, or may be shallow to deep organic. A distinctive small subset has soils with limestone near the surface, influencing soil chemistry. Natural fire is infrequent in this system, and varies from a minor to a significant influence on vegetational composition and structure. Infrequency of fire may be an important factor in differentiating this system from ~Atlantic Coastal Plain Peatland Pocosin and Canebrake

(CES203.267)$$ and the various wet longleaf pine forest systems. In a phase or component of this system on mucky peat soils (Terric or Typic Medisaprists) up to 3 m deep and occasionally on mucky sand or wet mineral soils with an organic epipedon, *Chamaecyparis thyoides* was the most common dominant species; it occurred in a fire-generated patch mosaic in which the various patch dominants are a variable combination of *Acer rubrum, Chamaecyparis thyoides, Nyssa biflora, Pinus serotina*, and *Taxodium*, most frequently *Taxodium ascendens*. While this is fire-dominated, it is only found in substantially fire-sheltered portions of the landscape where scarps or water bodies prevent easy access by fire, resulting in a long fire-return interval. The original vegetation constituted a true shifting mosaic. The original extent was up to 1 million acres of which at least 400,000 acres were Atlantic white-cedar in Mapzones 58 and 60. This is a long-interval, fire-dependent, forested peatland with its greatest extent found on the Pamlico Terrace of Virginia and North Carolina. The largest sites lie at less than 9 m (30 feet) above sea level (C. Frost pers. comm.).

Key Processes and Interactions: Fire is an important influence in a subset of this system. Communities dominated by *Chamaecyparis thyoides* depend on fire for regeneration of the canopy trees. The occurrence of fires on the time scale of several decades to a century or more may determine the mosaic of *Chamaecyparis thyoides* forests and other associations. Some areas may once have been canebrakes, with dominance of *Arundinaria* determined by more frequent fire. In the oak-dominated communities and in wetter *Taxodium* and *Nyssa* communities, fire is probably of little ecological significance because the vegetation is not flammable. Without fire as a major factor, most communities probably occur naturally as old-growth multi-aged forests dominated by gap-phase regeneration. Hurricanes may create larger canopy gaps, and sometimes cause more extensive damage. Examples in drowned river valleys are subject to influence by rising sea level and can be expected to evolve into tidal swamp systems, sometimes fairly quickly.

In specific relation to the *Chamaecyparis thyoides*-dominated phase of this system, succession pathways depend on water table depth at time of replacement fire. Having the water table at the surface results in regeneration of *Chamaecyparis thyoides* from the seedbank. If the water table is slightly to moderately below the surface, the seedbank is destroyed and succession is dominated by some combination of *Acer rubrum, Nyssa biflora, Pinus taeda*, and related taxa. If the water table is well below the surface, the seedbank is destroyed and a deeper hole is created in the peat. In this case, succession is dominated by *Taxodium distichum* and a deeper water area is created with *Chamaecyparis thyoides* only on the edge.

Threats/Stressors: Logging, land conversion, and hydrologic alteration have been the main threats to this system. Conversion to pine plantation destroys the natural vegetation, while other logging has often been followed by failure of regeneration of *Taxodium, Chamaecyparis thyoides*, or *Quercus* spp., changing the natural vegetation to long-term successional forests. Clearing for agriculture has destroyed much of the area of this system in the past, and continues to be a threat.

Ditching and artificial drainage have contributed to alteration and destruction of these systems, facilitating conversion and logging, and altering the hydrology of other examples. Reduced hydroperiod caused by ditches alters vegetation, and can make organic soils prone to destructive peat fires. In areas near sea level, ditches can also bring brackish or oligohaline tidal water into these nonriverine systems. Penetration of even mildly salty water, associated with storm surges or ongoing sea-level rise, stresses or kills the salt-intolerant vegetation in these communities. Road building also alters hydrology, both by the ditches that accompany them and by the filled road beds blocking natural sheetflow and potentially impounding water. Roads can also contribute to fragmentation and edge effect in examples of this system. Feral hogs (*Sus scrofa*) are an invasive species which is destructive in wetland forest ecosystems. *Lonicera japonica, Microstegium vimineum, Triadica sebifera*, and other non-native plants are a threat, especially to drier examples of this system.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from drainage and forestry practices which do not provide for the regeneration of the diverse trees and shrubs characteristic of these wetland forests. This can include the conversion to intensively managed *Pinus taeda* or *Pinus elliottii var. elliottii* plantations, which typically are bedded to reduce the exposure of planted trees to flooding. On the less wet sites with canopies of wetland oaks such as *Quercus laurifolia, Quercus michauxii*, and *Quercus pagoda*, logging which does not allow for the regeneration of these oaks would contribute to ecosystem collapse, including replacement of the oaks by ruderal trees such as *Acer rubrum, Liquidambar styraciflua, Liriodendron tulipifera, Pinus taeda*, and the invasive exotic tree *Triadica sebifera*. Similarly, logging of *Chamaecyparis thyoides* is often accompanied by lack of regeneration and conversion to a forest of ruderal tree species. Collapse can also result from oligohaline or brackish water entering the system through ditches. Occurrences adjacent to tidal swamps are gradually converted to that system as sea-level rises. Fragmentation can contribute to ecosystem collapse, by promoting invasive exotic plants.

Ecosystem collapse is characterized by drainage of the wetland forest site, and replacement of naturally occurring wetland trees, including *Quercus laurifolia, Quercus michauxii*, and *Quercus pagoda* by ruderal trees such as *Acer rubrum, Liquidambar styraciflua, Liriodendron tulipifera, Pinus taeda*, and the invasive exotic tree *Triadica sebifera*. Other invasive exotic plants often common in collapsed examples include *Lonicera japonica, Ligustrum sinense*, and *Lygodium japonicum*.

CES203.384 Southern Coastal Plain Nonriverine Basin Swamp

CES203.384 CLASSIFICATION

Concept Summary: This ecological system occupies large, seasonally inundated basins with peaty substrates in the southern and outermost portions of the Coastal Plain of the southeastern United States. These basins are nonriverine and do not receive overbank flooding. The southern limit of this system extends into central Florida, especially along the Atlantic Coast in Volusia and Brevard counties. Examples are generally forested; the vegetation is characterized by *Taxodium distichum, Nyssa biflora*, evergreen "bay" shrubs, and/or mixed hardwoods. Emergent *Pinus elliottii* may also be present. Some characteristic shrubs include *Cliftonia monophylla, Cyrilla racemiflora, Lyonia lucida*, and *Smilax laurifolia*.

- Water Tupelo - Swamp Tupelo: 103 (Eyre 1980) **<**

Distribution: This system is found in the southern portions of the Atlantic and East Gulf coastal plains, extending down the Florida peninsula. The southern limit of this system extends into central Florida along the Atlantic Coast in Volusia and Brevard counties (A. Johnson pers. comm.).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and C. Nordman

CES203.384 CONCEPTUAL MODEL

Environment: This system occupies large, seasonally inundated basins with peaty substrates. These basins are nonriverine and do not receive overbank flooding. Even though the ecological system tends to occur in large basins, the basin may become full of water, and then there will be some flowout. This is due to high rainfall, and probably is more common in winter, when evapotranspiration is lower than summer. During periods of drought, the amount of water flowing out of a basin swamp may be quite low or none at all, and parts of the basin may become dry. The water tends to be nutrient-poor and acidic, and often it appears tea-colored from tannins in the water (called blackwater).

Key Processes and Interactions: The primary source of water in basin swamps is local rainfall, with additional input from runoff and seepage from the surrounding uplands (FNAI 2010a). Flooding is a regular dynamic process. These basins are prone to long periods of inundation with limited waterflow. The deep parts of basin swamps may go without fire for decades or even centuries, while the drier outer edges can be more susceptible to frequent fire. Basin swamps within mesic flatwoods will burn more frequently than basin swamps within a matrix of mesic or hydric hammock. Without fire, bay shrubs and hardwoods increase in density and peat accumulates more rapidly. *Taxodium* and *Pinus* trees are tolerant of light surface fires, but muck fires burning into the peat can kill the trees, lower the ground surface, and transform a swamp into a pond, lake, marsh, or shrub bog (FNAI 2010a).

Threats/Stressors: Drainage and invasive species such as *Lygodium japonicum, Lygodium microphyllum, Triadica sebifera*, and feral hogs (*Sus scrofa*) are threats. Logging, agricultural runoff, lack of fire, and hydrological modifications are threats (Fowlkes et al. 2003, FNAI 2010a). Conversion to intensively managed pine plantations has been a threat (FNAI 2010a).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from fragmentation, invasion of the basin wetland by exotic species, hydrological modification, such as drainage or impoundment, and logging or intensive forestry practices which do not allow the characteristic trees to regenerate, but replaces them with intensively managed plantations of *Pinus elliottii* or *Pinus taeda*. Lack of fire may be associated with ecosystem collapse, but it might not be the cause. Ecosystem collapse is characterized by altered flooding regime, with the duration of flooding either shortened or lengthened and the replacement of the characteristic trees of a basin swamp wetland with ruderal or invasive exotic trees. Also, ecosystem collapse may be associated with the conversion of the forest to intensively managed plantations of *Pinus elliottii var. elliottii* or *Pinus taeda*.

CES203.548 West Gulf Coastal Plain Nonriverine Wet Hardwood Flatwoods

CES203.548 CLASSIFICATION

Concept Summary: This ecological system represents predominantly wet hardwood and hardwood-pine flatwoods of the West Gulf Coastal Plain of southern Arkansas, eastern Texas, and western Louisiana. Examples may be somewhat more common in the inland portions of the region but are also found in the Outer Coastal Plain as well. These areas are usually found on Pleistocene high terraces (EPA Ecoregion 35c) primarily associated with the Red and Mississippi rivers that are located above the current floodplain. The hydrology is controlled by local rainfall events and not by overbank flooding. Soils are fine-textured, and hardpans may be present in the subsurface. The limited permeability of these soils contributes to perched water tables during fairly substantial portions of the year (when precipitation is greatest and evapotranspiration is lowest). Saturation occurs not from overbank flooding but typically whenever precipitation events occur. The local landscape is often a complex of ridges and swales, usually occurring in close proximity. There is vegetation variability related to soil texture and moisture and disturbance history. Most examples support hardwood forests or swamps, which are often heavily oak-dominated. Important species are tolerant of inundation. They include *Liquidambar styraciflua, Quercus laurifolia, Quercus michauxii*, and *Quercus phellos*, with sparse coverage of wetland herbs such as *Carex glaucescens*. Some swales support unusual pockets of *Fraxinus caroliniana* and *Crataegus* spp. Some examples can contain *Pinus taeda*.

Distribution: This system is found in the West Gulf Coastal Plain, Upper West Gulf Coastal Plain, and Mississippi River Alluvial Plain (P. Faulkner pers. comm.).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne, J. Teague and L. Elliott

CES203.548 CONCEPTUAL MODEL

Environment: This system is found on the wettest inclusions of Pleistocene terraces in the West Gulf Coastal Plain of southern Arkansas, eastern Texas, and western Louisiana. The geology of this system is similar to that of ~West Gulf Coastal Plain Pine-Hardwood Flatwoods (CES203.278)$$, being associated with high Pleistocene terraces of the Lissie and upper Beaumont formations, as well as the Quaternary Fluviatile Terrace Deposits to the north. In terms of landforms, this system represents the lowest topographic position within the level to very gently undulating terraces occupied by flatwoods. Hydrology is controlled by local rainfall, not overbank flooding of nearby streams. Soils are fine-textured, with an impermeable subsurface horizon, which leads to a perched water table. Because of the lower topographic position of these flatwoods, saturated soil conditions tend to occur over extended periods of the year (Elliott 2011).

Key Processes and Interactions: The predominant ecological processes affecting this system are related to soil texture and moisture and disturbance history. These are wetlands that hold standing water for variable periods during the year after rainfall events. The wettest examples were likely not affected to a large degree by fires; however, they are often embedded in pyrogenic landscapes which did burn frequently (R. Evans pers. obs., T. Foti pers. comm.). The difference in the dynamics between this system and the

"non-wet" (dry-mesic, xero-hydric) flatwoods of the region (CES203.278) is their different structure: the wetter type occurs as a closed forest, the dry/mesic one as a more open forest or woodland (with an open canopy, a full herbaceous expression, and few shrubs). The fire regime is different as well: the xero-hydric type is short-interval, low-intensity, low-severity versus medium- to long-interval, low-intensity, high-severity for the wet one (D. Zollner pers. comm. 2006).
Threats/Stressors:
Ecosystem Collapse Thresholds:

CES203.278 West Gulf Coastal Plain Pine-Hardwood Flatwoods

CES203.278 CLASSIFICATION

Concept Summary: This ecological system represents predominantly mesic to dry flatwoods of limited areas of inland portions of the West Gulf Coastal Plain. These areas are usually found on Pleistocene high terraces that are located above current floodplains. The hydrology is controlled by local rainfall events and not by overbank flooding. Soils are fine-textured, and hardpans may be present in the subsurface. The limited permeability of these soils contributes to shallowly perched water tables during portions of the year when precipitation is greatest and evapotranspiration is lowest. Soil moisture fluctuates widely throughout the growing season, from saturated to very dry, a condition sometimes referred to elsewhere as xerohydric. Saturation occurs not from overbank flooding but typically whenever precipitation events occur. Local topography is a complex of ridges and swales, often in close proximity to one another. Ridges tend to be much drier than swales, which may hold water for varying periods of time. Within both ridges and swales, there is vegetation variability relating to soil texture and moisture and disturbance history. The driest ridges support *Pinus taeda* and *Quercus stellata*; more mesic ridges have *Pinus taeda* with *Quercus alba* and species such as *Symplocos tinctoria* and *Viburnum dentatum*. Fire may have been an important natural process in some examples of this system.

Distribution: This system is found in the inland portions of the West Gulf Coastal Plain, on nonriverine, Pleistocene high terraces.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, M. Pyne, J. Teague and L. Elliott

CES203.278 CONCEPTUAL MODEL

Environment: Areas occupied by this system are usually found on nonriverine, Pleistocene high terraces. These are mapped in the northern portion of East Texas as Quaternary Fluviatile Terrace (or Tile) deposits. It is found on very gently undulating to flat surfaces, with local topographic relief provided by ridges and swales. Soils tend to be fine-textured and typically have a somewhat impermeable subsurface horizon, which leads to a perched water table. Saturation results from local rainfall run-on, and alternates with seasonal drying, leading to a xerohydric hydroperiod. The limited permeability of these soils contributes to shallowly perched water tables during portions of the year when precipitation is greatest and evapotranspiration is lowest. Soil moisture fluctuates widely throughout the growing season, from saturated to very dry, a condition sometimes referred to elsewhere as xerohydric. Saturation occurs not from overbank flooding but typically whenever precipitation events occur. Local topography is a complex of ridges and swales, often in close proximity to one another. Ridges tend to be much drier than swales, which may hold water for varying periods of time.

Key Processes and Interactions: The difference in the dynamics between this system and the "wet" hardwood flatwoods of the region, i.e., ~West Gulf Coastal Plain Nonriverine Wet Hardwood Flatwoods (CES203.548)$$, is the different structure: the wetter type occurs as a closed forest, the dry/mesic (xero-hydric) one as a more open forest or woodland (with an open canopy, a full herbaceous expression, and few shrubs). The fire regime is different as well: the xero-hydric type is short-interval, low-intensity, low-severity versus medium- to long-interval, low-intensity, high-severity for the wet one (D. Zollner pers. comm. 2006).
Threats/Stressors:

M032. Southern Coastal Plain Evergreen Hardwood - Conifer Swamp

CES203.252 Atlantic Coastal Plain Streamhead Seepage Swamp-Pocosin-Baygall

CES203.252 CLASSIFICATION

Concept Summary: This ecological system encompasses seepage-fed wetlands in dissected landscapes of the Atlantic Coastal Plain, from southeastern Virginia south through South Carolina and into the Inner Coastal Plain of Georgia. Examples are usually associated with ravines or along headwater streams. Overbank flooding is a negligible influence. Fire may be an important force in some associations and not in others. Vegetation consists of open to closed forests or woodlands of acid-tolerant wetland hardwoods or pine. Generally there is a dense shrub layer consisting primarily of species shared with ~Atlantic Coastal Plain Peatland Pocosin and Canebrake (CES203.267)$$.
Related Concepts:

- Streamhead pocosins (Fleming et al. 2005) **<**
- Sweetbay - Swamp Tupelo - Redbay: 104 (Eyre 1980) **<**

Distribution: This ecological system is found in the Atlantic Coastal Plain, from southeastern Virginia south through South Carolina and into the Inner Coastal Plain of Georgia, primarily in the Fall-line Sandhills region; rarely in dissected terrain in the Outer Coastal Plain.
Nations: US
Concept Source: M. Schafale and R. Evans
Description Author: M. Schafale, R. Evans, C. Nordman and M. Pyne

CES203.252 CONCEPTUAL MODEL

Environment: This system occurs in dissected Coastal Plain terrain on sites saturated by seepage of shallow groundwater. Seasonal to permanent saturation combined with fire of only moderate to low frequency and woody vegetation are the unifying characteristics of this system. A stream is often present draining the site, but it is small, and overbank flooding is a negligible influence. Most examples are in bottoms of ravines, but some are on sideslopes or flats at the base of slopes. Most examples are in sandy areas where rapid soil drainage in the surrounding landscape supplies the seepage. Soils within the system itself are generally mucky sands or clays, or deeper organic soils. This system occurs in landscapes that had frequent fire under natural conditions.
Key Processes and Interactions: Seepage is the most important ecological factor determining where this system occurs. Seepage provides a steady source of water, so that soils remain saturated but seldom have surface flooding. The importance of fire varies

widely in this system. Fire is the most important dynamic process in many examples, but is of minor importance in others, and is probably an important driver of the different vegetation associations. Fire frequency and intensity vary among associations, from moderately frequent intense fires to infrequent low-intensity fires. This system occurs within larger upland landscapes that had frequent fire in the past, but the wetness of these headwater wetlands often limits fire spread into them. Associations dominated by *Pinus serotina* and evergreen shrubs such as *Ilex, Lyonia, Gaylussacia, Persea, Morella, Arundinaria tecta* and *Cyrilla*, or canebrakes dominated by *Arundinaria tecta* can have intense canopy fires that are the dominant influence on vegetation structure. Those dominated by *Chamaecyparis thyoides* have infrequent fire that may catastrophically kill the canopy trees, while also promoting *Chamaecyparis thyoides* regeneration. Associations with hardwood canopies, such as *Acer rubrum, Liriodendron tulipifera*, or *Nyssa biflora*, especially those with limited shrub abundance, are not very flammable and usually burn with low intensity and limited effect. Wind can be an important natural disturbance. Forests of *Chamaecyparis thyoides* are susceptible to heavy windthrow that can affect a substantial part of the canopy. Wind damage in hardwood and pine forests tends to consist mainly of small to medium-sized canopy gaps. In ravine bottom sites that have some streamflow, beavers can be an important influence. Beaver ponds convert the forested vegetation to open water. Upon abandonment, beaver pond sites go through a succession that may lead to a long-lasting mire community, or to regeneration of a swamp canopy and lower strata.

Threats/Stressors: Threats include logging, forestry site preparation or conversion to single-species forestry plantation, damming for ponds, input of sediment and nutrients from adjacent and upslope disturbed uplands, drainage (including minor drainage), eutrophication within urban and agricultural landscapes (from nutrient-laden stormwater runoff), invasive exotic plants such as *Lonicera japonica, Ligustrum sinense, Triadica sebifera, Lygodium japonicum*, and feral hog (*Sus scrofa*) rooting (Engeman et al. 2007). Sites can also be damaged indirectly through fragmentation and through alteration of groundwater input as a result of land use in adjacent uplands. For associations dependent on fire, inadequate fire is an additional threat. Even landscapes with frequent prescribed fire in adjacent uplands can be altered if fires are always conducted under wet conditions where they do not penetrate the streamhead wetlands.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from habitat fragmentation, logging, forestry site preparation or conversion to single-species forestry plantation, drainage (including minor drainage), or by substantial alteration of vegetation by sediment input, eutrophication, invasion by invasive exotic plants, and feral hog (*Sus scrofa*) rooting (Engeman et al. 2007). Those wetlands naturally prone to wildfire may succeed without fire to a forest vegetation dominated by less fire-tolerant trees such as *Liquidambar styraciflua, Pinus taeda, Acer rubrum, Quercus nigra*, and invasive exotic plants, such as *Triadica sebifera* and *Ligustrum sinense*. Collapse can be accelerated by fragmentation and isolation, which can leave species with non-viable populations and which makes examples more prone to invasion by weedy and non-native species as well as to sediment and nutrient input. Ecosystem collapse is characterized by conversion of the characteristic natural vegetation of these acidic wetlands to vegetation dominated by native weedy or invasive exotic plants, which may also be less fire-tolerant, such as *Liquidambar styraciflua, Pinus taeda, Acer rubrum, Quercus nigra*, and invasive exotic plants, such as *Triadica sebifera* and *Ligustrum sinense*.

CES203.501 Southern Coastal Plain Hydric Hammock

CES203.501 CLASSIFICATION

Concept Summary: This ecological system occupies flat lowlands along the southern and outermost portions of the Coastal Plain of the southeastern United States, usually over limestone substrates. The vegetation of this system is characterized by mixed hardwood species, often with hydric oak species common. In Florida, examples of this system are often found adjacent to the floodplain of spring-fed rivers with relatively constant flows. In some areas, such as the Big Bend region of Florida, they occupy large areas of broad, shallow, mucky or seepy wetlands but generally do not receive overbank flooding. In Alabama, this system is apparently confined to floodplains of the Mobile-Tensaw, where examples are topographically higher than the surrounding floodplains.

Related Concepts:
- Atlantic White-Cedar: 97 (Eyre 1980) **<**
- Cabbage Palmetto: 74 (Eyre 1980) **<**

Distribution: As currently documented, this system occurs in Florida, Georgia and rarely in southern Alabama. In Alabama, this system is apparently confined to floodplains of the Mobile-Tensaw (A. Schotz pers. comm.).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, C.W. Nordman and M. Pyne

CES203.501 CONCEPTUAL MODEL

Environment: Examples of this system are associated with limestone-rich sites. Soils may range from sand to clay to organic (FNAI 2010a). In Florida, examples of this system are often found adjacent to the floodplain of spring-fed rivers with relatively constant flows. In some areas, such as the Big Bend region of Florida, they occupy large areas of broad, shallow, mucky or seepy wetlands but generally do not receive overbank flooding (A. Johnson pers. comm.). In Alabama, this system is apparently confined to floodplains of the Mobile-Tensaw, where examples are topographically higher than the surrounding floodplains (A. Schotz pers. comm.).

Key Processes and Interactions: Saturation, but usually not inundation, is characteristic of the hydrology of some hydric hammocks; lower areas generally are prone to more flooding. The distributions of trees within hydric hammocks are influenced by the timing and depth of flooding (Vince et al. 1989). These are sites which are only occasionally subject to wildland fire (FNAI 2010a) and are dominated by mixed evergreen and deciduous forest, often with *Sabal palmetto* which is fire-tolerant.

Threats/Stressors: Conversion of hydric hammock to pine plantations has been a threat, especially damage to the soil from logging and forestry site preparation (FNAI 2010a). Drainage and other hydrological alteration are threats. Feral hogs (*Sus scrofa*) are a real threat; hydric hammock is a preferred habitat for them. Soil disturbance and canopy openings allow the spread of exotic invasive plants, particularly *Cinnamomum camphora, Imperata cylindrica, Lygodium japonicum, Lygodium microphyllum, Nephrolepis cordifolia, Paederia foetida, Schinus terebinthifolius, Tradescantia fluminensis*, and *Urena lobata* (FNAI 2010a). Threats to coastal hydric hammocks also include sea-level rise over the next century (FNAI 2010a).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from logging, site preparation and the conversion of these natural hydric forests to pine plantations. Ecological collapse can occur from the impacts of many invasive exotic species, and also from the effects of sea-level rise for coastal examples (FNAI 2010a). Ecosystem collapse is characterized by sites which have been logged, bedded and converted to pine plantation. Sites may be characterized by dominance by invasive exotic species of plants, or species tolerant of increased salinity or halinity from sea-level rise (for coastal examples).

CES203.505 Southern Coastal Plain Seepage Swamp and Baygall

CES203.505 CLASSIFICATION

Concept Summary: This wetland system consists of forested wetlands in acidic, seepage-influenced habitats of the East Gulf and Atlantic coastal plains, extending from Mississippi and the Florida Parishes of Louisiana east into southern Georgia and central Florida. These are mostly evergreen forests generally found at the base of slopes or other habitats where seepage flow is concentrated. Resulting moisture conditions are saturated or even inundated. The vegetation is characterized by *Magnolia virginiana* and *Nyssa biflora*. Examples occur in the outer portions of the Coastal Plain within the range of *Persea palustris*, and where *Magnolia virginiana* is an important or even dominant species. To the north this system grades into ~East Gulf Coastal Plain Northern Seepage Swamp (CES203.554)$$, where evergreen species are largely replaced by deciduous species in the canopy. Due to excessive wetness, these habitats are normally protected from fire except those which occur during extreme droughty periods. These environments are prone to long-duration standing water, and tend to occur on highly acidic, nutrient-poor soils.

Related Concepts:

- Atlantic White-Cedar: 97 (Eyre 1980) **<**
- Pond Pine: 98 (Eyre 1980) **<**
- Sweetbay - Swamp Tupelo - Redbay: 104 (Eyre 1980) **<**

Distribution: This system occurs in the East Gulf and Atlantic coastal plains, extending from Mississippi and the Florida Parishes of Louisiana east into the Outer Coastal Plain of southern Georgia and into central Florida.

Nations: US

Concept Source: R. Evans and M. Pyne

Description Author: R. Evans, M. Pyne, C. Nordman

CES203.505 CONCEPTUAL MODEL

Environment: These wetlands may occur in poorly developed upland drainages, narrow ravine bottoms, bases of steepheads, and small headwaters stream bottoms. In most cases, these wetlands are embedded in uplands with deep sandy soils. When this system is associated with streams, they tend to be low-gradient, with narrow, often braided channels and diffuse drainage patterns. Habitat also includes baygall vegetation in oval depressions (Carolina bays) in southern Georgia (e.g., in Liberty and Long counties, Georgia).

Key Processes and Interactions: Due to excessive wetness, these habitats are normally protected from fire except those which occur during extreme droughty periods. These environments are prone to long-duration standing water and tend to occur on highly acidic, nutrient-poor soils and saturated peat (FNAI 2010a). This system occurs in landscapes that had frequent fire in the past, but the wetness usually limited fire spread, creating an infrequent fire-return interval. While infrequent, fire intensity varies among associations; those dominated by evergreen shrubs such as *Ilex, Lyonia, Illicium, Cliftonia, Gaylussacia, Persea, Morella, Arundinaria*, and *Cyrilla* and with *Pinus serotina* or *Chamaecyparis thyoides* can produce intense canopy fire when they burn (especially when ladder fuels are present), while others probably experience only low-intensity surface fires because of low flammability. When severe drought has allowed the peat to dry, wildfire can burn out the peat. If shrubs survive, they will resprout, but if the roots of shrubs are killed, the site may respond to the intense fire and transition to herbaceous marsh or eventually *Taxodium - Nyssa* swamp vegetation (FNAI 2010a).

Threats/Stressors: Threats include habitat fragmentation, logging, forestry site preparation or conversion to single-species forestry plantation, drainage (including minor drainage), eutrophication within urban and agricultural landscapes (from nutrient-laden stormwater runoff), invasive exotic plants such as *Lonicera japonica, Ligustrum sinense, Triadica sebifera, Lygodium japonicum*, and feral hog (*Sus scrofa*) rooting (Engeman et al. 2007). Intense wildfire can also be a threat (FNAI 2010a).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from habitat fragmentation, logging, forestry site preparation or conversion to single-species forestry plantation, drainage (including minor drainage), eutrophication within urban and agricultural landscapes (from nutrient-laden stormwater runoff, and perhaps nitrogen deposition), invasive exotic plants, and feral hog (*Sus scrofa*) rooting (Engeman et al. 2007). Those wetlands naturally prone to fire, may succeed without fire to a forest vegetation dominated by less fire-tolerant trees such as *Liquidambar styraciflua, Pinus taeda, Acer rubrum, Quercus nigra* and invasive exotic plants. Ecosystem collapse is characterized by conversion of the characteristic natural vegetation of these acidic wetlands to vegetation dominated by native weedy or invasive exotic plants, which may also be less fire-tolerant, such as *Liquidambar styraciflua, Pinus taeda, Acer rubrum, Quercus nigra*, and invasive exotic plants.

CES203.372 West Gulf Coastal Plain Seepage Swamp and Baygall

CES203.372 CLASSIFICATION

Concept Summary: This West Gulf Coastal Plain ecological system consists of forested wetlands (often densely wooded) in acidic, seepage influenced wetland habitats. These wetlands may occur in poorly developed upland drainages, toeslopes, and small headwaters stream bottoms. These environments are prone to long duration standing water, and tend to have highly acidic, nutrient-poor soils. The vegetation is characterized by an overstory of *Magnolia virginiana, Nyssa sylvatica, Nyssa biflora*, and *Acer rubrum*, although there is some variation according to latitude. Understory vegetation throughout the region consistently supports the vines *Smilax laurifolia* and *Smilax walteri*, and a dense abundance of ferns, such as *Osmunda cinnamomea, Osmunda regalis var. spectabilis*, and *Woodwardia areolata*. In most cases, these wetlands are embedded in uplands with deep sandy soils, recharge areas for this wetland system. When these communities are associated with streams, they tend to be low gradient, with narrow, often braided channels and diffuse drainage patterns. Due to excessive wetness, these habitats are normally protected from fire except those which occur during extreme droughty periods. The limited examples in Oklahoma are somewhat depauperate and lack some of the more southern and eastern taxa (e.g., *Magnolia virginiana, Nyssa biflora*).

Distribution: This system is restricted to eastern Texas, western Louisiana, southern Arkansas, and extreme southeastern Oklahoma.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, M. Pyne, J. Teague and L. Elliott

CES203.372 CONCEPTUAL MODEL

Environment: This system occurs on saturated soils associated with springs and seepage flow in a variety of landscape positions. In the Outer Coastal Plain, these settings tend to be low landscape positions typically along low-gradient creeks, headwaters of drainages, or local depressions (Elliott 2011). The low-gradient creek channels tend to be highly meandering, often with multiple channels and extremely shallow banks. Nixon et al. (1983a) measured stream depths of 0.3-0.6 m and widths of less than 1 m in a study of this system. Inner Coastal Plain examples tend to be embedded within deep sandy slopes and uplands, and may also occur in association with flatwoods drainages (Martin et al. 1990, Martin and Smith 1991, Smith 1996a, Singhurst pers. comm. 2013). It may occur on a range of geological formations, including intermediate to high Pleistocene terraces, Eocene sands, the Catahoula Formation, and the Wilcox Formation. Soils are typically sandy to loamy soils, often with an impermeable subsurface layer that restricts water percolation. These sites are typically semipermanently saturated. These are typically soils of medium to strong acidity, with low available nutrients and significant organic accumulation (Elliott 2011). The deep, poorly drained, strongly acidic, loamy fine sand soils have high organic matter content (Brooks et al. 1993). Van Kley (1999a) indicates that these habitats, sometimes mapped as the Betis soil series and Guyton soil complex, are notably low in calcium and magnesium. Soils of other examples may be mapped as Lovelady (Arenic Glossudalf), Rentzel (Arenic Plinthaquic Paleudult), Corrigan (Typic Albaqualf), Melhomes (Humaqueptic Psammaquent), and Osier (Typic Psammaquent). This system is known from the Pleistocene Terraces and Tertiary uplands in Louisiana, Texas, Arkansas and to a limited extent in Oklahoma. Geologic formations where this system occurs include: Bentley (Intermediate Pleistocene Terraces), Willis (High Pleistocene Terraces), Fleming (Miocene), Catahoula (Oligocene), Cockfield (Eocene), Sparta (Eocene), Carrizo (Eocene), Wilcox (Eocene), Queen City (Eocene) and possibly the Vicksburg (Oligocene) and other formations.

Key Processes and Interactions: This system is maintained by groundwater seepage. Soils have high available water capacity and surface runoff is very slow to ponded. This ecological system is embedded within fire-maintained systems. The role of fire in this system was probably minimal except during droughts or in narrow occurrences where fire may have maintained an example of this system dominated by *Arundinaria gigantea*.

Threats/Stressors: Habitat loss, fragmentation, hydrological alterations (e.g., damming for small impoundments), and sedimentation are the primary threats facing this ecological system. Its current extent is estimated to be only 25 to 50% of its original extent in

Louisiana. Remaining occurrences are often surrounded by degraded or converted habitats and are impacted by forestry and other land management practices (LDWF 2005). Hydrologic alterations that degrade and destroy this ecological system include, but are not limited to, channelization of rivers of streams, drainage ditches, development of infrastructure, and groundwater removal. Other threats include physical damage from nearby and on-site land management activities, eutrophication within urban and agricultural landscapes (from nutrient-laden stormwater runoff), invasive exotic plants such as *Lonicera japonica, Ligustrum sinense, Microstegium vimineum*, and feral hog (*Sus scrofa*) rooting. Intense wildfire can also be a threat. If changes in regional climate bring about a decrease in precipitation, this could lead to drying and loss of this system.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from habitat conversion and fragmentation, hydrological alterations, including groundwater removal, drainage (including minor drainage), eutrophication within urban and agricultural landscapes (from nutrient-laden stormwater runoff, and perhaps nitrogen deposition), logging, forestry site preparation or conversion to single species forestry plantation, invasive exotic plants, and feral hog (*Sus scrofa*) rooting. Ecosystem collapse is characterized by conversion of the characteristic natural vegetation of these acidic wetlands to vegetation dominated by native weedy or invasive exotic plants.

M031. Southern Coastal Plain Floodplain Forest

CES203.247 Atlantic Coastal Plain Blackwater Stream Floodplain Forest

CES203.247 CLASSIFICATION

Concept Summary: This Atlantic Coastal Plain system, which is most abundant in the Carolinas and Georgia, occurs in floodplains of small streams that carry little mineral sediment (blackwater streams). These streams occur in low areas within sandy portions of the Coastal Plain. The water is usually strongly stained by tannins and other dissolved organics and has little suspended mineral sediment. Depositional landforms may be absent or present in limited variety and of small size. Soils are usually strongly acidic. The duration of flooding is long (semipermanent) in the wettest areas, and shorter in slightly higher gradient small streams. Some small blackwater streams near the Fall-line Sandhills have most of their flow from sandhill seepage and have limited fluctuation in water levels. But other blackwater stream channels may dry out during the late summer. In these cases, water tables are not far below the channel, and are high enough that the deeper depressions may still hold water. Vegetation varies from north to south, but generally consists almost entirely of forests of wetland trees, but occasional, small shrub-dominated sloughs may also be present. A variety of tree species may be present; wetter examples (especially toward the northern range limits of this system) are often strongly dominated by *Taxodium distichum* and *Nyssa biflora*. Other examples have mixtures of these species with *Quercus* spp. and other bottomland hardwoods tolerant of blackwater conditions. Species richness ranges from low to moderate, but is lower than in comparable brownwater systems. Flooding is an important ecological factor in this system and may be the most important factor separating it from adjacent systems. However, the high water table supported by inflow from adjacent areas also maintains these areas as wetlands. Flooding excludes non-flood-tolerant species. Unlike river systems, flooding tends to be variable and of shorter duration.

CES203.247 CONCEPTUAL MODEL

Environment: Examples of this system occur in floodplains of small streams of the Atlantic Coastal Plain that carry little mineral sediment (blackwater streams). These streams occur in low areas within sandy portions of the Coastal Plain (Smock and Gilinsky 1992). The water is usually strongly stained by tannins but has little suspended clay and is not turbid. Depositional landforms may be absent or may be present in limited variety and of small size. Soils are generally sandy in drier portions of the floodplain, mucky in wetter portions, or may be uniform organic soils. Soils are usually strongly acidic, but spring-fed rivers or streams may have local components with calcareous water and non-acidic soils. Flooding ranges from semipermanent in the wettest floodplains to intermittent and short in slightly higher areas and along higher gradient streams. Some small blackwater streams near the Fall-line Sandhills have most of their flow from sandhill seepage and have limited fluctuation in water levels, but other blackwater stream channels may dry out during the late summer. In these cases, water tables are not far below the channel, and are high enough that the deeper depressions may still hold water (Smock and Gilinsky 1992). Sediment oxygen demand is high in blackwater swamp areas which have long-duration flooding and high amounts of total organic carbon in the soil and sediments. Evidence suggests that blackwater streams may naturally be low in dissolved oxygen (Todd et al. 2010).

The fluvial features of riverine floodplains occur less frequently along small streams. These features, such as river terraces, oxbows, alluvial flats, point bars, and streamside levees, may occur, but on a smaller scale and sometimes are poorly developed. Fine-scale alluvial floodplain features may be abundant. In pre-European settlement forests, community diversity in these streamside systems was much more complex than in the modified landscapes of today. Fire and beaver activity created a mosaic whose elements included canebrakes, beaver ponds and grass-sedge meadows in abandoned beaver clearings, as well as the streamside zones and mixed hardwood and/or *Pinus* spp. forests that make up more than 95% of the cover that exists today. The most prominent evergreen south of Virginia is the shade-intolerant *Pinus taeda*, which manages to maintain itself by reproducing in larger (multi-tree) treefall gaps.

Key Processes and Interactions: Flooding is an important ecological factor in this system and may be the most important factor separating it from adjacent systems. Flooding brings nutrients and excludes non-flood-tolerant species. Unlike river systems, flooding tends to be variable and of shorter duration. It is unclear how important aquatic fauna are when the system is flooded, but they may be important. The small flows, low gradient, and binding of sediment by vegetation limit channel shifts and sediment movement, but floods may cause local disturbance by scouring. The areas flooded for the longest durations tend to have accumulations of organic sediments which deplete levels of aquatic dissolved oxygen (Todd et al. 2010). Most of these forests would exist naturally as multi-aged old-growth forests driven by gap-phase regeneration. Windthrow is probably the most important cause of canopy gaps.

Fire is probably more important than in larger river systems, because distances to uplands are short and because stream channels and sloughs are smaller and less effective as firebreaks. However, most of the vegetation is not very flammable and usually will not carry fire. Some of these areas apparently were once canebrakes, which presumably were maintained by periodic fire. Fire-return interval varied highly in this system. Except in canebrakes, most fires were very light surface fires, creeping in hardwood or pine litter with some thin, patchy cover of bottomland grasses such as *Chasmanthium laxum* and *Chasmanthium latifolium*. Flame lengths are typically 15-30 cm (6-12 inches) (Landfire 2007a). Even so, fire-scarred trees can be found in most small stream sites except in the wettest microsites. Stand-replacement fires are unknown in this type. Except where Native American burning was involved, fires likely occurred primarily during drought conditions and then often only when fire spread into bottomlands from more pyrophytic uplands. Trees may be partially girdled by fire in duff, followed by bark sloughing. While fire rarely killed the tree, this allowed entry of rot, which, in the moist environment, often resulted in hollow trees, providing nesting and denning habitat for many species of birds and animals. Surface fires occurred on a frequency ranging from about 3 to 8 years in streamside canebrake, streamside hardwood/canebrake, or pine, to 25 years or more in hardwood litter. Low areas having a long hydroperiod, islands, and areas protected from fire by backswamps and oxbows were virtually fire-free. Fire effects were largely limited to top-kill of shrubs and tree saplings less than 5 cm (2 inches) diameter, and the formation of hollow trees.

The distinctive dynamics of stream flooding and protected topographic position dominate the distinctive vegetation of this system. The small watersheds and sometimes higher gradients on these streams may limit floods to fairly short duration. Flooding is most common in the winter, but may occur in other seasons. The sorting of plants by depositional landforms of different heights suggests that wetness or depth of flood waters has significance. In higher gradient streams, flood waters have significant energy. Scouring and reworking of sediment make up an important factor on the streambanks, and channels may occasionally change course. In addition to disturbance, floods bring nutrient input, deposit sediment and disperse plant seeds. However, because of the limited sediment transport, nutrient input is less in blackwater stream systems than in other floodplains. Stream flooding rarely leads to canopy tree mortality.

The most significant natural disturbance along small streams is wind. Winds create gaps, usually of small to medium size, in which trees regenerate and where smaller vegetation temporarily proliferates. Winds affect streamside forests because of wet sandy or mucky soils, and trees that are shallow-rooted. Canopy tree mortality was generally limited to tree-by-tree or small group replacement. Windthrow formed the primary cause of tree mortality in bottomlands. The frequency of these events equates with major hurricanes occurring at approximately 20-year intervals. Tornado tracks can be found passing across uplands and bottomlands, leaving narrow swaths of felled trees. The majority of windthrow seems to have been the result of hurricanes and tornadoes spawned by them. However, some of the most abundant tree species of Coastal Plain blackwater stream floodplains, *Taxodium distichum* and *Nyssa biflora*, are notably stable in strong winds. Susceptibility to wind mortality may depend on the species composition of a given community.

Beavers were once an important part of the dynamics of these systems, one which is returning to higher frequency in some areas. Beavers can dam the main channel of many small streams, and create ponds which can cover the entire width of the floodplain for a stretch (M. Schafale pers. comm. 2013). Ponds are often built in series, so that as much as a kilometer or two of the stream may be affected. Most of the crucial parameters of beaver dynamics under natural conditions are unknown or poorly known. Abundance of beavers, duration of a colony in a given place, and whether dam sites were chosen at random or whether specific favorable sites were repeatedly used would have had major effects on the ecology of this system. The existence of a diverse flora of native aquatic plants of ponds, which appear to take long times to colonize a pond (they are found in greater diversity in 100+-year-old millponds than in younger impoundments) hints that beaver ponds may have been long-lasting features. Impoundment drowns the lower strata of plants and displaces non-aquatic fauna, leading to colonization by aquatic plants and shade-intolerant marsh herbs and shrubs. However, *Taxodium distichum* and *Nyssa biflora* trees in the swamp forest may survive to provide a partial to complete tree canopy. When beavers abandon a pond, the dam will eventually breach, but sometimes remains and at least partially impounds the area for a long time. With the limited mineral sediment input, long-standing ponds fill with muck, sometimes developing boggy vegetation that may persist for many years (M. Schafale pers. comm. 2013).

Threats/Stressors: The most critical anthropogenic threats are ongoing canopy removal from large-scale regeneration logging and intensive forest management; hydrological alteration, drainage and channel modifications; water quality impacts (eutrophication) from surrounding agriculture, range, development and urbanization; and water withdrawals. There are few, if any, remaining watersheds in the Coastal Plain that have not been significantly impacted by human activity (Smock and Gilinsky 1992).

Conversion of this type has primarily resulted from clearing of the forest cover, artificial impoundment, drainage through channelization, and levee building (Smock and Gilinsky 1992). These and other forms of ecosystem alteration continue to be extensive in these systems. Channelization isolates the channel from the floodplain, reducing the frequency and magnitude of floodplain inundation. In small floodplains, the spoil piles from channel digging can also cover a significant portion of the floodplain. Channel alteration, excessive scouring, and sediment deposition as a result of impervious surfaces and vegetation clearing in the watershed can be significant. Repeated logging disrupts the natural structure of the forests and may permanently alter their species composition. Feral hogs (*Sus scrofa*) conduct rooting of the soil, destroying native vegetation and soil-dwelling animals (Engeman et al. 2007).

Alteration of natural hydrologic processes through impoundment and channelization have severely disrupted the function, structure, and species composition of large areas of bottomland forest. In addition, the widespread introduction of *Ligustrum sinense, Microstegium vimineum*, and other exotic invasives has dramatically reduced native diversity in the understory of some examples. The most significant potential climate change effects over the next 50 years include alteration of waterflow, most likely periods of drought alternating with more intense storms. *Ligustrum sinense, Microstegium vimineum*, and other invasive exotic plants have dramatically reduced native diversity in the understory of some examples. The most significant potential climate change effects over the next 50 years include alteration of waterflow, most likely periods of drought alternating with more intense high-flow events associated with storms with heavy rain in areas of the watershed.

Ecosystem Collapse Thresholds: Ecological collapse of bottomland forests results from loss of the canopy and conversion to other uses, primarily from anthropogenic mechanical disturbance (land clearing for farms and agriculture), with the land remaining in an essentially permanently converted state. Ecological collapse can be direct, resulting from conversion, or it can also result from gradual degradation. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate. Runoff of fertilizers (nitrogen and phosphorus), animal waste, pesticides, and other chemicals can also contribute to collapse (Smock and Gilinsky 1992). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance.

IImpoundment and channelization also lead to ecological collapse, through severe disruption of the function, structure, and species composition of large areas of bottomland forest. Anthropogenic hydrologic alteration (e.g., flood control) removes the dynamism of the system and leaves some areas permanently flooded (impoundments) and leaves other areas without any flooding at all, essentially leaving them to function as uplands regardless of their former status as floodplains. Channelization prevents the floodplain from functioning as a natural system, turning the stream into a series of ditches that rapidly remove the water rather than allowing it to flow across the floodplain. In time, this will effectively turn the wetlands of the floodplain into uplands. Additional sources of indirect degradation include increased intensity of flooding, which can lead to channel deepening and scouring, and input of sediment, which can bury the streambed and significantly alter the organic-rich floodplain soils (M. Schafale pers. comm. 2013).

CES203.249 Atlantic Coastal Plain Small Blackwater River Floodplain Forest

CES203.249 CLASSIFICATION

Concept Summary: This ecological system encompasses the floodplains of small to medium blackwater rivers in the Atlantic Coastal Plain which are intermediate in size between the smaller streams and the largest rivers. Blackwater rivers originate in the sandy areas of the Coastal Plain, carry little sediment, and have less well-developed depositional alluvial landforms. The water is usually strongly stained by tannins but has little suspended clay and is not turbid. Soils are sandy or mucky, acidic, and infertile. Vegetation is a mosaic of cypress and gum swamps and bottomland hardwoods dominated by a limited set of oaks and other species. The lowest, wettest areas have some combination of *Taxodium distichum, Taxodium ascendens*, and *Nyssa biflora*. *Nyssa aquatica* is generally scarce or absent. Higher portions of the floodplain have forests with combinations of a small set of wetland oaks and other species, including *Quercus laurifolia, Quercus lyrata, Quercus nigra, Liquidambar styraciflua, Pinus taeda, Magnolia virginiana*, and other species. In general, vegetation is low in species richness.

CES203.249 CONCEPTUAL MODEL

Environment: Examples of this system occur in floodplains of medium to small coastal plain rivers that carry little mineral sediment (blackwater rivers). These rivers have their headwaters in sandy portions of the Atlantic Coastal Plain. The water is usually strongly stained by tannins but has little suspended clay and is not turbid. Depositional landforms such as natural levees and backswamps are usually not well-developed, but point bars, ridge-and-swale systems (scrollwork), and sloughs caused by river meandering may be prominent. Soils are generally sandy in drier portions of the floodplain, mucky in wetter portions, and are very acidic (Smock and Gilinsky 1992). Spring-fed rivers may have calcareous water and non-acidic soils. Flooding ranges from semipermanent in the wettest areas to intermittent and short on the higher portions of the floodplain. Sediment oxygen demand is high in blackwater swamp areas which have long-duration flooding and high amounts of total organic carbon in the soil and sediments. Evidence suggests that blackwater streams may naturally be low in dissolved oxygen (Todd et al. 2010). The sandy soils may make some higher areas within the floodplain well-drained and dry when not flooded. The highest terraces may no longer flood at all and belong to a different system.

Saturation and flooding by acidic water, high in tannins is a key process. These waters carry very little sediment, and are the color of dark tea. This is a linear to large-patch ecological system; stands may be contiguous over thousands of acres. The largest examples could be called matrix examples of this ecological system. Examples are by nature linear, and tend to be narrow. The Satilla River in Georgia is about 375 km in length, and may be the largest example. The lower floodplain is about 2 km across; an approximate size of 750 km² could be used as a working upper bound. There may be limited areas with trees greater than 150 years. Probably there are many stands aged 70-100 years, and many that are younger than 70 years. Stands that have not had extensive timber removal will probably have more woody debris and constitute better habitat for component animal and plant species.

Key Processes and Interactions: Flooding is the most important ecological factor in this system. Frequency and duration of flooding determine the occurrences of different associations and separate the system from other kinds of wetlands. Flooding brings nutrients and excludes non-flood-tolerant species. When flooded, the system may have a substantial aquatic faunal component, with high densities of invertebrates, and may play an important role in the life cycle of fish in the associated river. Unusually long or deep floods may stress vegetation or act as a disturbance for some species. Larger floods cause local disturbance by scouring and depositing sediment along channels, and occasionally causing channel shifts. However, the low-gradient and binding of sediment by vegetation generally make these processes much slower and less frequent than in river systems of most other regions. The areas flooded for the longest durations tend to have high amounts of total organic carbon in the soil and sediments which deplete levels of aquatic dissolved oxygen (Todd et al. 2010).

Except for primary successional communities such as bars, most forests exist naturally as multi-aged old-growth forests driven by gap-phase regeneration. Windthrow is probably the most important cause of gaps. In addition to periodic flooding, the formation of windfall gaps is a dominant ecological processes in bottomland hardwood forests. Windfall gaps occur from the local scale (a single mature canopy tree) to the landscape scale (effects of tornadoes and hurricanes). When canopy trees fall, seedlings in the understory are released and compete for a spot in the canopy. This leads to dense areas of herbaceous and woody vegetation in windfall gaps of all sizes. This is a major process in forest regeneration in bottomland hardwood forests.

Flooding is more frequent on the lower terraces but frequently floods higher terraces (Wharton zones IV and V). Catastrophic floods can cause the loss of canopy over large areas. Canopy decline and reproductive failure can create late-seral open stands. Duration of flooding varies with the placement of a site in the landscape and is a dominant process affecting vegetation on a given site. Flooding can deposit alluvium or scour the ground, depending on the landscape position of a site and the severity of the flood event.

Fire is not believed to be important, due to low flammability of much of the vegetation, wetness, and abundance of natural firebreaks. Fire is infrequent on the lower terraces, but was frequent historically on older terraces outside the floodplain and crept into the floodplains. Putnam (1951, cited in Wharton et al. 1982) states that a serious fire season occurs on an average of about every 5 to 8 years in the bottomland hardwood forests of the Mississippi Alluvial Plain. Some areas of bottomlands apparently were once occupied by canebrakes, which presumably were maintained through deliberate fall burning by Native Americans. Infrequent, mild surface fires would occur in the system; however, they would not alter species composition or structure.

Changes in hydrology due to the activities of beaver are also an important ecological process in bottomland hardwood forests. Beaver impoundments kill trees (sometimes over large areas) and may create open-water habitat, cypress-tupelo stands, or cause stand replacement. Meandering streams are dynamic and frequently change course, eroding into the floodplain and depositing new point bars, thus creating new habitat for early-seral plant communities. Insect outbreaks would occur infrequently in closed-canopy states.

Threats/Stressors: Conversion of this type has primarily resulted from removal of characteristic canopy species through logging, intensive forestry management, fragmentation, hydrological alteration, and runoff of fertilizers (nitrogen and phosphorus), animal waste, pesticides, and other chemicals (Smock and Gilinsky 1992). Clearing, impoundment, drainage through channelization, levee building, and other forms of ecosystem alteration have been and continue to be extensive in these systems. These alterations have severely disrupted the function, structure, and species composition of large areas of bottomland forest (Sharitz and Mitsch 1993).

Fragmentation of forest stands into smaller and smaller patches leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Viable forest patches must be large enough to allow for processes that maintain plant and animal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Increases in forest edges versus forest interior of patches favor common and weedy species over specialists. In terms of generalists, this includes white-tailed deer, raccoons, opossums, and brown-headed cowbirds. These species affect others through activities such as increased browsing, nest predation, etc. (Harris 1989). Feral hogs (*Sus scrofa*) conduct rooting of the soil, destroying native vegetation and soil-dwelling animals. Edge effects occur around forest patches, and are more intense and disruptive in small patches, and with more abrupt edges. Patches with natural edges are probably fairly functional, but sharp artificial edges lead to increased mortality of the trees and more severe deterioration of ecological processes. If intact natural forest patches are buffered by areas of low-intensity forest management, that is, for example, preferable to being adjacent to agricultural land (Harris 1989).

Hydrologic functioning may also be impaired by upstream impoundments, water withdrawals, interbasin transfers, etc. These reduce the frequency and magnitude of flooding events. In general, this would lessen the dynamism of the flooding regime, altering the formation of microtopographic features, scouring and deposition, etc. Invasive exotic plants are a threat; timber removal can change the species composition. Erosion from cleared and regularly plowed uplands has led to significant siltation in the past. Today, forest best management practices and streamside management zones can control or reduce erosion which reaches floodplains, rivers and creeks. *Ligustrum sinense, Microstegium vimineum*, and other invasive exotic plant species have reduced native plant diversity in the understory.

The most significant potential climate change effects over the next 50 years include alteration of waterflow, most likely periods of drought alternating with more intense storms.

Ecosystem Collapse Thresholds: Ecological collapse of bottomland forests results from loss of the canopy and conversion to other uses, primarily from anthropogenic mechanical disturbance (land clearing for farms and agriculture), with the land remaining in an essentially permanently converted state. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate. Runoff of fertilizers (nitrogen and phosphorus), animal waste, pesticides, and other chemicals can also contribute to collapse (Smock and Gilinsky 1992).

Ecological collapse can also result from fragmentation. Viable forest patches must be large enough to allow for processes that maintain plant and animal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance. Harris (1989) states that to be functional, patches of older growth bottomland forest must be at least 30 ha in size, and should be surrounded and buffered by tracts of younger timber or closed-canopy stands that are not necessarily removed from all forestry operations.

Impoundment and channelization also lead to ecological collapse, through severe disruption of the function, structure, and species composition of large areas of bottomland forest. Anthropogenic hydrologic alteration (e.g., flood control) removes the dynamism of the system and leaves some areas permanently flooded (impoundments) and leaves other areas without any flooding at all, essentially leaving them to function as uplands regardless of their former status as floodplains. Channelization essentially prevents the floodplain from functioning as a natural system, turning the river into a series of ditches that rapidly remove the water rather than allowing it to flow across the natural floodplain. In time, this will effectively turn the wetlands of the floodplain into uplands.

CES203.250 Atlantic Coastal Plain Small Brownwater River Floodplain Forest

CES203.250 CLASSIFICATION

Concept Summary: This ecological system encompasses the floodplains of small to medium brownwater rivers of the Atlantic Coastal Plain which are intermediate in size between the smaller streams and the largest rivers. Brownwater rivers originate in clayey areas and carry substantial amounts of mineral sediment, creating well-developed deposition alluvial landforms and fertile soils. These rivers have their headwaters in the Piedmont, Blue Ridge, Interior Plateaus, or in portions of the Coastal Plain where fine-textured sediment predominates. Vegetation is a mosaic of cypress and gum swamps, oak-dominated bottomland hardwoods, and mixed levee forests, with only local examples of embedded non-forested communities. The lowest, wettest areas are dominated by a combination of *Taxodium distichum* and *Nyssa aquatica*. Natural levees and riverfronts have a diverse mixture of trees, including *Platanus occidentalis, Celtis laevigata, Fraxinus pennsylvanica, Acer negundo*, and others. Moderate to high parts of the floodplain away from the levee are usually dominated by bottomland hardwoods, including wetland oaks such as *Quercus laurifolia, Quercus michauxii, Quercus pagoda*, and sometimes a number of other species including *Liquidambar styraciflua*.

CES203.250 CONCEPTUAL MODEL

Environment: Examples of this system occur in floodplains of medium to small Coastal Plain rivers that carry significant mineral sediment (brownwater or redwater rivers). These rivers have their headwaters in the Piedmont, Blue Ridge, Interior Plateaus, or in portions of the Coastal Plain where fine-textured sediment predominates. The water generally carries substantial amounts of silt, clay, and sometimes sand. Depositional landforms such as point bars, natural levees, backswamps, and ridge-and-swale systems (scrollwork) are well-developed and form patterns of significant variation in flooding duration and nutrient input. Soil texture varies from sandy to clayey. Soils are generally fertile and not strongly acidic. Flooding ranges from semipermanent in the wettest areas to intermittent and short on the higher portions of the floodplain. The highest terraces may no longer flood at all and belong to a different system.

Key Processes and Interactions: Flooding is the most important ecological factor in this system. Frequency and duration of flooding determines the occurrences of different associations and separates the system from other kinds of wetlands. Flooding brings nutrients and excludes non-flood-tolerant species. When flooded, the system has a substantial aquatic faunal component, with high densities of invertebrates, and may play an important role in the life cycle of fish in the associated river. Unusually long or deep floods may stress vegetation or act as a disturbance for some species. Larger floods cause local disturbance by scouring and depositing sediment along channels, and occasionally causing channel shifts. However, the low gradient and binding of sediment by vegetation generally makes these processes much slower and less frequent than in river systems of most other regions. Except for primary successional communities such as bars, most forests exist naturally as multi-aged old-growth forests driven by gap-phase regeneration. Windthrow is probably the most important cause of gaps. Fire is not believed to be important, due to low flammability of much of the vegetation, wetness, and abundance of natural firebreaks. However, some areas of bottomlands apparently were once canebrakes, which presumably were maintained by periodic fire.

Threats/Stressors: Conversion of this type has primarily resulted from removal of characteristic canopy species through logging, intensive forestry management, fragmentation, hydrological alteration, and runoff of fertilizers (nitrogen and phosphorus), animal waste, pesticides, and other chemicals (Smock and Gilinsky 1992). Clearing, impoundment, drainage through channelization, levee building, and other forms of ecosystem alteration have been and continue to be extensive in these systems. These alterations have severely disrupted the function, structure, and species composition of large areas of bottomland forest, with local to global implications (Sharitz and Mitsch 1993).

Fragmentation of forest stands into smaller and smaller patches leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Increases in edges versus interior of patches favor common and weedy species over specialists. In terms of generalists, this includes white-tailed deer, raccoons, opossums, and brown-headed cowbirds. These species affect others through activities such as increased browsing, nest predation, etc. (Harris 1989). Feral hogs (*Sus scrofa*) conduct rooting of the soil, destroying native vegetation and soil-dwelling animals. Edge effects occur around forest patches, and are more intense and disruptive in small patches, and with more abrupt edges. Patches with natural edges are probably fairly functional, but sharp artificial edges lead to increased mortality of the trees and more severe deterioration of ecological processes. If intact natural forest patches are buffered by areas of low-intensity forest management, that is, for example, preferable to being adjacent to agricultural land (Harris 1989).

Hydrologic functioning may also be impaired by upstream impoundments, water withdrawals, interbasin transfers, etc. These reduce the frequency and magnitude of flooding events. In general, this would lessen the dynamism of the flooding regime, altering the formation of microtopographic features, scouring and deposition, etc. Invasive exotic plants are a threat, timber removal can change the species composition. Erosion from cleared and regularly plowed uplands has led to significant siltation in the past. Today, forest best management practices and streamside management zones can control or reduce erosion which reaches floodplains, rivers and creeks. In addition, the widespread introduction of *Ligustrum sinense, Microstegium vimineum*, and other exotic invasives has dramatically reduced native diversity in the understory.

The most significant potential climate change effects over the next 50 years include alteration of water flow, most likely periods of drought alternating with more intense storms.

Ecosystem Collapse Thresholds: Ecological collapse of bottomland forests results from loss of the canopy and conversion to other uses, primarily from anthropogenic mechanical disturbance (land clearing for farms and agriculture), with the land remaining in an essentially permanently converted state. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate. Runoff of fertilizers (nitrogen and phosphorus), animal waste, pesticides, and other chemicals can also contribute to collapse (Smock and Gilinsky 1992).

Ecological collapse can also result from fragmentation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance. Harris (1989) states that to be functional, patches of older growth bottomland forest must be at least 30 ha in size, and should be surrounded and buffered by tracts of younger timber or closed-canopy stands that are not necessarily removed from all forestry operations.

Impoundment and channelization also lead to ecological collapse, through severe disruption of the function, structure, and species composition of large areas of bottomland forest. Anthropogenic hydrologic alteration (e.g., flood control) removes the dynamism of the system and leaves some areas permanently flooded (impoundments) and leaves other areas without any flooding at all, essentially leaving them to function as uplands regardless of their former status as floodplains. Channelization essentially prevents the floodplain from functioning as a natural system, turning the river into a series of ditches that rapidly remove the water rather than allowing it to flow across the land. In time, this will effectively turn the wetlands of the floodplain into uplands.

CES203.299 East Gulf Coastal Plain Freshwater Tidal Wooded Swamp

CES203.299 CLASSIFICATION

Concept Summary: This ecological system encompasses the tidally flooded portions of river floodplains which flow into the northern Gulf of Mexico east of the Mississippi River. Large outflows of freshwater keep salinity levels at a minimum, and flooding is of short enough duration to allow survival of tree canopies. Stands are dominated by a combination of *Nyssa aquatica, Nyssa biflora, Taxodium distichum*, and *Fraxinus pennsylvanica*. Other plants that are typically present include *Magnolia virginiana, Sabal palmetto, Juniperus virginiana var. silicicola, Cyrilla racemiflora, Quercus laurifolia, Sabal minor, Taxodium ascendens, Cliftonia* *monophylla, Pinus elliottii var. elliottii, Chamaecyparis thyoides, Hypericum nitidum, Cladium mariscus ssp. jamaicense*, and *Persea palustris*. These swamps may be regularly flooded at least twice daily.

Distribution: This system includes river floodplains which flow into the northern Gulf of Mexico east of the Mississippi River, including the Appalachicola, the Ochlockonee, the St. Marks, the Suwanee, and the Wakulla rivers.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans and M. Pyne

CES203.299 CONCEPTUAL MODEL

Environment: This system occurs in lower reaches of river floodplains and along estuary shorelines, in places regularly or irregularly flooded by lunar or wind tides. The water has little salt content, due to distance from the ocean and/or strong freshwater input. Soils may be mineral or organic. Soils are generally permanently saturated even when the tide is low. The transition of the hydrology to flood dominance rather than tidal dominance may be very gradual.

Key Processes and Interactions: Regular or irregular tidal flooding with freshwater is the ecological factor that makes this system distinct. These swamps may be regularly flooded at least twice a day for several hours and remain inundated for days during flood or storm events (Wharton et al. 1982, FNAI 1990). River floods may also seasonally affect this system. Wind and flooding are the dominant disturbance agents in this type and this includes wind damage from hurricanes and tornadoes as well as inundation of young stands. Canopy gaps can be created by high winds, such as from nor'easters, tropical storms and hurricanes (Nordman 2013). Infrequent intrusion of saltier water, which is stressful or fatal to many of the plant species, is an important periodic disturbance created by storms. Insect outbreaks would occur infrequently in these closed-canopy forests (Landfire 2007a). This system generally appears to be in a shifting relationship with tidal freshwater marshes of the same region. Most marshes have standing dead trees in them, suggesting they recently were swamps. But, conversely, some marshes are being invaded with trees and may be turning into swamps. Freshwater tidal marshes generally occur at the shallow edge of tidal rivers and streams, where river and tidal flow is high, and the vegetation is affected by the changing meanders of the tidal channel. Rising sea level is driving shifts in the communities of this system, causing upstream non-tidal swamps to develop into this system (as they become subject to tides) and causing parts of this system to turn into brackish marshes. In areas not too strongly affected by saltwater intrusion or drowning by rising sea level, these communities can be expected to exist as old-growth, multi-aged forests.

Threats/Stressors: Saltwater intrusion and related rising sea level are the most significant threats. River channel dredging can lead to changes in the salinity and tidal regime. Dams have reduced river flows and downstream sediment movement, and altered the timing of flows. Roads and utility lines can contribute to fragmentation of forests, exposing the edges of stands to wind damage. Invasive exotic species are threats, including plants such as *Triadica sebifera*, invasive exotic *Phragmites australis*, and animals such as feral hogs (*Sus scrofa*). During storm surges and seasonally high tides with sea-level rise over the next century, the lower areas of tidal wooded swamp will be more prone to saltwater intrusions. Tidal influence probably will extend further upstream, and salt and brackish water will reach further upstream, especially during periods of low river and stream flows (Nordman 2013).

Conversion of this type has primarily resulted from repeated removal of the canopy through logging; however, logging is less of a threat to this system than to others, but it does occur. Impacts of logging include loss of natural vegetation structure, altered canopy composition, soil disturbance (which is a great risk in these wet, often organic soils), and increased risk of exotic plant invasions. Along with fragmentation, this is the most critical direct anthropogenic threat. Many areas of tidal wooded swamps in Georgia and South Carolina were cleared for rice cultivation more than 200 years ago.

The most significant potential climate change effects over the next 50 years include rising sea level and its effects. Tidal swamps are very sensitive to climate change (Edwards et al. 2012). Rising sea levels due to climate change can kill the trees and convert the tidal forest to brackish tidal marsh. In areas where floodplain swamp is continuous between non-tidal and tidal, areas somewhat upstream of what is now tidal will become tidal if the sea-level rises. During storm surges and seasonally high tides with sea-level rise over the next century, the lower areas of tidal wooded swamp will be more prone to the intrusion of salt and brackish water. Tidal influence probably will extend further upstream, and saltwater will reach further upstream, especially during low river and stream flows (Nordman 2013). In addition, climate change may alter waterflows, presumably with periods of drought alternating with more intense storms.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from saltwater intrusion (linked to rising sea levels due to climate change) which can kill the trees and convert the tidal forest to brackish tidal marsh. Mechanical alteration of the riverbed morphology through channelization may alter the salinity and tidal regime, exacerbating the saltwater intrusion, and accelerating the possible system collapse. Many examples have been altered, though not completely destroyed, by logging which removed cypress without creating conditions for its regeneration (M. Schafale pers. comm. 2013).

CES203.489 East Gulf Coastal Plain Large River Floodplain Forest

CES203.489 CLASSIFICATION

Concept Summary: This system represents a geographic subset of Southern Floodplain Forest. Examples may be found along large rivers of the East and Upper East Gulf Coastal Plain, especially the Apalachicola, Alabama/Cahaba, Tombigbee, Pascagoula, and Pearl rivers, all of which ultimately drain into the Gulf of Mexico. Several distinct plant communities can be recognized within this system that may be related to the array of different geomorphologic features present within the floodplain. Some of the major geomorphic features associated with different community types include natural levees, point bars, meander scrolls, oxbows, and sloughs. Vegetation generally includes forests dominated by bottomland hardwood species and other trees tolerant of flooding. However, herbaceous and shrub vegetation may be present in certain areas as well.

CES203.489 CONCEPTUAL MODEL

Environment: This system represents a geographic subset of Kuchler's (1964) Southern Floodplain Forest. Examples of this system are generally forested with stands of bottomland hardwood species and other trees tolerant of flooding. Local composition varies depending upon actual position within the floodplain, disturbance history, and underlying soils and geology. Although most examples of this system may be thought of as acidic, some examples of this system flow through regions with sufficient calcareous influence to effect vegetation composition. Some of the major geomorphic features associated with different community types include natural levees, point bars, meander scrolls, oxbows, and sloughs (Sharitz and Mitsch 1993).

Key Processes and Interactions: In pre-European settlement forests, community diversity in these bottomland systems was much more complex than in the modified landscapes of today. Fire, beaver activity, and flooding of varied intensity and frequency created a mosaic whose elements included canebrake, grass and young *Betula-Platanus* beds on reworked gravel or sand bars, beaver ponds, and grass-sedge meadows in abandoned beaver clearings, as well as the streamside zones and mixed hardwood and/or pine forests that make up more than 95% of the land cover that exists today.

The dominant ecological processes in bottomland hardwood forests are windfall gaps and periodic flooding. Windfall gaps occur on the local scale (the fall of a single mature canopy tree) as well as the landscape scale (storms, hurricanes). When canopy trees fall, seedlings in the understory are released and compete for a spot in the canopy. This leads to dense areas of herbaceous and woody vegetation in windfall gaps of all sizes. This is a major process in forest regeneration in bottomland hardwood forests. Canopy decline and reproductive failure can create late-seral open stands.

Flooding is more frequent on the lower terraces but frequently impacts higher terraces as well (Wharton et al. (1982) zones IV & V). Catastrophic floods can cause the loss of canopy over large areas, and large coastal areas are also impacted by storm surges from hurricanes and tropical storms as well as by salt deposition in the immediate coastal area. The duration of flooding varies with the placement of a particular site in the landscape and is a dominant process affecting vegetation on a given site. Flooding can deposit alluvium or scour the ground, depending on the landscape position of a site and the severity of the flood event.

Fire is infrequent and of limited importance in lower, wetter areas, but was historically important in the older and higher terraces, especially areas adjacent to upland pine or pine flatwoods, and also crept into the floodplains. Putnam (1951 as cited in Wharton et al. 1982) states that a serious fire season occurs on an average of about every 5 to 8 years in the bottomland hardwood forests of the Mississippi Alluvial Plain. It is conjectured that Native Americans maintained canebrakes by deliberate fall burning. Infrequent, mild surface fires would occur in the system and would cause changes in composition and structure due to low fire tolerance.

Changes in hydrology due to the activities of beaver are also an important ecological process in bottomland hardwood forests. Beaver impoundments kill trees (sometimes over large areas) and may create open water habitat, cypress-tupelo stands, or cause stand replacement. Meandering streams are dynamic and frequently change course, eroding into the floodplain and depositing new point bars, thus creating new habitat for early-seral plant communities. In addition, insect outbreaks would occur infrequently in closed-canopy states, opening up the canopy at least temporarily.

Threats/Stressors: Fragmentation and hydrological alteration are the major threats to bottomland hardwood systems. Clearing, impoundment, drainage through channelization, levee building, and other forms of ecosystem alteration have been and continue to be extensive in these systems. Fragmentation of forest stands into smaller and smaller patches leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Increases in edges versus interior of patches favor common and weedy species over specialists. In terms of generalists, this includes white-tailed deer, raccoons, opossums, and brown-headed cowbirds. These species affect others through activities such as increased browsing, nest predation, etc. (Harris 1989). Edge effects occur around forest patches and are more intense and disruptive in small patches, and with more abrupt edges. Patches with natural edges are probably fairly functional, but sharp artificial edges lead to increased mortality of the trees and more severe deterioration of ecological processes. If intact natural forest patches are buffered by areas of low-intensity forest management, that is, for example, preferable to being adjacent to agricultural land (Harris 1989). Alteration of natural hydrologic processes through impoundment and channelization have severely disrupted the function, structure, and species composition of large areas of bottomland forest.

Ecosystem Collapse Thresholds: Ecological collapse of bottomland forests results from loss of the canopy and conversion to other uses, primarily from anthropogenic mechanical disturbance (land clearing for farms and agriculture), with the land remaining in an essentially permanently converted state. This effect is most evident and widespread in the upper terraces, whose deep and fertile soils are very productive. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate.

Ecological collapse can also result from fragmentation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance. Harris (1989) states that to be functional, patches of older growth bottomland forest must be at least 30 ha in size, and should be surrounded and buffered by tracts of younger timber or closed-canopy stands that are not necessarily removed from all forestry operations.

Impoundment and channelization also lead to ecological collapse, through severe disruption of the function, structure, and species composition of large areas of bottomland forest. Anthropogenic hydrologic alteration (e.g., flood control) removes the dynamism of the system and leaves some areas permanently flooded (impoundments) and leaves other areas without any flooding at all, essentially leaving them to function as uplands regardless of their former status as floodplains. Channelization essentially prevents the floodplain from functioning as a natural system, turning the river into a series of ditches that rapidly remove the water rather than allowing it to flow across the land. In time, this will effectively turn the wetlands of the floodplain into uplands.

CES203.559 East Gulf Coastal Plain Small Stream and River Floodplain Forest

CES203.559 CLASSIFICATION

Concept Summary: This is a predominantly forested system of the East Gulf Coastal Plain associated with small brownwater rivers and creeks. In contrast to ~East Gulf Coastal Plain Large River Floodplain Forest (CES203.489)$$, it has fewer major geomorphic floodplain features typically associated with large river floodplains. Those features that are present tend to be smaller and more closely intermixed with one another, resulting in less obvious vegetational zonation. Bottomland hardwood tree species are typically important and diagnostic, although mesic hardwood species are also present in areas with less inundation, such as upper terraces and possibly second bottoms. As a whole, flooding occurs annually, but the water table usually is well below the soil surface throughout most of the growing season. Areas impacted by beaver impoundments are also included in this system.

Distribution: This system is found in the East Gulf Coastal Plain, from the coast northward and inland to the extent of unconsolidated sediments in Kentucky.
Nations: US
Concept Source: M. Pyne and R. Evans
Description Author: M. Pyne and R. Evans

CES203.559 CONCEPTUAL MODEL

Environment: This system is associated with small brownwater rivers and creeks of the East Gulf Coastal Plain. It is confined to floodplains or terraces of streams and creeks. This system is dependent on a natural hydrologic regime, especially annual to episodic flooding. These landscapes usually encompass a variety of habitats resulting from natural hydrological spatial patterns (i.e., meander scars, sloughs, gravel bars, old depressions, and/or oxbows are present). Most component associations are temporarily flooded, with the possible addition of smaller-scale seasonally flooded features such as beaver-created herbaceous wetlands and shrub-dominated features. Some larger examples of this system include the Escambia, the Yellow (Alabama, Florida), the Choctawhatchee, the Chattahoochee, and the Flint rivers.

Key Processes and Interactions: In pre-European settlement forests, community diversity in these bottomland systems was much more complex than in the modified landscapes of today. Fire, beaver activity, and flooding of varied intensity and frequency created a mosaic whose elements included canebrake, grass and young *Betula-Platanus* beds on reworked gravel or sand bars, beaver ponds, and grass-sedge meadows in abandoned beaver clearings, as well as the streamside zones and mixed hardwood and/or pine forests that make up more than 95% of the land cover that exists today.

Flooding is the principal disturbance in this system. When flooded, these systems may have a substantial aquatic faunal component, with high densities of invertebrates, and may play an important role in the life cycle of fish in the associated river. Unusually long or deep floods may stress vegetation or act as a disturbance for some species. Flood waters have significant energy. Larger floods cause local disturbance by scouring and depositing sediment along channels and occasionally causing channel shifts. There are two general types of floods: occasional catastrophic, prolonged floods (due to beaver activity or other severe event); and more frequent repeated minor flooding (i.e., several minor floods within a 10 year period). Flooding is more frequent on the lower terraces but frequently floods higher terraces (Wharton et al. (1982) zones IV and V). Catastrophic floods can cause the loss of canopy over large areas. Canopy decline and reproductive failure can create late-seral open stands. Duration of flooding varies with the placement of a site in the landscape and is a dominant process affecting vegetation on a given site. Flooding can deposit alluvium or scour the ground, depending on the landscape position of a site and the severity of the flood event. The sorting of plant communities by depositional landforms of different height suggest that wetness or depth of flood waters helps drive this process. Scouring and reworking of sediment make up an important factor in bar and bank communities. In addition to disturbance, floods bring nutrient input, deposit sediment, and disperse plant seeds (Landfire 2007a).

In addition to periodic flooding, the dominant ecological process in bottomland hardwood forests is the formation of windfall gaps, which can occur on the local scale (a single mature canopy tree) as well as the landscape scale (effects of tornadoes or hurricanes). Except for primary successional communities such as bars, most forests exist naturally as multi-aged old-growth forests driven by gap-phase regeneration. Windthrow is probably the most important cause of gaps, and is the primary cause of mortality in bottomlands. Major storms or hurricanes occurring at approximately 20-year intervals would have impacted whole stands. When canopy trees fall, seedlings in the understory are released and compete for a spot in the canopy. This leads to dense areas of herbaceous and woody vegetation in windfall gaps of all sizes. This is a major process in forest regeneration in bottomland hardwood forests.

Fire is infrequent and of limited importance in lower, wetter areas, but was historically important in the older and higher terraces, and also crept into the floodplains. Putnam (1951 as cited in Wharton et al. 1982) states that a serious fire season occurs on an average of about every 5 to 8 years in the bottomland hardwood forests of the Mississippi Alluvial Plain. It is conjectured that Native Americans maintained canebrakes by deliberate fall burning. Infrequent, mild surface fires would occur in the system; however, they would not alter species composition or structure. Except in canebrake, most fires were very light surface fires, creeping in hardwood or pine litter with some thin, patchy cover of bottomland grasses such as *Chasmanthium laxum* and *Chasmanthium latifolium*. Flame lengths were mostly 15 to 30 cm (6-12 inches). Fire-scarred trees can be found in most small stream sites except in the wettest microsites. Stand-replacement fires are unknown in this type. Except where Native American burning was involved, fires likely occurred primarily during drought conditions and then often only when fire spread into bottomlands from more pyrophytic uplands. Trees may be partially girdled by fire in duff, followed by bark sloughing. While fire rarely killed the tree, this allowed entry of rot, which, in the moist environment, often resulted in hollow trees, providing nesting and denning habitat for many species of birds and animals. Surface fires occurred on a frequency ranging from about 3 to 8 years in streamside canebrake, streamside hardwood/canebrake, or pine, to 25 years or more in hardwood litter. Low areas having a long hydroperiod, islands, and areas protected from fire by backswamps and oxbows were virtually fire-free. Fire effects were largely limited to top-kill of shrubs and tree saplings less than 5 cm (2 inches) in diameter, and formation of hollow trees (Landfire 2007a).

Changes in hydrology due to the activities of beaver is also an important ecological process in bottomland hardwood forests. Beaver impoundments kill trees (sometimes over large areas) and may create open water habitat, cypress-tupelo stands, or cause stand replacement. Meandering streams are dynamic and frequently change course, eroding into the floodplain and depositing new point bars, thus creating new habitat for early-seral plant communities. In addition, insect outbreaks would occur infrequently in closed canopy states.

The distinctive dynamics of stream flooding and protected topographic position dominate the forming of the distinctive vegetation of this system. Not all of the factors are well known. Gradients of most of these rivers limit floods to fairly short duration. Flooding is most common in the winter, but may occur in other seasons.

Threats/Stressors: The most critical anthropogenic threats to bottomland hardwood systems are fragmentation and hydrological alteration. Clearing, impoundment, drainage through channelization, levee building, and other forms of ecosystem alteration have been and continue to be extensive in these systems. Fragmentation of forest stands into smaller and smaller patches leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Increases in edges versus interior of patches favor common and weedy species over specialists. In terms of generalists, this includes white-tailed deer, raccoons, opossums, and brown-headed cowbirds. These species affect others through activities such as increased browsing, nest predation, etc. (Harris 1989). Edge effects occur around forest patches, and are more intense and disruptive in small patches, and with more abrupt edges. Patches with natural edges are probably fairly functional, but sharp artificial edges lead to increased mortality of the trees and more severe deterioration of ecological processes. If intact natural forest patches are buffered by areas of low-intensity forest management, that is, for example, preferable to being adjacent to agricultural land (Harris 1989). Alteration of natural hydrologic processes through impoundment and channelization have severely disrupted the function, structure, and species composition of large areas of bottomland forest. The most significant potential climate change effects over the next 50 years include alteration of water flow, most likely periods of drought alternating with more intense storms.

Ecosystem Collapse Thresholds: Ecological collapse of bottomland forests results from loss of the canopy and conversion to other uses, primarily from anthropogenic mechanical disturbance (land clearing for farms and agriculture), with the land remaining in an essentially permanently converted state. This effect is most evident and widespread in the upper terraces, whose deep and fertile soils are very productive. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate.

Ecological collapse can also result from fragmentation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance. Harris (1989) states that to be functional, patches of older growth bottomland forest must be at least 30 ha in size, and should be surrounded and buffered by tracts of younger timber or closed-canopy stands that are not necessarily removed from all forestry operations.

Impoundment and channelization also lead to ecological collapse, through severe disruption of the function, structure, and species composition of large areas of bottomland forest. Anthropogenic hydrologic alteration (e.g., flood control) removes the dynamism of the system and leaves some areas permanently flooded (impoundments) and leaves other areas without any flooding at all, essentially leaving them to function as uplands regardless of their former status as floodplains. Channelization essentially prevents the floodplain from functioning as a natural system, turning the river into a series of ditches that rapidly remove the water rather than allowing it to flow across the land. In time, this will effectively turn the wetlands of the floodplain into uplands.

CES203.490 Mississippi River Bottomland Depression

CES203.490 CLASSIFICATION

Concept Summary: This system represents semipermanently flooded to saturated depressional areas of the lower Mississippi River Alluvial Valley, from southern Illinois south to Mississippi and Louisiana. These areas have a distinctly longer hydroperiod than other parts of the landscape. Typical and characteristic trees in examples of this system include *Acer rubrum var. drummondii, Carya aquatica, Fraxinus profunda, Gleditsia aquatica, Nyssa aquatica, Nyssa biflora, Planera aquatica, Quercus lyrata, Quercus palustris, Salix nigra*, and *Taxodium distichum*. Some characteristic shrubs include *Cephalanthus occidentalis, Cornus foemina, Decodon verticillatus, Forestiera acuminata, Itea virginica*, and *Planera aquatica*. Herbs are uncommon, but *Ludwigia peploides, Sagittaria lancifolia, Ceratophyllum* spp., *Elodea* spp., *Potamogeton* spp., and *Lemna minor* may be found. It includes the "green ash ponds" on Macon Ridge in northeastern Louisiana.

CES203.490 CONCEPTUAL MODEL

Environment: Examples of this system are found in depressions and backswamps of the lower Mississippi River Alluvial Valley, from southern Illinois south to Mississippi and Louisiana. These areas have a distinctly longer hydroperiod than other parts of the landscape. Along the Macon Ridge in northeast Louisiana, ponds dominated by *Fraxinus pennsylvanica* occur only in small depressions of generally less than an acre to only a few acres. They are considered isolated wetlands since they do not receive alluvial flooding (LNHP 2009).

Key Processes and Interactions: Flooding is more frequent and of longer duration in these depressions and on the lower terraces than the upper ones. Catastrophic floods of long duration as well as wind events can cause the loss of canopy over large areas, and large coastal areas are also impacted by storm surges from hurricanes. The duration of flooding varies with the placement of a particular site in the landscape and is a dominant process affecting vegetation on a given site. Flooding can deposit alluvium or scour the ground, depending on the landscape position of a site and the severity of the flood event. Fire is infrequent and of limited importance in these lower, wetter areas, but could affect them during periods of prolonged drought. Changes in hydrology due to the activities of beaver are also an important ecological process in bottomland hardwood forests. Beaver activity can add to the dynamics of the system, altering habitat over large areas. Beaver impoundments kill trees (sometimes over large areas) but may also create open water habitat, cypress-tupelo stands, or cause stand replacement.

Threats/Stressors: Conversion of this type has primarily resulted from hydrological alteration which converts, degrades, and fragments this system. In addition, repeated canopy removal is an additional threat to bottomland hardwood systems. Alteration of natural hydrologic processes through impoundment and channelization has severely disrupted the function, structure, and species composition of large areas of bottomland forest. These depressions may be the only part of the floodplain forest that retains a natural canopy, but they become surrounded by agricultural land and isolated on the landscape, losing their ecological value as part of a larger landscape. Clearing, impoundment, drainage through channelization, levee building, and other forms of ecosystem

alteration have been and continue to be extensive in these systems. If intact natural forest patches are buffered by areas of low-intensity forest management, that is, for example, preferable to being adjacent to agricultural land (Harris 1989). The most significant potential climate change effects over the next 50 years may include periods of prolonged drought, which would cause these depressions to dry out, making them vulnerable to conversion to other land uses (e.g., agriculture).
Ecosystem Collapse Thresholds: Ecological collapse of bottomland forests results from loss of the canopy and conversion to other uses, primarily from anthropogenic mechanical disturbance (land clearing for farms and agriculture), with the land remaining in an essentially permanently converted state. This effect is less evident and widespread in these depressions, which have longer hydroperiods. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate.

Ecological collapse can also result from fragmentation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance. Harris (1989) states that to be functional, patches of older growth bottomland forest must be at least 30 hectares in size, and should preferably be at least surrounded and buffered by tracts of younger timber or closed-canopy stands that are not necessarily removed from all forestry operations.

Impoundment and channelization also lead to ecological collapse, through severe disruption of the function, structure, and species composition of large areas of bottomland forest. Anthropogenic hydrologic alteration (e.g., flood control) removes the dynamism of the system and leaves some areas permanently flooded (impoundments) and leaves other areas without any flooding at all, essentially leaving them to function as uplands regardless of their former status as floodplains. Channelization essentially prevents the floodplain from functioning as a natural system, turning the river into a series of ditches that rapidly remove the water rather than allowing it to flow across the land. In time, this will effectively turn the wetlands of the floodplain into uplands. Even these wettest depressions can be affected by these activities.

CES203.195 Mississippi River Low Floodplain (Bottomland) Forest

CES203.195 CLASSIFICATION

Concept Summary: These "low bottomlands" are usually seasonally flooded in backswamps, with flooding more frequent than every five years, usually more frequently than every two years, generally by still water that may be impounded behind natural levees, and are classed as Low Gradient Riverine Backwater wetlands in hydrogeomorphic classifications. Low bottomlands occur along the Mississippi River and its tributaries in the Mississippi River Alluvial Plain ecoregion. Prolonged flooding dominates this system, and its duration is greater than in the adjacent Mississippi River Riparian Forest. *Quercus lyrata* is the characteristic dominant species, with *Carya aquatica, Forestiera acuminata*, and other species characteristic of longer hydroperiod environments. Soils are clayey with poor internal drainage.
Related Concepts:

- Overcup Oak - Water Hickory: 96 (Eyre 1980) <

Distribution: This system is found in the Mississippi Alluvial Plain from southern Illinois south to Mississippi and Louisiana.

Concept Source: T. Foti and M. Pyne
Description Author: T. Foti and M. Pyne

CES203.195 CONCEPTUAL MODEL

Environment: These "low bottomlands" are usually seasonally flooded in backswamps, with flooding more frequent than every five years, usually more frequently than every two years, generally by still water that may be impounded behind natural levees, and are classed as Low Gradient Riverine Backwater wetlands in hydrogeomorphic classifications (Klimas et al. 1981).

Key Processes and Interactions: Changes in soils and vegetation of this system are much slower than in the adjacent Mississippi River riparian forest. Flooding is the principal disturbance in this system. Unusually long or deep floods may stress vegetation or act to regenerate some species. Larger floods cause local disturbance by scouring and depositing sediment along channels and occasionally causing channel shifts. Duration of flooding varies with the placement of a site in the landscape and is a dominant process affecting vegetation on a given site. Flooding can deposit alluvium or scour the ground, depending on the landscape position of a site and the severity of the flood event. Flooding occurs in lower terraces more frequently than in the higher ones. Occasional, long-duration flooding can cause the loss of canopy over large areas. This canopy decline and reproductive failure can create late-seral open stands. Duration of flooding varies with the placement of a site in the landscape and is a dominant process affecting vegetation on a given site. Flooding can deposit alluvium or scour the ground, depending on the landscape position of a site and the severity of the flood event.

In addition to periodic flooding, the dominant ecological process in bottomland hardwood forests is the formation of windfall gaps, which can occur on the local scale (a single mature canopy tree) as well as the landscape scale (effects of tornadoes or hurricanes). When canopy trees fall, seedlings in the understory are released and compete for a spot in the canopy. This leads to dense areas of herbaceous and woody vegetation in windfall gaps of all sizes. This is a major process in forest regeneration in bottomland hardwood forests.

The fire history of this type is poorly understood, in part because there has been the widespread assumption that fire was not a factor in its ecological dynamics. However, the presence of extensive cane understories and canebrakes indicates that fire was much more common than is generally believed. These canebrakes exist as a patch community maintained by wind and fire. Fire presumably played a lesser role in this system than in the related "high bottomlands." This system is also bordered by a number of upland communities from which fire would have occasionally burned down into the bottoms, especially in drought years. Beaver activity causes changes in hydrology, and this is an important ecological process in bottomland hardwood forests; the effects are poorly understood at the landscape level, especially in the presettlement context. Beaver impoundments can kill trees (sometimes over large areas) and may create open water habitat or cypress-tupelo stands, or cause stand replacement. Meandering streams are dynamic and frequently change course, eroding into the floodplain and depositing new point bars, thus creating new habitat for early-seral plant communities. In addition, insect outbreaks would occur infrequently in closed-canopy states.

Threats/Stressors: The most critical anthropogenic threats are conversion to other land uses, as well as repeated timber harvesting and intensive silvicultural practices. Clearing, drainage and other forms of ecosystem alteration constitute major threats and continue to be extensive in the Mississippi Alluvial Plain (Foti 2001). Fragmentation is also a major threat to bottomland hardwood systems. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Increases in edges over interior of patches favor common and weedy species over specialists. In terms of generalists, this includes white-tailed deer, raccoons, opossums, and brown-headed cowbirds. These species affect others through activities such as increased browsing, nest predation, etc. (Harris 1989). Edge effects occur around forest patches and are more intense and disruptive in small patches, and with more abrupt edges. Patches with natural edges are probably fairly functional, but sharp artificial edges lead to increased mortality of the trees and more severe deterioration of ecological processes. If intact natural forest patches are buffered by areas of low-intensity forest management, that is preferable to being adjacent to agricultural land (Harris 1989). In addition, the alteration of natural hydrologic processes through impoundment and channelization have severely disrupted the function, structure, and species composition of large areas of bottomland forest. The most significant potential climate change effects over the next 50 years include alteration of waterflow, most likely periods of drought alternating with more intense storms.

Ecosystem Collapse Thresholds: Ecological collapse of bottomland forests results from loss of the canopy, primarily from anthropogenic mechanical disturbance (land clearing for farms and agriculture), with the land remaining in an essentially permanently converted state. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate. Extensive timber harvesting or conversion for biomass (short rotation hardwoods) as well as intensive silvicultural practices will also lead to ecosystem collapse.

Ecological collapse can also result from fragmentation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance. If patches of older growth bottomland forest are to be functional, they must be at least 30 ha in size, and should at least be surrounded and buffered by tracts of younger timber or closed-canopy stands that are not necessarily removed from all forestry operations (Harris 1989).

Impoundment and channelization also lead to ecological collapse, through severe disruption of the function, structure, and species composition of large areas of bottomland forest. Channelization essentially prevents the floodplain from functioning as a natural system, turning the river into a series of ditches that rapidly remove the water rather than allowing it to flow across the land. In time, this will effectively turn the wetlands of the floodplain into uplands.

CES203.190 Mississippi River Riparian Forest

CES203.190 CLASSIFICATION

Concept Summary: This ecological system consists of riverfront vegetation, which is generally temporarily (but rarely seasonally) flooded, on point bars and natural levees adjacent to the river that formed them. The period between floods is less than five years, and the flooding is caused by water flowing directly from the channel. Examples occur along the lower Mississippi River and its tributaries in the Mississippi River Alluvial Plain ecoregion. They are classed as Low Gradient Riverine Overbank wetlands in a hydrogeomorphic classification. The flooding is of shorter duration than on adjacent backswamps where water is impounded behind riverfront natural levees, and is of longer duration than on adjacent high bottomlands that are typically temporarily flooded. Soils are typically sandier than those of low bottomlands. *Arundinaria gigantea* is a common understory component in these forests on natural levees and higher point bars, and may become dominant after thinning or removal of the overstory. Willow and cottonwood sandbars may have an open-canopy (woodland) structure.

Distribution: This system is found in the Mississippi Alluvial Plain from southern Illinois south to Mississippi and Louisiana.
Nations: US
Concept Source: T. Foti, M. Pyne
Description Author: T. Foti and M. Pyne

CES203.190 CONCEPTUAL MODEL

Environment: Stands of this system are generally temporarily (but rarely seasonally) flooded on point bars and natural levees adjacent to the river that formed them, with flooding more frequent than every five years, by flowing water directly from the stream. They are classed as Low Gradient Riverine Overbank wetlands in a hydrogeomorphic classification (Klimas et al. 2004). Flooding is of lower duration than on adjacent backswamps where water is impounded behind riverfront natural levees. Flooding is of longer duration than on adjacent high bottomlands that are typically temporarily flooded. Soils are typically sandier than those of low bottomlands.
Key Processes and Interactions: Often on sites with rapid soil deposition and, therefore, with rapid development of vegetation from low-diversity willow- and cottonwood-dominated communities to more diverse communities dominated by sycamore, pecan, sugarberry, green ash or Nuttall oak. Regeneration is through small treefall gaps or large tornado tracks.

CES203.282 Northern Atlantic Coastal Plain Tidal Swamp

CES203.282 CLASSIFICATION

Concept Summary: This system encompasses freshwater to oligohaline tidally-flooded deciduous forests and shrublands in lower river floodplains and edges of estuaries of the North Atlantic Coastal Plain. This system is restricted to narrow zones along upper tidal reaches of Inner Coastal Plain rivers and tributaries which have sufficient volumes of freshwater and short flooding to support tree canopies. These areas are influenced by lunar tides up to 1 m (3 feet), but diluting freshwater flows from upstream, keeping salinity levels below 0.5 ppt. Deciduous hardwood species predominate, especially *Nyssa biflora* and/or *Fraxinus profunda* or *Fraxinus pennsylvanica*. In Maryland and Virginia, *Taxodium distichum* may be locally dominant.
Related Concepts:

- Baldcypress: 101 (Eyre 1980) <

Distribution: This system ranges from the James River, Virginia, northward to the New Jersey Coastal Plain. Possible occurrence of this system in Pennsylvania requires additional study. Examples are probably most common in the Chesapeake Bay region.
Nations: US
Concept Source: R. Evans and P. Coulling
Description Author: R. Evans, P. Coulling, L.A. Sneddon

CES203.282 CONCEPTUAL MODEL

Environment: This association occurs along fresh reaches of tidal rivers, usually receiving diurnal or irregular tidal flooding. There is distinct hummock-and-hollow microtopography with hollows flooded during higher tides. Soil is generally organic-rich and contains a

frequently deep organic horizon over silty alluvial deposits. Pronounced hummock-and-hollow microtopography is characteristic. Hollows are inundated by diurnal tides; hummocks may be only irregularly flooded, and the tops of hummocks are only rarely (less than annually) submerged (Rheinhardt and Hershner 1992).
Key Processes and Interactions: Development and persistence of this association appears to be limited downstream by halinity and upstream by the availability of sufficient sediment. Hence, tidal hardwood swamps are associated primarily with the upper (higher halinity) end of the freshwater portion of the halinity gradient and typically occur on higher landscape positions adjacent to tidal freshwater marshes (Rheinhardt and Hershner 1992). These swamps are maintained by regular biomass input deposited by regular tidal flow.
Threats/Stressors: sea-level rise is projected to inundate this forest type. Crown die-back and tree mortality are already visible in many areas, generally attributed to the upstream shift in salinity gradient as a result of sea-level rise. Other stressors include water quality degradation from upland water inputs, residential or commercial development, alteration of natural tidal regime, and invasive species (*Iris pseudacorus*) (NYNHP 2013d). Suitable habitat must be available upstream to accommodate migration of tidal swamps as sea-level rises (Reinhardt and Hershner 1992). In the southern portion of the range, this system is threatened by the invasive species *Murdannia keisak*. Another threat is the emerald ash borer (*Agrilus planipennis*) which in general could have profound negative impacts to all *Fraxinus* spp. found in this system.
Ecosystem Collapse Thresholds: Ecosystem collapse occurs when tidal regime is altered, either by tidal restriction limiting the deposition of biomass, or by lack of suitable area to support migration of tidal swamps as sea-level rises. Collapse also occurs when the system is abutted by largely unnatural habitat, such as development or shore stabilization; average buffer width <10 m and/or in poor condition; characteristic species absent; 50% or more reduction in original extent, >10% cover of invasive species; hydrologic regime altered by diversions, withdrawals, or source (Faber-Langendoen et al. 2011).

CES203.065 Red River Large Floodplain Forest

CES203.065 CLASSIFICATION

Concept Summary: This floodplain forest system is specifically restricted to the main stem of the Red River in the West Gulf Coastal Plain and Upper West Gulf Coastal Plain of southwestern Arkansas, adjacent Texas, and Louisiana. Several distinct plant communities can be recognized within this system that may be related to the array of different geomorphic features present within the floodplain. Some of the major geomorphic features associated with different community types within the system include natural levees, point bars, meander scrolls, oxbows, and sloughs. The vegetation generally includes forests dominated by bottomland hardwood species and other trees tolerant of flooding, including bald-cypress and water tupelo. Herbaceous and shrub vegetation may also be present in certain areas. Some canopy trees that may occur in examples of this system include *Betula nigra, Platanus occidentalis, Fraxinus pennsylvanica, Celtis laevigata, Liquidambar styraciflua, Ulmus americana, Nyssa biflora, Populus deltoides, Salix nigra*, and *Quercus texana*. Components with longer hydroperiods may contain *Quercus lyrata, Gleditsia aquatica, Carya aquatica, Nyssa aquatica*, and *Taxodium distichum*. Smaller trees include *Quercus similis, Quercus sinuata var. sinuata, Ulmus crassifolia*, and *Carpinus caroliniana*. Shrubs include *Alnus serrulata, Forestiera acuminata, Planera aquatica, Cephalanthus occidentalis, Ilex decidua, Crataegus viridis, Sabal minor*, and *Itea virginica*. Herbs are limited due to the length of flooding, but some examples are *Boehmeria cylindrica, Mikania scandens*, and *Lysimachia radicans*. Typical floating aquatic plants include *Nelumbo lutea, Nuphar advena, Nymphaea odorata*, and *Lemna minor*.

Distribution: This system is restricted to the main stem of the Red River in the West Gulf Coastal Plain and Upper West Gulf Coastal Plain of southwestern Arkansas, adjacent Texas, and Louisiana. Its range is conceptually coincident with the vast majority of Subsection 234Ai of Keys et al. (1995), excluding the portion of 234Ai within TNC Ecoregion 42 (Mississippi River Alluvial Plain). Its range is also coincident with EPA Ecoregion 35g (Red River Bottomlands) (EPA 2004). The portion of the Red River to the west (231Em of Keys et al. 1995) is treated as part of ~West Gulf Coastal Plain Large River Floodplain Forest (CES203.488)$$.

Nations: US

Concept Source: M. Pyne, R. Evans, T. Foti

Description Author: R. Evans, T. Foti, M. Pyne, L. Elliott and J. Teague

CES203.065 CONCEPTUAL MODEL

Environment: Some of the major geomorphic features associated with different community types within the system include natural levees, point bars, meander scrolls, oxbows, and sloughs (Sharitz and Mitsch 1993). The "flatwoods" of the upper terraces within the floodplain are a different system. The geology is Quaternary alluvial deposits. Landforms include the floodplains of the Red River and its major tributaries. Some local topographic variation exists and includes terraces and oxbows. The soils include loams and other bottomland soils (Elliott 2011).

Key Processes and Interactions: This system is maintained by natural large river hydrological processes (e.g., meanders, flooding, backswamps, natural levees). Occasional, long duration flooding can cause the loss of canopy over large areas. This canopy decline and reproductive failure can create late-seral open stands. Duration of flooding varies with the placement of a site in the landscape and is a dominant process affecting vegetation on a given site. Meandering rivers are dynamic and change course, eroding into the floodplain and depositing new point bars, thus creating new habitat for early-seral plant communities. Changes in hydrology due to the activities of beaver are also an important ecological process in bottomland hardwood forests. Beaver activity causes changes in hydrology, and this is an important ecological process in bottomland hardwood forests; the effects are poorly understood at the landscape level, especially in the presettlement context. Beaver impoundments kill trees (sometimes over large areas) but may also create open water habitat, cypress-tupelo stands, or cause stand replacement. In addition to periodic flooding, the dominant ecological process in bottomland hardwood forests is the formation of windfall gaps, which can occur on the local scale (a single mature canopy tree) as well as the landscape scale (tornadoes or hurricanes). When canopy trees fall, seedlings in the understory are released and compete for a spot in the canopy. This leads to dense areas of herbaceous and woody vegetation in windfall gaps of all sizes. This is a major process in forest regeneration in bottomland hardwood forests. This system is also bordered by a number of upland communities from which fire would have occasionally burned down into the bottoms, especially in drought years.

Threats/Stressors: The primary threats to this system are conversion to agriculture and developed land uses, repeated timber harvesting, alteration of natural hydrological processes (e.g., dams, levees, draining, ditching, dredging), intensive silvicultural practices, fragmentation, and water pollution. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Increases in edges over interior of patches favor common and weedy species over specialists. In terms of generalists, this includes white-tailed deer, raccoons, opossums, and brown-headed cowbirds. These species affect others through activities such as increased browsing, nest predation, etc. (Harris 1989). Edge effects occur around forest patches, and are more intense and disruptive in small patches, and with more abrupt edges. Patches with natural edges are probably fairly functional, but sharp artificial edges lead to increased mortality of the trees and more severe deterioration of ecological processes. Intact natural forest patches buffered by areas of low-intensity forest management tend to be in better condition than those adjacent to agricultural land (Harris 1989). The most significant potential

climate change effects over the next 50 years include alteration of waterflow, caused by periods of drought alternating with more intense storms.
Ecosystem Collapse Thresholds: Ecological collapse of bottomland forests results from loss of the canopy, primarily from anthropogenic mechanical disturbance (land clearing for farms and agriculture), with the land remaining in an essentially permanently converted state. This effect is most evident and widespread in the upper terraces, whose deep and fertile soils are very productive. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate. Extensive timber harvesting or conversion for biomass (short-rotation hardwoods) as well as intensive silvicultural practices will also lead to ecosystem collapse. Ecological collapse can also result from fragmentation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance. If patches of older growth bottomland forest are to be functional, they must be at least 30 hectares in size, and should at least be surrounded and buffered by tracts of younger timber or closed-canopy stands that are not necessarily removed from all forestry operations (Harris 1989). Impoundment and channelization also lead to ecological collapse, through severe disruption of the function, structure, and species composition of large areas of bottomland forest. Anthropogenic hydrologic alteration (e.g., flood control) removes the dynamism of the system and leaves some areas permanently flooded (impoundments) and leaves other areas without any flooding at all, essentially leaving them to function as uplands regardless of their former status as floodplains. Channelization essentially prevents the floodplain from functioning as a natural system, turning the river into a series of ditches that rapidly remove the water rather than allowing it to flow across the land. In time, this will effectively turn the wetlands of the floodplain into uplands. Even the wettest depressions can be affected by these activities.

CES203.240 Southern Atlantic Coastal Plain Tidal Wooded Swamp

CES203.240 CLASSIFICATION

Concept Summary: This system encompasses the tidally flooded areas in lower river floodplains and edges of estuaries of the Atlantic Coastal Plain from southeastern Virginia southward to northern Florida that have sufficiently freshwater and short enough flooding to be able to support tree canopies. *Taxodium, Nyssa*, or *Fraxinus* generally dominate. Swamps may be either regularly flooded by lunar tides or irregularly flooded by wind tides.
Related Concepts:

- Baldcypress: 101 (Eyre 1980) **<**
- Southern Redcedar: 73 (Eyre 1980) **<**

Distribution: This system is found along the Atlantic Coast from southeastern Virginia southward to northern Florida.
Nations: US
Concept Source: M. Schafale and R. Evans
Description Author: M. Schafale, R. Evans, M. Pyne and C. Nordman

CES203.240 CONCEPTUAL MODEL

Environment: This system occurs in lower reaches of river floodplains and along estuary shorelines, in places regularly or irregularly flooded by lunar or wind tides. The water has little salt content, due to distance from the ocean and/or strong freshwater input. Soils may be mineral or organic. Soils are generally permanently saturated even when the tide is low. The transition of the hydrology to flood dominance rather than tidal dominance may be very gradual.

Key Processes and Interactions: Regular or irregular tidal flooding with freshwater is the ecological factor that makes this system distinct. These swamps may be regularly flooded at least twice a day for several hours and remain inundated for days during flood or storm events (Wharton et al. 1982, FNAI 1990). River floods may also seasonally affect this system. Wind and flooding are the dominant disturbance agents in this type and this includes wind damage from hurricanes and tornadoes as well as inundation of young stands. Canopy gaps can be created by high winds, such as from nor'easters, tropical storms and hurricanes (Nordman 2013). Infrequent intrusion of saltier water, which is stressful or fatal to many of the plant species, is an important periodic disturbance created by storms. Insect outbreaks would occur infrequently in these closed-canopy forests (Landfire 2007a). This system generally appears to be in a shifting relationship with tidal freshwater marshes of the same region. Most marshes have standing dead trees in them, suggesting they recently were swamps. But, conversely, some marshes are being invaded with trees and may be turning into swamps. Freshwater tidal marshes generally occur at the shallow edge of tidal rivers and streams, where river and tidal flow is high, and the vegetation is affected by the changing meanders of the tidal channel. Rising sea level is driving shifts in the communities of this system, causing upstream non-tidal swamps to develop into this system (as they become subject to tides) and causing parts of this system to turn into brackish marshes. In areas not too strongly affected by saltwater intrusion or drowning by rising sea level, these communities can be expected to exist as old-growth, multi-aged forests.

Threats/Stressors: Saltwater intrusion and related rising sea level are the most significant threats. River channel dredging can lead to changes in the salinity and tidal regime. Dams have reduced river flows and downstream sediment movement, and altered the timing of flows. Roads and utility lines can contribute to fragmentation of forests, exposing the edges of stands to wind damage. Invasive exotic species are threats, including plants such as *Triadica sebifera*, invasive exotic *Phragmites australis*, and animals such as feral hogs (*Sus scrofa*). During storm surges and seasonally high tides with sea-level rise over the next century, the lower areas of tidal wooded swamp will be more prone to saltwater intrusions. Tidal influence probably will extend further upstream, and salt and brackish water will reach further upstream, especially during periods of low river and stream flows (Nordman 2013). Conversion of this type has primarily resulted from repeated removal of the canopy through logging; however, logging is less of a threat to this system than to others, but it does occur. Impacts of logging include loss of natural vegetation structure, altered canopy composition, soil disturbance (which is a great risk in these wet, often organic soils), and increased risk of exotic plant invasions. Along with fragmentation, this is the most critical direct anthropogenic threat. Many areas of tidal wooded swamps in Georgia and South Carolina were cleared for rice cultivation more than 200 years ago.

The most significant potential climate change effects over the next 50 years include rising sea level and its effects. Tidal swamps are very sensitive to climate change (Edwards et al. 2012). Rising sea levels due to climate change can kill the trees and convert the tidal forest to brackish tidal marsh. In areas where floodplain swamp is continuous between non-tidal and tidal, areas somewhat upstream of what is now tidal will become tidal if the sea-level rises. During storm surges and seasonally high tides with sea-level rise over the next century, the lower areas of tidal wooded swamp will be more prone to the intrusion of salt and brackish water. Tidal influence probably will extend further upstream, and saltwater will reach further upstream, especially during low river and stream flows (Nordman 2013). In addition, climate change may alter waterflows, presumably with periods of drought alternating with more intense storms.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from saltwater intrusion (linked to rising sea levels due to climate change) which can kill the trees and convert the tidal forest to brackish tidal marsh. Mechanical alteration of the riverbed morphology through channelization may alter the salinity and tidal regime, exacerbating the saltwater intrusion, and accelerating the possible system collapse. Many examples have been altered, though not completely destroyed, by logging which removed cypress without creating conditions for its regeneration (M. Schafale pers. comm. 2013).

CES203.493 Southern Coastal Plain Blackwater River Floodplain Forest

CES203.493 CLASSIFICATION

Concept Summary: This ecological system occurs along certain river and stream drainages of the southern Coastal Plain of Florida, Alabama, Mississippi, and southwestern Georgia that are characterized by dark waters high in particulate and dissolved organic materials, and that generally lack floodplain development. In most cases these are streams that have their headwaters in sandy portions of the Outer Coastal Plain. Consequently, they carry little mineral sediment or suspended clay particles and are not turbid except after the heaviest rain events. The water is classically dark in color due to concentrations of tannins, particulates, and other materials derived from drainage through swamps or marshes. In comparison with spring-fed rivers and brownwater rivers of the region, this system tends to be much more acidic in nature and generally lacks extensive and continuous floodplains and levees. Steep banks alternating with floodplain swamps are more characteristic. This system includes mixed rivers, with a mixture of blackwater and spring-fed tributaries such as the Suwannee River. Canopy trees typical of this system are obligate to facultative wetland species such as *Taxodium distichum, Nyssa aquatica*, and *Chamaecyparis thyoides*.

Description Author: R. Evans, A. Schotz, M. Pyne

CES203.493 CONCEPTUAL MODEL

Environment: The rivers in which this system occurs are characterized by dark waters high in particulate and dissolved organic materials, and that generally lack floodplain development. In most cases these are streams that have their headwaters in sandy portions of the Outer Coastal Plain (Smock and Gilinsky 1992). Consequently, they carry little mineral sediment or suspended clay particles and are not turbid except after the heaviest rain events. The water is classically dark in color due to concentrations of tannins, particulates, and other materials derived from drainage through swamps or marshes (FNAI 1990). In comparison with spring-fed rivers and brownwater rivers of the region, this system tends to be much more acidic in nature and generally lacks extensive and continuous floodplain and levees; steep banks alternating with floodplain swamps are more characteristic (FNAI 1990). This system includes mixed rivers, with a mixture of blackwater and spring-fed tributaries such as the Suwannee River.

This is a linear to large-patch ecological system; stands may be contiguous over thousands of acres. The largest examples could be called matrix examples of this ecological system. Examples are by nature linear and tend to be narrow. The Satilla River in Georgia is about 375 km in length and may be the largest example. The lower floodplain is about 2 km across, an approximate size of 750 square km could be used as a working upper bound. There may be limited areas with trees greater than 150 years. Probably there are many stands aged 70-100 years, and many that are younger than 70 years. Stands that have not had extensive timber removal will probably have more woody debris and constitute better habitat for component animal and plant species. Areas that have been logged may become dominated by *Pinus taeda, Liquidambar styraciflua*, and *Acer rubrum* with a common shrub being *Morella cerifera*.

Key Processes and Interactions: Flooding is the most important ecological factor in this system. Frequency and duration of flooding determine the occurrences of different associations and separate the system from other kinds of wetlands. Flooding brings nutrients and excludes non-flood-tolerant species. When flooded, the system may have a substantial aquatic faunal component, with high densities of invertebrates, and may play an important role in the life cycle of fish in the associated river. Unusually long or deep floods may stress vegetation or act as a disturbance for some species. Larger floods cause local disturbance by scouring and depositing sediment along channels, and occasionally causing channel shifts. However, the low gradient and binding of sediment by vegetation generally makes these processes much slower and less frequent than in river systems of most other regions. The areas flooded for the longest durations tend to have high amounts of total organic carbon in the soil and sediments which deplete levels of aquatic dissolved oxygen (Todd et al. 2010).

Except for primary successional communities such as bars, most forests exist naturally as multi-aged old-growth forests driven by gap-phase regeneration. Windthrow is probably the most important cause of gaps. In addition to periodic flooding, the formation of windfall gaps is a dominant ecological processes in bottomland hardwood forests. Windfall gaps occur from the local scale (a single mature canopy tree) to the landscape scale (effects of tornadoes and hurricanes). When canopy trees fall, seedlings in the understory are released and compete for a spot in the canopy. This leads to dense areas of herbaceous and woody vegetation in windfall gaps of all sizes. This is a major process in forest regeneration in bottomland hardwood forests.

Flooding is more frequent on the lower terraces but frequently floods higher terraces (Wharton et al. (1982) zones IV and V). Catastrophic floods can cause the loss of canopy over large areas. Canopy decline and reproductive failure can create late-seral open stands. Duration of flooding varies with the placement of a site in the landscape and is a dominant process affecting vegetation on a given site. Flooding can deposit alluvium or scour the ground, depending on the landscape position of a site and the severity of the flood event.

Fire is not believed to be important, due to low flammability of much of the vegetation, wetness, and abundance of natural firebreaks. Fire is infrequent on the lower terraces, but was frequent historically on older terraces outside the floodplain and crept into the floodplains. Putnam (1951 as cited in Wharton et al. 1982) states that a serious fire season occurs on an average of about every 5 to 8 years in the bottomland hardwood forests of the Mississippi Alluvial Plain. Some areas of bottomlands apparently were once occupied by canebrakes, which presumably were maintained through deliberate fall burning by Native Americans. Infrequent, mild surface fires would occur in the system; however, they would not alter species composition or structure.

Changes in hydrology due to the activities of beaver are also an important ecological process in bottomland hardwood forests. Beaver impoundments kill trees (sometimes over large areas) and may create open water habitat, cypress-tupelo stands, or cause stand replacement. Meandering streams are dynamic and frequently change course, eroding into the floodplain and depositing new point bars, thus creating new habitat for early-seral plant communities. Insect outbreaks would occur infrequently in closed canopy states.

Threats/Stressors: Conversion of this type has primarily resulted from removal of characteristic canopy species through logging, intensive forestry management, fragmentation, hydrological alteration, and runoff of fertilizers (nitrogen and phosphorus), animal waste, pesticides, and other chemicals (Smock and Gilinsky 1992). Clearing, impoundment, drainage through channelization, levee building, and other forms of ecosystem alteration have been and continue to be extensive in these systems. These alterations have severely disrupted the function, structure, and species composition of large areas of bottomland forest, with local to global implications (Sharitz and Mitsch 1993).

Fragmentation of forest stands into smaller and smaller patches leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Increases in edges versus interior of patches favor common and weedy species over specialists. In terms of generalists, this includes white-tailed deer, raccoons, opossums, and brown-headed cowbirds. These species affect others through activities such as increased browsing, nest predation, etc. (Harris 1989). Feral hogs (*Sus scrofa*) conduct rooting of the soil, destroying native vegetation and soil-dwelling animals. Edge effects occur around forest patches and are more intense and disruptive in small patches, and with more abrupt edges. Patches with natural edges are probably fairly functional, but sharp artificial edges lead to increased mortality of the trees and more severe deterioration of ecological processes. If intact natural forest patches are buffered by areas of low-intensity forest management, that is, for example, preferable to being adjacent to agricultural land (Harris 1989).

Hydrologic functioning may also be impaired by upstream impoundments, water withdrawals, interbasin transfers, etc. These reduce the frequency and magnitude of flooding events. In general, this which would lessen the dynamism of the flooding regime, altering the formation of microtopographic features, scouring and deposition, etc. Invasive exotic plants are a threat, timber removal can change the species composition. Erosion from cleared and regularly plowed uplands has led to significant siltation in the past. Today, forest best management practices and streamside management zones can control or reduce erosion which reaches floodplains, rivers and creeks. In addition, the widespread introduction of *Ligustrum sinense, Microstegium vimineum*, and other exotic invasives has dramatically reduced native diversity in the understory. The most significant potential climate change effects over the next 50 years include alteration of waterflow, most likely periods of drought alternating with more intense storms.

Ecosystem Collapse Thresholds: Ecological collapse of bottomland forests results from loss of the canopy and conversion to other uses, primarily from anthropogenic mechanical disturbance (land clearing for farms and agriculture), with the land remaining in an essentially permanently converted state. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate. Runoff of fertilizers (nitrogen and phosphorus), animal waste, pesticides, and other chemicals can also contribute to collapse (Smock and Gilinsky 1992).

Ecological collapse can also result from fragmentation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance. Harris (1989) states that to be functional, patches of older growth bottomland forest must be at least 30 ha in size, and should be surrounded and buffered by tracts of younger timber or closed-canopy stands that are not necessarily removed from all forestry operations.

Impoundment and channelization also lead to ecological collapse, through severe disruption of the function, structure, and species composition of large areas of bottomland forest. Anthropogenic hydrologic alteration (e.g., flood control) removes the dynamism of the system and leaves some areas permanently flooded (impoundments) and leaves other areas without any flooding at all, essentially leaving them to function as uplands regardless of their former status as floodplains. Channelization essentially prevents the floodplain from functioning as a natural system, turning the river into a series of ditches that rapidly remove the water rather than allowing it to flow across the land. In time, this will effectively turn the wetlands of the floodplain into uplands.

CES202.324 Southern Piedmont Large Floodplain Forest

CES202.324 CLASSIFICATION

Concept Summary: This ecological system consists of vegetated communities along Piedmont rivers, south of the James River in Virginia, where flooding and flood-related environmental factors affect vegetation composition and dynamics. Well-developed examples of this system occur in the Triassic basins. The vegetation includes both non-forested bar and scour communities and the more extensive forested floodplain communities. Forests are generally differentiated by depositional landforms such as levees, sloughs, ridges, terraces, and abandoned channel segments. The system is affected by flooding through wetness, scouring, deposition of material, and input of nutrients. Piedmont floodplain systems are generally quite distinct from Coastal Plain ones, with steeper river gradients, harder rocks and more limited floodplain development. The near absence of *Taxodium distichum, Nyssa aquatica*, and other species of the Coastal Plain corresponds well to the geologic boundary in most places.

CES202.324 CONCEPTUAL MODEL

Environment: Examples of this ecological system occur near rivers, on floodplains and terraces affected by river flooding and on emergent bars and banks within channels. The site usually includes distinct depositional landforms, including levees, sloughs, ridges, terraces, and abandoned channel segments. The relative extent of these features varies among the stretches of different rivers depending on factors such as channel morphology (Edwards et al. 2013). The substrate is primarily alluvium. Soils are usually sandy to loamy, but include local clayey and gravelly areas. Soils are generally fertile, among the most nutrient-rich in the Piedmont region. Emergent and vegetated bars of gravel to cobbles are included here as well, as are scoured bedrock areas. Floods are generally of short duration, and wetness is a major influence only within channels and where water is ponded in local depressions. The geologic substrate may be of any kind, but geological substrates in the Piedmont are primarily acidic. A special case is the soft Triassic sedimentary rocks of the Piedmont, where even small streams develop large floodplains with well-developed fluvial landforms and therefore fall into this category.

Key Processes and Interactions: The dynamics of river flooding influence the distinctive vegetation of this ecological system. The large rivers have the largest watersheds in the region, but the gradients of most of these rivers limit floods to fairly short duration. Flooding is most common in the winter, but may occur in other seasons. The sorting of plant communities by depositional landforms of different height suggest that duration of wetness or depth of flood waters may be of significance, though it has much less influence than in the Coastal Plain. Flood waters have significant energy, and scouring and reworking of sediment are an important factor in bar and bank communities. However, in the forested floodplains, flood disturbances that kill established woody plants are rare, and canopy population dynamics are dominated by windthrow. In addition to disturbance, floods bring nutrient input, deposit sediment, and disperse plant seeds.

Wind disturbance is at least as important in this system as other Piedmont forests, perhaps more important than in uplands because of frequently wet and less dense soils and more shallowly-rooted trees. Fire does not appear to be a dominant factor, and most floodplain vegetation is not very flammable. However, historical references to canebrakes dominated by *Arundinaria gigantea* suggest that fire may have once been more possible and more important in at least some portions.

These systems are commonly subject to a variety of indirect modern human influences beyond those that affect most forests. A large fraction of the large Piedmont rivers have been dammed, and power generation and regulation of waterflow create unnatural flood regimes. Extensive erosion of uplands, caused by poor agricultural practices dating back to colonial times, transported large amounts of sediment into floodplains (Edwards et al. 2013). As in uplands, large floodplains often have substantial areas in cultivation. River bottoms were the focus of agriculture among Native Americans, so some of these systems have a long history of human clearing. A number of exotic plant species have invaded floodplains, more than in any other Piedmont ecological system. These include *Ligustrum sinense*, which can form extensive and continuous stands in the understories of floodplain forests (Edwards et al. 2013).

Threats/Stressors: Fragmentation and hydrological alteration are the major threats to bottomland hardwood systems. Clearing, impoundment, drainage through channelization, levee building, and other forms of ecosystem alteration have been and continue to be extensive in these systems. Fragmentation of forest stands into smaller and smaller patches leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Increases in edges versus interior of patches favor common and weedy species over specialists. In terms of generalists, this includes white-tailed deer, raccoons, opossums, and brown-headed cowbirds. These species affect others through activities such as increased browsing, nest predation, etc. (Harris 1989). Edge effects occur around forest patches, and are more intense and disruptive in small patches, and with more abrupt edges. Patches with natural edges are probably fairly functional, but sharp artificial edges lead to increased mortality of the trees and more severe deterioration of ecological processes. If intact natural forest patches are buffered by areas of low-intensity forest management, that is, for example, preferable to being adjacent to agricultural land (Harris 1989). Alteration of natural hydrologic processes through impoundment and channelization have severely disrupted the function, structure, and species composition of large areas of bottomland forest.

Ecosystem Collapse Thresholds: Ecological collapse of bottomland forests results from loss of the canopy and conversion to other uses, primarily from anthropogenic mechanical disturbance (land clearing for farms and agriculture), with the land remaining in an essentially permanently converted state. This effect is most evident and widespread in the upper terraces, whose deep and fertile soils are very productive. Areas that have been cleared and subsequently abandoned may develop successional vegetation that contains a subset of the characteristic species but is depauperate.

Ecological collapse can also result from fragmentation. Viable forest patches must be large enough to allow for processes that maintain floral and faunal species composition and structure at the landscape scale (Harris 1989, Sharitz and Mitsch 1993). Fragmentation leads to disruption of natural processes such as plant succession, nutrient cycling, and litter accumulation. The disruption of biotic processes tracks the degree of degradation by fragmentation and anthropogenic disturbance. Harris (1989) states that to be functional, patches of older growth bottomland forest must be at least 30 ha in size, and should be surrounded and buffered by tracts of younger timber or closed-canopy stands that are not necessarily removed from all forestry operations.

Impoundment and channelization also lead to ecological collapse, through severe disruption of the function, structure, and species composition of large areas of bottomland forest. Anthropogenic hydrologic alteration (e.g., flood control) removes the dynamism of the system and leaves some areas permanently flooded (impoundments) and leaves other areas without any flooding at all, essentially leaving them to function as uplands regardless of their former status as floodplains. Channelization essentially prevents the floodplain from functioning as a natural system, turning the river into a series of ditches that rapidly remove the water rather than allowing it to flow across the land. In time, this will effectively turn the wetlands of the floodplain into uplands.

CES202.323 Southern Piedmont Small Floodplain and Riparian Forest

CES202.323 CLASSIFICATION

Concept Summary: This ecological system consists of vegetated communities along streams and small rivers in the Piedmont of the southeastern United States where flooding and flood-related environmental factors affect vegetation composition and dynamics. The vegetation includes both non-forested bar and scour communities, as well as more extensive forested floodplain communities. The forests of these smaller floodplains and bottomlands are not differentiated by depositional landforms such as levees, sloughs, ridges, terraces, and abandoned channel segments, because these features are small and flooding regimes are variable. The system is affected by flooding through wetness, scouring, deposition of material, and input of nutrients. Piedmont floodplain systems are generally quite distinct from Coastal Plain ones, with steeper river gradients, harder rocks and more limited floodplain development. The near absence of *Taxodium distichum, Nyssa* spp., and other species of the Coastal Plain corresponds well to the geologic boundary in most places.

CES202.323 CONCEPTUAL MODEL

Environment: Examples occur on moderately to very high-gradient streams over a wide range of elevations, near streams and small rivers, on floodplains and terraces affected by river flooding and includes emergent bars and banks within channels. Depositional landforms, including levees, sloughs, ridges, terraces, and abandoned channel segments may be present, but occur less frequently and are smaller than the scale of the communities of the floodplain. Fine-scale alluvial floodplain features are abundant. The substrate is primarily alluvium. Soils are usually sandy to loamy, but include local clayey and gravelly areas. Soils are generally fertile, among the most nutrient-rich in the Piedmont region. Alluvial soils may be as important a factor as ongoing flooding in differentiating these systems from adjacent uplands. Emergent and vegetated bars of gravel to cobbles occur occasionally but are generally not extensive or as distinctive as they are on larger rivers. Floods are generally of short duration, and wetness is a major influence only within channels and where water is ponded in local depressions. The geologic substrate may be of any kind, but areas on Triassic sediments tend to have large floodplain systems even on fairly small streams.

Key Processes and Interactions: The distinctive dynamics of stream flooding are presumably the primary reason for the distinctive vegetation of this system, though not all of the factors are well known. Small rivers and streams with small watersheds have more variable flooding regimes that larger rivers. Floods tend to be of short duration and unpredictably variable as to season and depth. Flood waters may have significant energy in higher gradient systems, but scouring and reworking of sediment rarely affect more than small patches. They are important in maintaining the small non-forested patches. In the forested floodplains, flood disturbances that kill established woody plants are rare, and canopy population dynamics are dominated by windthrow. In addition to disturbance, floods bring nutrient input, deposit sediment, and disperse plant seeds.

In pre-European settlement forests, community diversity in these streamside systems was much more complex than in the modified landscapes of today. Fire, beaver activity, and flooding of varied intensity and frequency created a mosaic whose elements included canebrake, grass and young *Betula-Platanus* beds on reworked gravel or sand bars, beaver ponds, and grass-sedge meadows in abandoned beaver clearings, as well as the streamside zones and mixed hardwood and/or pine forests that make up more than 95% of the land cover that exists today.

Flooding is the major disturbance process affecting the vegetation, with the substrate more rapidly drained than in flat floodplain areas. The higher gradients of most of these streams and rivers limit floods to fairly short duration. Flooding is most common in the winter, but may occur in other seasons particularly in association with hurricanes, tornados, or microbursts from thunderstorms. Flood waters may have significant energy in higher gradient systems, but scouring and reworking of sediment are important in maintaining the small non-forested patches of the bar and bank communities. Flooding can act as a replacement disturbance in areas where beavers impounded a channel or in rare years with severe prolonged flood events. There are two general types of floods: occasional catastrophic, prolonged floods (due to beaver activity or other severe event); and more frequent repeated minor flooding (i.e., several minor floods within a 10-year period).

The wind disturbance associated with flooding is very significant along small streams because of wet and less dense soils and shallow-rooted trees. Canopy tree mortality from more common windstorms would have resulted in tree-by-tree or small group replacement. Windthrow is the primary cause of mortality in bottomlands. Major storms or hurricanes occurring at approximately 20-year intervals would have impacted whole stands. Tornado tracks can be found passing across uplands and bottomlands [see one such indicated on a map of Umstead State Park, Raleigh, NC], leaving narrow swaths of felled trees (Landfire 2007a). The majority of windthrow in the Piedmont seems to have been the result of hurricanes and tornadoes spawned by them. Even though the Piedmont is removed from the coast by 25 to over 100 miles, extensive windthrow occurred in middle-aged and old-growth trees in Piedmont bottomlands following Hurricane Fran in 1996 (Xi et al. 2008). Bottomland *Quercus* species, even though seemingly in more sheltered positions, were much more heavily affected than hardwoods on adjacent uplands. Gaps as large as one hectare were seen intermixed in areas with extensive single-tree windthrow. Windthrow may also occur because of thunderstorm microbursts or tornados. In addition, ice damage is an infrequent but potentially catastrophic disturbance.

Fire does not appear to be a dominant factor, and most floodplain vegetation is not very flammable. However, historical references to canebrakes dominated by *Arundinaria gigantea* suggest that fire may have once been more possible and more important in at least some portions.

Threats/Stressors: These systems are less commonly subject to alteration of flood regimes by upstream impoundments than are large rivers, but these alterations have extensively altered flood frequency and duration in some areas. Extensive erosion of uplands, caused by poor agricultural practices dating back to colonial times, transported large amounts of sediment into floodplains. Glenn (1911) cited numerous examples of extensive bank erosion in streams of the upper Piedmont of North Carolina. It is conceivable that all of the streams of the Piedmont have undergone such extensive bank erosion and channel downcutting that they have all been fundamentally altered since European settlement. In addition, a number of exotic plant species have invaded floodplains, more than in any other Piedmont system. Ireland et al. (1939) discuss how erosion in the Piedmont leads to massive head-cutting and gully formation, a process that continues to the present day.

The widespread introduction of *Ligustrum sinense, Microstegium vimineum*, and other exotic invasives has dramatically reduced native diversity in the understory.

Fluctuations in rainfall amount and frequency would be expected to affect the abundance and distribution of early- and later-successional vegetation types within the floodplain. Different climate change scenarios would be assumed to promote different outcomes; without better historical baseline data, it is hard to know how these different possible futures relate to past trends. Undoubtedly, the greatest historic stressors have been the conversion to intensive agriculture in the 1800-1950 period (with subsequent abandonment and re-establishment of forest vegetation) and the construction of dams for mills, hydropower, and water supply during the same period (Wharton 1978). The most significant potential climate change effects over the next 50 years include alteration of waterflow, most likely periods of drought alternating with more intense storms.

Ecosystem Collapse Thresholds: Ecosystem collapse results from the effects of urbanization and the consequent loss of forest cover, accompanied by direct alteration of channel morphology, and increased input of nutrients, oxygen-demanding organics, and toxic substances (Mulholland and Lenat 1992). Collapse has occurred where the native forest and herbaceous vegetation have been removed (as occurred throughout much of the Piedmont between about 1800 and 1950), and the land converted to agricultural uses (pasture and cropland). This land clearing led to and accelerated the process of erosion, gully formation, and massive downcutting of the landscape, with the formation of new stream channels in the new land surface. This new land surface has in many cases become revegetated with the abandonment of agriculture in these severely eroded lands. The present ecosystem is in effect a secondary system, with a diminished flora and fauna, in particular with a larger proportion of *Pinus taeda* than in the presettlement landscape, and the widespread introduction of *Ligustrum sinense, Microstegium vimineum*, and other exotic invasives. The construction of dams for mills, hydropower, and water supply during the historical period (ca. 1800-1950) has led to local ecological collapse due to impoundment of the areas behind the dams, as well as severe alteration of the flooding regime downstream.

CES203.488 West Gulf Coastal Plain Large River Floodplain Forest

CES203.488 CLASSIFICATION

Concept Summary: This system represents a geographic subset of Kuchler's (1964) Southern Floodplain Forest found west of the Mississippi River. Examples may be found along large rivers of the West Gulf Coastal Plain and Upper West Gulf Coastal Plain, especially the Trinity, Neches, Sabine, and others. Several distinct plant communities can be recognized within this system that may be related to the array of different geomorphic features present within the floodplain. Some of the major geomorphic features associated with different community types include natural levees, point bars, meander scrolls, oxbows, and sloughs. Vegetation generally includes forests dominated by bottomland hardwood species and other trees tolerant of flooding, including bald-cypress and water tupelo. Some other trees which may be associated with examples of this system include *Acer rubrum var. drummondii, Betula nigra, Carya aquatica, Celtis laevigata, Fraxinus pennsylvanica, Liquidambar styraciflua, Platanus occidentalis, Gleditsia aquatica, Nyssa aquatica, Nyssa biflora, Pinus taeda, Populus deltoides, Quercus laurifolia, Quercus lyrata, Quercus michauxii, Quercus nigra, Quercus pagoda, Quercus phellos, Quercus similis, Quercus texana, Salix nigra, Ulmus americana*, and *Ulmus crassifolia*. Smaller areas of herbaceous- and shrub-dominated vegetation may also be present in certain areas. Shrubs and small trees include *Alnus serrulata, Arundinaria gigantea, Carpinus caroliniana, Cephalanthus occidentalis, Clethra alnifolia, Cornus foemina, Crataegus viridis, Forestiera acuminata, Ilex decidua, Itea virginica, Morella cerifera, Planera aquatica, Sabal minor*, and *Ditrysinia fruticosa*. Vines may include *Berchemia scandens* and *Smilax bona-nox*. Herbaceous species may include *Boehmeria cylindrica, Carex complanata, Carex debilis, Carex intumescens, Carex joorii, Leersia virginica, Lycopus virginicus, Mikania scandens, Saccharum baldwinii*, and *Typha latifolia*. Aquatic and floating herbs include *Lemna minor, Nelumbo lutea, Nuphar advena*, and *Nymphaea odorata*.

Distribution: This system occurs along large rivers of the West and Upper West Gulf coastal plains, especially the Trinity, Neches, Sabine, and others, as well as the portion of the Red River represented by Keys et al. (1995) (231Em) at the Oklahoma-Texas border.
Nations: US
Concept Source: R. Evans and T. Foti
Description Author: R. Evans, T. Foti, M. Pyne and L. Elliott

CES203.488 CONCEPTUAL MODEL

Environment: Some of the major geomorphic features associated with different community types within this system include natural levees, point bars, meander scrolls, oxbows, and sloughs (Sharitz and Mitsch 1993). This system typically occupies Quaternary Alluvial geology along major rivers including the Trinity (downstream of Cobb Creek), Neches, Angelina, Sabine, Sulphur, and San Jacinto, and a few of their major tributaries. Landforms include broad floodplains with significant development of bottomland soils. These areas include an array of local geomorphic features such as natural levees, point bars, meander scrolls, oxbows, terraces, and sloughs. This system occupies soils of various textures derived from alluvial processes of the associated rivers. The hydrology of these soils is variable, including temporary, seasonal, and semipermanent flooding regimes.

CES203.459 West Gulf Coastal Plain Near-Coast Large River Swamp

CES203.459 CLASSIFICATION

Concept Summary: These swamp forests are found along rivers flowing through the Gulf Coast Prairies and Marshes region of the Outer Coastal Plain of western Louisiana and adjacent Texas. Included are areas where the rivers enter bays and estuaries along the northern Gulf of Mexico that are somewhat tidally influenced. This is restricted to Vermillion Bay in Louisiana west to and including Galveston Bay and Trinity Bay in Texas. Stands of vegetation included in this system are typically dominated by *Taxodium distichum, Nyssa aquatica*, or perhaps a combination of these species. These are forested areas in an area primarily dominated by marshes. Other species are usually more minor components of the canopy, including *Fraxinus pennsylvanica, Acer negundo*, and the exotic tree *Triadica sebifera*. These swamps are typically interspersed with marshes of the coastal region.

Distribution: This system is found along rivers flowing through the Gulf Coast Prairies and Marshes (TNC Ecoregion 31) of the Outer Coastal Plain of western Louisiana and adjacent Texas. This is restricted to EPA 34g (Texas-Louisiana Coastal Marshes) from Vermillion Bay in Louisiana west to, and including Galveston Bay and Trinity Bay in Texas (EPA 2004).
Nations: US
Concept Source: J. Teague and R. Evans
Description Author: J. Teague, R. Evans, M. Pyne and L. Elliott

CES203.459 CONCEPTUAL MODEL

Environment: The environment of this system consists of rivers flowing through the Gulf Coast Prairies and Marshes ecoregion of the Outer Coastal Plain of western Louisiana and adjacent Texas. This includes somewhat tidally-influenced areas where the rivers enter bays and estuaries along the northern Gulf of Mexico. The geological substrate consists of Quaternary alluvium deposited within the Beaumont/Deweyville surfaces. Landforms include the large river floodplains of the Sabine, Neches, and Trinity rivers near the coast, often with some tidal influence. Typical soils include bottomland soils of the near-coast region. Stands are generally distributed downstream of Interstate Highway 10 (a coincidental landmark for the distribution of this system). On the Neches River, this is nearly coincident with the area downstream of the confluence with Pine Island Bayou (Elliott 2011).

CES203.487 West Gulf Coastal Plain Small Stream and River Forest

CES203.487 CLASSIFICATION

Concept Summary: This is a predominantly forested system of the West Gulf Coastal Plain associated with small rivers and creeks. In contrast to ~West Gulf Coastal Plain Large River Floodplain Forest (CES203.488)$$, examples of this system have fewer major geomorphic floodplain features. Those features that are present tend to be smaller and more closely intermixed with one another, resulting in less obvious vegetational zonation. Bottomland hardwood tree species are typically important and diagnostic, although mesic hardwood species are also present in areas with less inundation, such as upper terraces and possibly second bottoms. As a whole, flooding occurs annually, but the water table usually is well below the soil surface throughout most of the growing season. Areas impacted by beaver impoundments are also included in this system. Stands of this system are typically dominated by hardwood tree species such as *Liquidambar styraciflua, Quercus nigra, Celtis laevigata, Fraxinus pennsylvanica, Betula nigra, Quercus laurifolia, Ulmus americana, Ulmus crassifolia, Ulmus alata, Ulmus rubra, Quercus michauxii, Quercus texana, Quercus pagoda, Quercus falcata, Platanus occidentalis, Diospyros virginiana, Gleditsia triacanthos*, and *Acer rubrum*. Wetter sites tend to be dominated by more flood-tolerant species such as *Taxodium distichum, Nyssa aquatica, Gleditsia aquatica, Carya aquatica, Quercus lyrata, Quercus similis, Planera aquatica*, and *Quercus phellos*.

Distribution: West Gulf Coastal Plain.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, M. Pyne and L. Elliott

CES203.487 CONCEPTUAL MODEL

Environment: This system is associated with small rivers and creeks in the West Gulf Coastal Plain. It largely occurs on Quaternary alluvium, but may also be found on other mapped geologic surfaces on drainages lacking significant alluvial development. This system occupies small rivers, streams, creeks, and upland drainages. These sites tend to be higher in the watershed where less depositional activity occurs. The local geomorphological variation tends to be less than in ~West Gulf Coastal Plain Large River Floodplain Forest (CES203.488)$$. Soils are bottomland soils on small streams. A minority of sites are seasonally or semipermanently flooded (Elliott 2011).
Key Processes and Interactions:
Threats/Stressors:
Ecosystem Collapse Thresholds:

M154. Southern Great Plains Floodplain Forest & Woodland

CES203.714 Central Texas Coastal Prairie Riparian

CES203.714 CLASSIFICATION

Concept Summary: This system occurs in upland drainages as they coarse through the relatively level landscape of the coastal prairie in Texas. It represents vegetation bordering upland drainages that are mostly incised, erosional features with very little alluvial deposition. Woody vegetation often shares composition with that of floodplains along larger rives and streams of the region. Species may include *Celtis laevigata, Ulmus crassifolia, Carya illinoinensis, Salix nigra, Prosopis glandulosa, Vachellia farnesiana, Quercus nigra, Quercus fusiformis, Prosopis glandulosa, Diospyros texana, Condalia hookeri, Ziziphus obtusifolia*, and *Aloysia gratissima*. The herbaceous layer may contain species such *Elymus virginicus, Chasmanthium latifolium, Calyptocarpus vialis, Verbesina virginica*, and *Chloracantha spinosa*. Though woody vegetation is the predominant vegetation type in this system, it may also include small areas that lack a significant woody component.

CES203.713 Central Texas Coastal Prairie River Floodplain

CES203.713 CLASSIFICATION

Concept Summary: This system occurs in the Gulf Coast Prairies and Marshes region of Texas. It occupies alluvial settings along rivers, streams and larger drainages. This wetland and upland transition area supports a correspondingly similar mixture of wetland/upland vegetation types that are primarily deciduous or mixed evergreen-deciduous forests. In addition, this system also expresses a transition from northeast to southwest. In the northeastern parts of the range, *Quercus fusiformis* is a common component, as are a few other trees and shrubs with a more eastern affinity such as *Celtis laevigata, Ulmus crassifolia, Sabal minor, Cephalanthus occidentalis, Forestiera acuminata*, and/or *Cornus drummondii*. In the southwestern parts of the range, trees and shrubs with a western and subtropical affinity such as *Fraxinus berlandieriana, Prosopis glandulosa, Vachellia farnesiana*, and *Ehretia anacua* become more prominent.
Related Concepts:

CES203.715 Columbia Bottomlands Forest and Woodland

CES203.715 CLASSIFICATION

Concept Summary: This system occupies a generally level landscape encompassing the historic floodplains of the Brazos, Colorado, and San Bernard rivers of the Coastal Prairie region of Texas. The level to gently rolling uplands are punctuated by a series of swales, depressions, terraces, and natural levees. Significant local topographic relief can be associated with these features. Much of the flooding experienced by this system results from seasonal precipitation and tropical storms, not from overbank flooding. A range of communities are expressed along a moisture gradient ranging from the wettest sites along stream margins and depressions, to somewhat drier sites on ridges and natural levees. Soils are frequently clayey or loamy bottomlands.

Distribution: This system occupies a large area encompassing the historic floodplains of the Brazos, Colorado, and San Bernard rivers in the Coastal Prairie region of the Texas Gulf Coast. Chocolate Bayou represents the eastern extent of this system as the forest grades into systems more closely resembling ~West Gulf Coastal Plain Small Stream and River Forest (CES203.487)$$ to the northeast. Tres Palacios Creek represents the southwestern limit of this system, as floodplains further south and west share closer affinity to coastal rivers such as the Mission and Aransas.

Nations: US

Concept Source: L. Elliott, D. Diamond, A. Treuer-kuehn, D. German, J. Teague

Description Author: L. Elliott and J. Teague

CES203.715 CONCEPTUAL MODEL

Environment: This system occurs on Quaternary alluvium and adjacent Pleistocene terraces (Beaumont and Lissie formations) along the Brazos, San Bernard, and Colorado rivers (as they pass through these Pleistocene formations), and adjacent streams such as Oyster Creek, Caney Creek, and Linnville Bayou. It occupies a generally level landscape, punctuated by a series of swales, depressions, and natural levees. Much of the flooding experienced by this system results from seasonal precipitation and tropical storms. Overbank flooding is infrequent, occurring about every 15 to 25 years. Soils are frequently clayey bottomlands (such as Pledger or Brazoria clays) or loamy bottomlands (such as those of the Asa or Norwood series), but also found on blackland and claypan soils within the basin.

CES303.651 Edwards Plateau Floodplain Terrace

CES303.651 CLASSIFICATION

Concept Summary: This forest/woodland system occurs on floodplain terraces along perennial rivers and streams in central Texas. Canopy dominants may include *Ulmus crassifolia, Juniperus ashei, Celtis laevigata, Quercus fusiformis, Fraxinus albicans, Platanus occidentalis, Acer negundo, Juglans major, Quercus macrocarpa*, or *Carya illinoinensis*. *Carya illinoinensis* may be more likely to occur in deeper and better-developed alluvial soils. Occurrences typically have a multi-layered physiognomy with a woody understory and patchy ground flora. Alluvial sedimentation processes dominate the formation and maintenance of this system. However, overgrazing and/or overbrowsing may influence recruitment of overstory species and composition of the understory and herbaceous layers.

Distribution: This system occurs along larger permanent rivers and streams throughout the Edwards Plateau of Texas and possibly adjacent ecoregions. It occurs from the Leon watershed in the Limestone Cutplain (EPA 29e) south to the edge of the Bacones Canyonlands (EPA 30c), west through the Edwards Plateau and north to the Pecan Bayou and Concho River watersheds in the lower Limestone Plains (EPA 27j) and lower Crosstimbers (EPA 29c) (EPA 2001).
Nations: US
Concept Source: L. Elliott and J. Teague
Description Author: L. Elliott and J. Teague

CES303.651 CONCEPTUAL MODEL

Environment: This system is found in central Texas and usually occupies Quaternary alluvial deposits often within drainages underlain by Cretaceous limestones, or drainages that receive outwash from landscapes dominated by these limestones (Elliott 2011). Landforms include valley floors of large rivers and perennial streams. This system tends to occupy broad valley bottoms with alluvial deposits on the Edwards Plateau, and rivers and large creeks where outwash from the Edwards Plateau influences the substrate (Elliott 2011). Soils include bottomland soils of various types (loamy, clayey, and sandy).
Key Processes and Interactions: Alluvial sedimentation processes dominate the formation and maintenance of this system. However, overgrazing and/or overbrowsing may influence recruitment of overstory species and composition of the understory and herbaceous layers.

CES303.652 Edwards Plateau Riparian

CES303.652 CLASSIFICATION

Concept Summary: This system occurs in various situations along small and intermittent streams of the Edwards Plateau, with drier representatives occurring in the western plateau and the Stockton Plateau, and moister representatives (such as communities dominated by *Juglans microcarpa* and *Brickellia laciniata*) in the eastern plateau. Representatives of this system typically occur in stream-scoured situations and vary in the openness of the habitat and physiognomy. Woodland examples may have *Quercus fusiformis, Platanus occidentalis, Taxodium distichum, Fraxinus albicans, Fraxinus pennsylvanica, Ulmus crassifolia, Celtis laevigata* (including *var. reticulata*), *Acer negundo, Prosopis glandulosa, Quercus buckleyi, Juniperus ashei, Salix nigra*, and/or *Sapindus saponaria*. Shrub species that may be encountered in the understory of these woodlands include *Juglans microcarpa, Chilopsis linearis, Baccharis* spp., *Salix nigra, Juniperus ashei, Sapindus saponaria, Cornus drummondii, Sophora secundiflora, Sideroxylon lanuginosum, Diospyros texana, Ungnadia speciosa, Prosopis glandulosa, Cephalanthus occidentalis*, and/or *Aloysia gratissima*. Substantial patches of herbaceous cover may be present and often include species such as *Andropogon glomeratus, Panicum virgatum, Cladium mariscus ssp. jamaicense, Tripsacum dactyloides, Setaria scheelei, Nassella leucotricha, Eleocharis* spp., *Brickellia* spp., *Justicia americana, Hydrocotyle* spp., and/or *Muhlenbergia lindheimeri*.

Distribution: This system is found along minor streams and tributaries throughout the Edwards Plateau.

Nations: US

Concept Source: L. Elliott and J. Teague

Description Author: J. Teague and L. Elliott

CES303.652 CONCEPTUAL MODEL

Environment: This system occurs on minor intermittent streams and tributaries throughout the Edwards Plateau of Texas. Its geology is usually Quaternary deposits along headwater streams. These may be alluvial or gravel deposits and are often within drainages dominated by limestone or other calcareous substrates on the Edwards Plateau or where substrate is influenced by outwash from the Edwards Plateau. This riparian system occupies small streams, either intermittent or perennial. These sites tend to be in erosional situations, as opposed to broad alluvial depositional sites. This system was mapped by TPWD in areas upstream of significant development of bottomland soils on soil types of the surrounding uplands. It includes vegetation along very small streams, reaching upstream to spring heads and runs (Elliott 2011).

CES205.710 Southeastern Great Plains Floodplain Forest

CES205.710 CLASSIFICATION

Concept Summary: This ecological system is found in the floodplains of medium and larger rivers of the East Central Texas Plains, Texas Blackland Prairie Regions, Crosstimbers, and the southeastern edge of the Central Great Plains (Level 3 Ecoregions 33, 32, 29 and 27 respectively). Alluvial soils and sedimentation processes typify this system. Periodic, intermediate flooding and deposition (every 5-25 years) dominates the formation and maintenance of this system. Dominant communities within this system range from floodplain forests to wet meadows to gravel/sand flats; however, they are linked by underlying soils and the flooding regime. Canopy dominants may include *Carya illinoinensis, Ulmus crassifolia, Ulmus americana, Celtis laevigata, Quercus nigra, Platanus occidentalis, Acer negundo, Quercus macrocarpa, Morus rubra, Fraxinus pennsylvanica, Salix nigra*, and *Sapindus saponaria var. drummondii*. Overgrazing and/or overbrowsing may influence recruitment of overstory species and composition of the understory and herbaceous layers. Shrub species may include *Callicarpa americana, Ilex decidua, Sideroxylon lanuginosum, Diospyros virginiana, Juniperus virginiana, Cornus drummondii*, and *Viburnum rufidulum*, which may occur as dense patches following disturbance, but are otherwise generally fairly sparse. Vines such as *Berchemia scandens, Campsis radicans, Vitis* spp., *Parthenocissus quinquefolia*, and *Nekemias arborea* may be conspicuous. Herbaceous cover includes *Elymus virginicus, Verbesina virginica, Chasmanthium latifolium, Chasmanthium sessiliflorum, Tripsacum dactyloides, Symphyotrichum drummondii var. texanum, Geum canadense, Sanicula canadensis, Panicum virgatum, Galium* spp., and *Carex* sp. Herbaceous cover may be quite high, especially in situations where shrub cover is low. The environment and vegetation of this system become generally and correspondingly drier from east to west with moister representatives (such as communities containing *Quercus phellos, Quercus pagoda, Quercus alba*, and *Quercus lyrata*) occurring along the eastern and northeastern margins of the range. Representatives of this system may vary in the openness of the habitat and physiognomy.

Distribution: This system is found along major river floodplains in the East Central Texas Plains, Texas Blackland Prairie Regions, Crosstimbers, and the southeastern edge of the Central Great Plains (Level 3 Ecoregions 33, 32, 29 and 27, respectively, *sensu* Griffith et al. (2004)). Rivers such as the Sulphur (and tributaries such as White Oak and Cuthand creeks), Sabine (and Lake Fork), Trinity (and its major tributaries), Navasota, portions of the Lower and Middle Brazos rivers (and major tributaries), portions of the middle and upper Red River, and portions of the Guadalupe, Colorado, and San Antonio rivers downstream of the Edwards Plateau ecoregion may support this system.

Nations: US

Concept Source: J. Eidson, M. Pyne, L. Elliott and J. Teague

Description Author: M. Pyne and J. Teague

CES205.710 CONCEPTUAL MODEL

Environment: This system occupies relatively broad flats at low topographic positions, along large streams where alluvial deposition dominates. Rivers such as the Sulphur (and tributaries such as White Oak and Cuthand creeks), Sabine (and Lake Fork), Trinity (and its major tributaries), Navasota, and portions of the Lower and Middle Brazos (and its major tributaries), Colorado, Guadalupe, Lavaca, Navidad, and San Antonio rivers may support this system. The geological setting is Quaternary Alluvium (Elliott 2011). It is found in the floodplains of medium and larger rivers of the East Central Texas Plains, Texas Blackland Prairie Regions, Cross Timbers, and the southeastern edge of the Central Great Plains (Level 3 Ecoregions 33, 32, 29 and 27, respectively, *sensu* Griffith et al. (2004)). Bottomland Ecological Sites (including Loamy, Sandy, and Clayey) characterize this system. Soils are primarily alluvial and range from sandy to dense clays.

Key Processes and Interactions: Periodic and intermediate flooding is the most significant process controlling this system and is expected every 5 to 25 years. Grazing and conversion to agriculture can significantly impact this system and can lead to the degradation or extirpation of the majority of prairie and wet meadow communities from this system. Fire occurs infrequently relative to surrounding systems. Fuels tend to stay moister due to shady conditions and low topographic position. Other disturbances include ice storm/blowdowns, which are capable of setting back small to large patches; as well as beaver pond

flooding, which even though a small-patch event, is expected to cycle throughout the forest over the long term, perhaps at a scale of hundreds or thousands of years.
Threats/Stressors:

M034. Rocky Mountain-Great Basin Montane Riparian & Swamp Forest

CES304.768 Columbia Basin Foothill Riparian Woodland and Shrubland

CES304.768 CLASSIFICATION

Concept Summary: This is a low-elevation riparian system found on the periphery of the mountains surrounding the Columbia River Basin, along major tributaries and the main stem of the Columbia at relatively low elevations. This is the riparian system associated with all streams at and below lower treeline, including permanent, intermittent and ephemeral streams with woody riparian vegetation. These forests and woodlands require flooding and some gravels for reestablishment. They are found in low-elevation canyons and draws, on floodplains, or in steep-sided canyons, or narrow V-shaped valleys with rocky substrates. Sites are subject to temporary flooding during spring runoff. Underlying gravels may keep the water table just below the ground surface and are favored substrates for cottonwood. Large bottomlands may have large occurrences, but most have been cut over or cleared for agriculture. Rafted ice and logs in freshets may cause considerable damage to tree boles. Beavers crop younger cottonwood and willows and frequently dam side channels occurring in these stands. In steep-sided canyons, streams typically have perennial flow on mid to high gradients. Important and diagnostic trees include *Populus balsamifera ssp. trichocarpa, Alnus rhombifolia, Populus tremuloides, Celtis laevigata var. reticulata, Betula occidentalis*, or *Pinus ponderosa*. Important shrubs include *Crataegus douglasii, Philadelphus lewisii, Cornus sericea, Salix lucida ssp. lasiandra, Salix eriocephala, Rosa nutkana, Rosa woodsii, Amelanchier alnifolia, Prunus virginiana*, and *Symphoricarpos albus*. Grazing is a major influence in altering structure, composition, and function of the system.

Description Author: G. Kittel

CES304.768 CONCEPTUAL MODEL

Environment: This is a low-elevation riparian system found on the periphery of the mountains surrounding the Columbia River Basin, along major tributaries and the main stem of the Columbia at relatively low elevations. This is the riparian system associated with all streams at and below lower treeline, including permanent, intermittent and ephemeral streams with woody riparian vegetation. These forests and woodlands require flooding and some fresh exposed gravel for reestablishment. They are found in low-elevation canyons and draws, on floodplains, or in steep-sided canyons, or narrow V-shaped valleys with rocky substrates. Sites are subject to temporary flooding during spring runoff. Underlying gravels may keep the water table just below the ground surface and are favored substrates for cottonwood. Large bottomlands may have large occurrences, but most have been cut over or cleared for agriculture. Rafted ice and logs in freshets may cause considerable damage to tree boles. Beavers crop younger cottonwood and willows and frequently dam side channels occurring in these stands. In steep-sided canyons, streams typically have perennial flow on mid to high gradients.

Key Processes and Interactions: The majority of these forests and woodlands require flooding and freshly deposited gravel/sand for seedling establishment. The natural hydrologic cycle in these reaches includes high spring and early summer flow pulses from snowmelt run off and a natural drawdown into late-summer and fall months. Spring and early summer months also see a rise of the underlying alluvial groundwater table as well as natural lowering of the groundwater in late summer into fall months. High flows and flooding scour (removal) and deposit sediments that stimulate growth of cottonwoods and willows, replenish nutrients, move seeds and aquatic organisms (Merritt and Wohl 2002). These processes stimulate and revive riparian ecosystems. Some reaches are supported by groundwater discharge where flood disturbances are less vital to long-term viability.

Threats/Stressors: Conversion of this type has commonly come from conversion to agricultural development, road development, changes in hydrology either by flooding reaches under reservoirs or complete draining of reaches by 100% upstream diversion by dams and other flood-control activities. Historic and contemporary land-use practices have impacted hydrologic, geomorphic, and biotic structure and function of riparian areas in eastern Washington. Human land uses both within the riparian area as well as in adjacent and upland areas have fragmented many riparian reaches which has reduced connectivity between riparian patches and riparian and upland areas. Adjacent and upstream land uses also have the potential to contribute excess nutrients into riparian areas. Reservoirs, water diversions, ditches, roads, and human land uses in the contributing watershed can have a substantial impact on the hydrology regime. Management effects on woody riparian vegetation can be obvious, e.g., removal of vegetation by dam construction, roads, logging, or they can be subtle, e.g., removing beavers from a watershed, removing large woody debris, or construction of a weir dam for fish habitat. Continuous heavy grazing is a major influence in altering structure, composition, and function of the community (Kauffman et al. 2004). In general, excessive grazing by livestock or native ungulates leads to less woody cover and an increase in sod-forming grasses particularly on fine-textured soils. Less palatable species, such as *Juncus balticus* and *Equisetum* spp., increase with livestock use. In many areas, *Phalaris arundinacea* has almost completed displaced native herbaceous vegetation thereby causing a conversion from native to ruderal vegetation. Although the presence of *Phalaris* is often due to changes in hydrology or physical disturbances, once established it can become a stressor in and of itself. Non-native plants or animals, which can have wide-ranging impacts, also tend to increase with these stressors. All of these stressors have resulted in many riparian areas being incised, supporting altered riparian plant communities, as well as numerous non-native species (WNHP 2011).

In the Pacific Northwest regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation, averaged over all models, are small (+1 to +2%), and some models project wetter autumns and winters and drier summers. Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models (Littell et al. 2009). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. This change will result in less winter snow accumulation, higher winter streamflows, earlier spring snowmelt, earlier peak spring streamflow and lower summer streamflows in rivers that depend on snowmelt (as do most rivers in the Pacific Northwest) (Littell et al. 2009).

Potential climate change effects could include: further reduction in summer flows (Littell et al. 2009); increases in extreme high precipitation events over the next half-century (Littell et al. 2009); earlier high-flow pluses that may negatively affect cottonwood species dominance as their seed production is timed for June-July high flow for distribution onto wet sand and gravel bars (Boes and Strauss 1994, Merritt and Wohl 2002), so cottonwood-dominated streams may shift to other deciduous tree species; drop in groundwater table; and increased fire frequency due to warmer temperatures resulting in drier fuels; the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from excessive grazing to the point of severe soil erosion and total loss of vegetative cover; dewatering of stream by upstream diversions; channelization and encroachment that armors banks and eliminates any overbank flooding or processes to occur.

Environmental Degradation (from WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Stream reaches have <25% of a buffered perimeter, or buffer is <49 m in width; area within the buffer has >50% non-native cover, barren ground, highly compacted or otherwise disrupted soils, moderate or greater intensity of human visitation or recreation or no buffer exists at all. Waterflow has been substantially diminished by human activity. Concrete, or artificially hardened, channels through most of the site. Any of these conditions or combination of conditions rates as moderate-severity: The surrounding buffer is between 25-49% of the occurrence perimeter, the average buffer width is between 50-99 m, after adjusting for slope. There is moderate (25-50%) cover of non-native plants, moderate or extensive soil disruption; moderate intensity of human visitation or recreation. Water source is primarily urban runoff, direct irrigation, pumped water, artificially impounded water, or other artificial hydrology. There is evidence of severe aggradation or degradation of most of the channel.

Disruption of Biotic Processes (from WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Within the occurrence itself the cover of native plants is <50%, invasive species are abundant (>10% absolute cover). Native increasers are >20% cover. The vegetation is severely altered from reference standard such that expected strata are absent or dominated by ruderal ("weedy") species, or comprised of planted stands of non-characteristic species, or unnaturally dominated by a single species. Most or all indicator/diagnostic species are absent. Any of these conditions or combination of conditions rates as moderate-severity: Canopy cover of native plants is between 50 to <85%, invasive species prevalent (3-10% absolute cover), and native increasers are between 10-20% cover. Species diversity/abundance is different from reference standard condition, but still largely composed of native species characteristic of the type. This may include ruderal ("weedy") species. Many indicator/diagnostic species may be absent.

CES304.045 Great Basin Foothill and Lower Montane Riparian Woodland and Shrubland

CES304.045 CLASSIFICATION

Concept Summary: This system occurs in mountain ranges of the Great Basin and along the eastern slope of the Sierra Nevada within a broad elevation range from about 1220 m (4000 feet) to over 2135 m (7000 feet). This system often occurs as a mosaic of multiple communities that are tree-dominated with a diverse shrub component. The variety of plant associations connected to this system reflects elevation, stream gradient, floodplain width, and flooding events. Dominant trees may include *Abies lowiana, Alnus incana, Betula occidentalis, Populus angustifolia, Populus balsamifera ssp. trichocarpa, Populus fremontii, Salix laevigata, Salix gooddingii*, and *Pseudotsuga menziesii*. Dominant shrubs include *Artemisia cana, Cornus sericea, Salix exigua, Salix lasiolepis, Salix lemmonii*, or *Salix lutea*. Herbaceous layers are often dominated by species of *Carex* and *Juncus*, and perennial grasses and mesic forbs such *Deschampsia cespitosa, Elymus trachycaulus, Glyceria striata, Iris missouriensis, Maianthemum stellatum*, or *Thalictrum fendleri*. Introduced forage species such as *Agrostis stolonifera, Poa pratensis, Phleum pratense*, and the weedy annual *Bromus tectorum* are often present in disturbed stands. These are disturbance-driven systems that require flooding, scour and deposition for germination and maintenance. Livestock grazing is a major influence in altering structure, composition, and function of the system.

Distribution: Occurs in mountain ranges of the Great Basin and along the eastern slope of the Sierra Nevada within a broad elevation range from about 1220 m (4000 feet) to over 2135 m (7000 feet).

Nations: US

Concept Source: J. Nachlinger and K. Schulz
Description Author: J. Nachlinger, K.A. Schulz, G. Kittel

CES304.045 CONCEPTUAL MODEL

Environment: This system is found in low-elevation canyons and draws, on floodplains, steep-sided canyons, or narrow V-shaped valleys with rocky substrates. This includes both perennial and intermittent streams. Sites are typically subject to temporary flooding during spring or late winter runoff. Overbank flooding and some gravel areas are required for regeneration of these riparian forests and woodlands, especially for cottonwoods.

Key Processes and Interactions: The hydrologic regime is naturally highly variable temporally and spatially among the streams and rivers of this system. Where present, spring discharges from bedrock aquifers provide flows unaffected by rainfall and snowmelt. Otherwise, stream and river flows - where they occur, at what magnitudes, and when and how often - are subject to wide fluctuations as a result of the wide variation in where and when precipitation takes place, what form the precipitation takes (rain versus snow), and where and when snowmelt takes place (e.g., Abell et al. 2000, Levick et al. 2008, Miller et al. 2010a). Intense runoff associated with intense rainfall events is highly erosive, resulting in rapid reconfiguration of aquatic and riparian macrohabitats particularly along reaches with sand and gravel substrates. Fire disturbances occur in riparian zones, but are generally less severe and less often than in neighboring uplands (Reeves et al. 2005).

Threats/Stressors: Conversion of this type has commonly comes from agricultural development, road development, changes in hydrology either by flooding reaches under reservoirs or complete draining of reaches by 100% upstream diversion by dams and other flood-control activities. Riparian areas and their aquatic communities are directly affected by concentrated grazing, cutting of woody vegetation for timber and firewood, residential development, river channelization, regulation or diversion of flows, wildfire suppression, trapping (principally beaver), exotic species (both terrestrial and aquatic plants and animals), unregulated recreation (both motorized and nonmotorized), road building, mining, pollution, farming, channel dredging, bank armoring, and construction of dams and levees. These same communities are indirectly affected by human activities across their surrounding watersheds that alter watershed runoff and groundwater recharge and discharge via altered ground cover and water diversions and withdrawals, or cause pollution, including from atmospheric deposition.

Invasive plant species may be one of the greatest agents of change in occurrences of this system. Invasive plant species such as salt-cedar and Russian-olive have invaded nearly all of the riparian systems to varying degrees and can convert many miles of riparian zone into undesirable monotypes.

By 2060, models forecast substantial increases in maximum temperatures for all months of the year, with the greatest increases concentrated during the summer. July and August monthly maximum temperatures are projected to increase by 5.5° and 6.5°F, respectively, more than two standard deviations above the average values from the 80-year baseline (1900-1979), where as November and December minimum temperatures only increase by one standard deviation beyond the baseline values (Comer et al. 2013a). Potential climate change effects could include the following (edited excerpt from Comer et al. 2013a): "The forecasted changes in temperature and precipitation patterns would be expected to result in several effects on riparian resources in the ecoregion, as discussed by Melack et al. (1997), Field et al. (1999), Mote (2006), Christensen and Lettenmaier (2007), Chambers and Pellant (2008), Brown and Mote (2009), Covich (2009), Das et al. (2009), Dettinger et al. (2009), McCabe and Wolock (2009), Cayan et al. (2010), Miller et al. (2010a), USBOR (2011). These include: higher evapotranspiration rates leading to an earlier, more rapid seasonal drying-down of riparian occurrences; increased water stress in basin-floor phreatophyte communities; shrinkage of areas of perennial flow/open water, coupled with higher water temperatures at locations/times when water temperatures are not controlled by groundwater discharges or snowmelt; persistence of these hydrologic conditions later into the fall or early winter; reduced groundwater recharge in the mountains and reduced recharge to basin-fill deposits along the mountain-front/basin-fill interface; and more erosive mid/late-summer runoff events in those areas experiencing increased July/August precipitation, potentially with associated channel down-cutting and expanded deposition of the eroded sediment in lower-elevation gravel fans. Warmer winters will likely decrease mortality among insect and fungal pests, leading to an increase in morbidity and mortality among overstory trees such as cottonwood and willows, which are prone to disease and pest damage already. As smaller water sources dry and become unusable, wildlife, domestic livestock, and humans will increase use of larger or more stable water sources.

Based on the ways in which these hydrologic factors affect ecological dynamics in riparian resources, persistence of these hydro-meteorological impacts over multiple decades could result in several long-term impacts at both high and low elevations, as discussed by many of the authors cited above, and also by Harper and Peckarsky (2006), Hultine et al. (2007), Martin (2007), Chambers and Wisdom (2009), Jackson et al. (2009), and Seavy et al. (2009). These include: loss of riparian vegetation at lower elevations where the frequency and spatial extent of seasonal flows determines the spatial limits of this vegetation; loss of basin-floor phreatophyte (deep-rooted plants that obtain water from groundwater sources) communities as a result of lower near-surface ground elevations; declines in the spatial extent and biodiversity of perennial streams and open waters as a result of shrinkage and warmer temperatures; reduced discharge to springs and seeps as a result of reduced aquifer recharge; a continuation of normal "warm-season" aquatic ecological dynamics later into the fall as a result of seasonally normal (baseline) overnight near-freezing temperatures becoming less common in many areas until later in the fall; and a possible de-coupling of the places and timing of emergence of insects, the plants on which they depend, and the animals that feed on the insects, as individual species respond to different cues from air and water temperatures, water availability, and flow conditions."

Ecosystem Collapse Thresholds: Ecological collapse tends to result from dewatering of streams by diversions and groundwater pumping lowering the water table, continued heavy grazing by domestic livestock that completely removes all native vegetation and results in severe erosion and streambank collapse. Continued heavy trampling by recreational uses, especially motorized recreation, within the riparian area that causes soil compaction and tears up vegetation. Cutting of woody vegetation to the point of compete upper canopy removal.

Environmental Degradation: Any of these conditions or combination of conditions rates as high-severity: Streamflow is severely modified with very few high flows and increase flows in late summer and fall. Stream channel is extensively disconnected from floodplain by dikes, tide gates, elevated culverts, etc. Banks are very eroded and broken down, no longer overhanging and shading the stream channel, soil compaction is severe, severe erosion evident. Buffer area is lacking. Riparian zone has become highly fragmented where the corridor is no longer continuous, but broken into small segments. Bare soil areas substantially contribute to altered hydrology or other long-lasting impacts. Deep ruts from ORVs or machinery may be present, or livestock pugging and/or trails are widespread. Water will be channeled or ponded. Any of these conditions or combination of conditions rates as moderate-severity: Streamflow is moderately modified from natural hydrograph, some flushing spring flows occur but not as frequently and in lower magnitudes than historically. Bank collapse and erosion is evident in part of the occurrence. Buffer to riparian zone is less than 50 m in some areas around the occurrence. Fragmentation has occurred in only part of the occurrence.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: Invasive species dominate the stand, native plants comprise less than 20% of the site, total vegetative canopy is greatly reduced (<20%). Canopy extremely homogeneous, sparse, or absent (<10% cover). No reproduction of native woody species. Any of these conditions or combination of conditions rates as moderate-severity: Invasive species are present to abundant but native species still comprise at least 50% relative cover. Somewhat homogeneous in density and age OR <50% canopy cover. Saplings/seedlings of native woody species (cottonwood/willow) present but in low abundance; little regeneration by native species.

CES306.803 Northern Rocky Mountain Conifer Swamp

CES306.803 CLASSIFICATION

Concept Summary: This ecological system occurs in the northern Rocky Mountains from northwestern Wyoming north into the Canadian Rockies and west into eastern Oregon and Washington. It is dominated by conifers on poorly drained soils that are saturated year-round or may have seasonal flooding in the spring. These are primarily on flat to gently sloping lowlands, but also occur up to near the lower limits of continuous forest (below the subalpine parkland). It can occur on steeper slopes where soils are shallow over unfractured bedrock. This system is indicative of poorly drained, mucky areas, and areas are often a mosaic of moving water and stagnant water. Soils can be woody peat, muck or mineral but tend toward mineral. Stands generally occupy sites on benches, toeslopes or valley bottoms along mountain streams. Associations present include wetland phases of *Thuja plicata, Tsuga heterophylla*, and *Picea engelmannii* forests. The wetland types are generally distinguishable from other upland forests and woodlands by shallow water tables and mesic or hydric undergrowth vegetation; some of the most typical species include *Athyrium filix-femina, Dryopteris* spp., *Lysichiton americanus, Equisetum arvense, Senecio triangularis, Mitella breweri, Mitella pentandra, Streptopus amplexifolius, Calamagrostis canadensis*, or *Carex disperma*.

CES306.804 Northern Rocky Mountain Lower Montane Riparian Woodland and Shrubland

CES306.804 CLASSIFICATION

Concept Summary: This ecological system of the northern Rocky Mountains and the east slopes of the Cascades consists of deciduous, coniferous, and mixed conifer-deciduous forests that occur on streambanks and river floodplains of the lower montane and foothill zones. Riparian forest stands are maintained by annual flooding and hydric soils throughout the growing season. Riparian forests are often accompanied by riparian shrublands or open areas dominated by wet meadows. *Populus balsamifera* is the key indicator species. Several other tree species can be mixed in the canopy, including *Populus tremuloides, Betula papyrifera, Betula occidentalis, Picea mariana*, and *Picea glauca*. *Abies grandis, Thuja plicata*, and *Tsuga heterophylla* are commonly dominant canopy species in British Columbia, western Montana and northern Idaho occurrences, in lower montane riparian zones. Shrub understory components include *Cornus sericea, Acer glabrum, Alnus incana, Betula papyrifera, Oplopanax horridus*, and *Symphoricarpos albus*. Ferns and forbs of mesic sites are commonly present in many occurrences, including such species as *Athyrium filix-femina, Gymnocarpium dryopteris*, and *Senecio triangularis*.

Distribution: This system is found in the northern Rocky Mountains.
Nations: CA, US

Concept Source: M.S. Reid
Description Author: M.S. Reid and G. Kittel

CES306.804 CONCEPTUAL MODEL

Environment: Alluvial soils along perennial and intermittent streams. Valley type is an important variable, as riparian woodlands are mostly found in V-shaped, steep valleys with many large boulders and coarse soils or U-shaped gullies formed by glacial processes. These systems can also be found in broad unconfined reaches with deeper soils and more complex geomorphic surfaces. Narrow and steep (i.e., confined) occurrences have minimal to no floodplain development, whereas less steep and wider valley bottoms (i.e., unconfined) occurrences are often associated with substantial floodplain development (Gregory et al. 1991).

Key Processes and Interactions: Natural disturbance regimes are the primary influence on riparian system characteristics. Maintained by the complex interaction of hydrological and geomorphological processes which influence periodic flooding and hydric soils, riparian systems are the most dynamic of all forested, woodland and shrub systems. Hydrogeomorphology determines the form, composition and function of riparian woodland and shrub systems. Typically occurring in watersheds with snow-dominated hydrological processes, sometimes mixed rain and snow, these riparian systems are further influenced by the variability of inter-annual and seasonal weather patterns. Typical flow regimes of British Columbia's central interior plateau and mountains are snow-(nival) dominated. Precipitation falls as snow and is stored for long periods of time, resulting in low winter flows, and peak flows following snowmelt in May to July (depending on annual temperature variations and snow depth). Glacial snow regimes are similar to nival, except that high flows may continue until August or September (Eaton and Moore 2010). Periods of peak flow have greatest influence on channel morphology and vegetation dynamics. Large woody debris is important for affecting channel morphology.

Beaver can be important hydrogeomorphic driver of montane riparian systems, especially along unconfined reaches. The direct, local presence of beaver creates a heterogeneous complex of wet meadows, marshes and riparian shrublands and increases species richness on the landscape. Naiman et al. (1988) note that beaver-influenced streams are very different from those not impacted by beaver activity by having numerous zones of open water and vegetation, large accumulations of detritus and nutrients, more wetland areas, having more anaerobic biogeochemical cycles, and in general are more resistance to disturbance.

Threats/Stressors: Conversion of this type has commonly come from agricultural development, roads, dams and other flood-control activities that drown reaches under reservoirs or dewater streams through upstream diversions, as well as grazing of domestic animals, urban and industrial development. Historic and contemporary land-use practices have impacted hydrologic, geomorphic, and biotic structure and function of riparian areas. Human land uses both within the riparian area as well as in adjacent and upland areas have fragmented many riparian reaches which has reduced connectivity between riparian patches and riparian and upland areas. Adjacent and upstream land uses also have the potential to contribute excess nutrients into riparian areas. Reservoirs, water diversions, ditches, roads, and human land uses in the contributing watershed can have a substantial impact on the hydrologic regime, reducing high flows and augmenting low flows (Eaton and Moore 2010). Management effects on woody riparian vegetation can be obvious, e.g., removal of vegetation by dam construction, roads, logging, diverting and blocking waterflow, or they can be subtle, e.g., removing beavers from a watershed, removing large woody debris, or construction of a weir dam for fish habitat. In general, excessive livestock or native ungulate use leads to soil damage and increased invasion of non-native species, less woody cover and an increase in sod-forming grasses particularly on fine-textured soils. Undesirable forb species, such as stinging nettle and horsetail, increase with livestock use. Non-native plants or animals, which can have wide-ranging impacts, also tend to increase with these stressors. All of these stressors have resulted in some riparian areas being incised and down cut, which alters riparian plant communities (changes their successional state, for example from woody dominated to herbaceous dominated), and also may result in an increase in non-native species (WNHP 2011).

Climate change effects are likely to most profoundly affect natural disturbance regimes (Haughian et al. 2012, Wiensczyk et al. 2012) and the effects on riparian systems likely more rapidly than climate change effects on more stable systems with less frequent natural disturbance regimes. Average temperature has already increased roughly 1.5°F compared to the 1960-1979 baseline period in the southwestern U.S., including the southern Rocky Mountains (Karl et al. 2009, Wiensczyk et al. 2012). Predictions are for 3.5-5.5°F increase in average temperatures by mid-century (Karl et al. 2009). Predictions also suggest an increase in probability of droughts, and that droughts will be exacerbated by warmer temperatures. Increased temperatures will drive declines in spring snowpack and Colorado River flow (Karl et al. 2009). For the higher elevations, in areas where it snows, a warmer climate means major changes in the timing of runoff: streamflow increases in winter and early spring, and then decreases in late spring, summer, and fall. This shift in streamflow timing has already been observed over the past 50 years (Peterson et al. 2008), with the peak of spring runoff shifting from a few days earlier in some places to as much as 25 to 30 days earlier in others (Stewart et al. 2004). This trend is projected to continue, with runoff shifting 20 to 40 days earlier within this century. Reductions in summer water availability are expected to see reductions of about 10% in colder regions such as the Rocky Mountains (Karl et al. 2009). Moreover, increased flood risk in the southern Rocky Mountains is likely to result from a combination of decreased snow cover on the lower slopes of high mountains, and an increased fraction of winter precipitation falling as rain and therefore running off more rapidly (Knowles et al. 2006). The increase in rain on snow events will also result in rapid runoff and flooding (Bales et al. 2006).

Potential climate change effects could include: a shift away from cottonwood-dominated reaches due to shift in timing of high flows and seed distribution of *Populus* spp., as riparian *Populus* species do not survive in the seed bank for more than 2 weeks to 1 month (Schreiner 1974); lower streamflows in late summer and early fall leading to earlier senescence of vegetation, which may shift species composition to more drought-tolerant and heat-tolerant species such as tamarix (which may move north with warmer climates (Kerns et al. 2009); lower groundwater tables due to less recharge and lower streamflows, which may result in loss of deep-rooted riparian species; and higher flooding and greater sedimentation may result in increase in woody species over herbaceous species (Stromberg et al. 2010b).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from excessive grazing or heavy recreational use to the point of severe soil erosion and total loss of vegetative cover, or total conversion to non-native or upland species; dewatering of stream by upstream diversions; channelization and encroachment that armors banks and eliminates any overbank flooding or other flooding processes to occur.

Environmental Degradation (from CNHP 2010b and WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Natural hydrologic regime is not restorable, waterflow has been substantially diminished by human activity. The stream channel and or banks are made of concrete, or artificially hardened, through most of the site. Severe erosion of both banks. Extensively disconnected from floodplain by dikes, tide gates, elevated culverts, etc. The system remains fundamentally compromised despite restoration of some processes. Disturbance is extensive and significant enough to have >70% impact on species composition and soil compaction, causing excessive erosion. Any of these conditions or combination of conditions rates as moderate-severity: Natural hydrologic regime altered by upstream dams, local drainage, diking, filling, digging, or dredging. Alteration is extensive but potentially restorable over several decades. Streambanks may be severely altered. Streambanks are moderately stable with bank held in place by trees and boulders and eroded elsewhere, extensive erosion and bank undercutting. Disturbance is extensive and significant enough to have notable (between 50-70%) impact on soil compaction, causing excessive erosion.

Disruption of Biotic Processes (from CNHP 2010b and WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Non-native species are dominant over significant portions of area, with little potential for control. No perennial vegetation to waterline; recently exposed tree roots common; tree falls and/or severely undercut trees common. No reproduction of native woody species. Any of these conditions or combination of conditions rates as moderate-severity: Non-native species may be widespread but potentially manageable with restoration of most natural processes. Perennial vegetation to waterline sparse (mainly scoured or removed by lateral erosion); recently exposed tree roots and fine root hairs common. Saplings/seedlings of native woody species present but in low abundance; little regeneration by native species.

CES304.060 Northern Rocky Mountain Wooded Vernal Pool

CES304.060 CLASSIFICATION

Concept Summary: These wooded vernal pools are small shallow circumneutral freshwater wetlands of glacial origin that partially or totally dry up as the growing season progresses. They are documented to occur in northern Idaho and western Montana. These vernal ponds and wetlands usually fill with water over the fall, winter and early spring, but then at least partially dry up towards the end of the growing season. Depending on annual patterns of temperature and precipitation, the drying of the pond may be complete or partial by the fall. These sites are usually shallow and less than 1 m in depth, but can be as much as 2 m deep. The pool substrate is a poorly drained, often clayey layer with shallow organic sediments. The freshwater ponds have pH ranges from 6.2 to 7.8 with most measurements between 6.5 and 7.5, i.e., relatively neutral. The ponds in Montana were thought to be isolated, but it has been shown that in high water years the ponds spill over, and there is an exchange of surface water between ponds. The pools have a ring of trees surrounding the ponds that provide shade and influence their hydrology. A variety of tree species dominant the upper canopy, including *Abies grandis, Abies lasiocarpa, Larix occidentalis, Picea engelmannii, Pinus contorta, Pseudotsuga menziesii*, and the broadleaf trees *Populus balsamifera ssp. trichocarpa, Fraxinus latifolia*, and, to a lesser extent, *Populus tremuloides* and

Betula papyrifera. Common shrubs include *Alnus incana, Cornus sericea, Rhamnus alnifolia*, and *Salix* spp. *Alopecurus aequalis, Callitriche heterophylla, Carex vesicaria, Eleocharis palustris*, and *Phalaris arundinacea* are common herbaceous plant associates.

CES306.821 Rocky Mountain Lower Montane-Foothill Riparian Woodland and Shrubland

CES306.821 CLASSIFICATION

Concept Summary: This ecological system is found throughout the Rocky Mountain and Colorado Plateau regions within a broad elevational range from approximately 900 to 2800 m. This system often occurs as a mosaic of multiple communities that are tree-dominated with a diverse shrub component. It is dependent on a natural hydrologic regime, especially annual to episodic flooding. Occurrences are found within the flood zone of rivers, on islands, sand or cobble bars, and immediate streambanks. It can form large, wide occurrences on mid-channel islands in larger rivers or narrow bands on small, rocky canyon tributaries and well-drained benches. It is also typically found in backwater channels and other perennially wet but less scoured sites, such as floodplains swales and irrigation ditches. In some locations, occurrences extend into moderately high intermountain basins where the adjacent vegetation is sage steppe. Dominant trees may include *Acer negundo, Populus angustifolia, Populus deltoides, Populus fremontii, Pseudotsuga menziesii, Picea pungens, Salix amygdaloides*, or *Juniperus scopulorum*. Dominant shrubs include *Acer glabrum, Alnus incana, Betula occidentalis, Cornus sericea, Crataegus rivularis, Forestiera pubescens, Prunus virginiana, Rhus trilobata, Salix monticola, Salix drummondiana, Salix exigua, Salix irrorata, Salix lucida, Shepherdia argentea*, or *Symphoricarpos* spp. Exotic trees of *Elaeagnus angustifolia* and *Tamarix* spp. are common in some stands. Generally, the upland vegetation surrounding this riparian system is different and ranges from grasslands to forests. In the Wyoming Basins, the high-elevation *Populus angustifolia*-dominated rivers are included here, including along the North Platte, Sweetwater, and Laramie rivers. In these situations, *Populus angustifolia* is extending down into the sage steppe zone of the basins.

Concept Source: NatureServe Western Ecology Team

Description Author: M.S. Reid and G. Kittel

CES306.821 CONCEPTUAL MODEL

Environment: This system is dependent on a natural hydrologic regime, especially annual to episodic flooding. It is found within the flood zone of rivers, on islands, sand or cobble bars, and immediate streambanks. It can form large, wide occurrences on mid-channel islands in larger rivers or narrow bands on small, rocky canyon tributaries and well-drained benches. It is also typically found in backwater channels and other perennially wet but less scoured sites, such as floodplains swales and irrigation ditches. It may also occur in upland areas of mesic swales and hillslopes below seeps and springs. The climate of this system is continental with typically cold winters and hot summers. Surface water is generally high for variable periods. Soils are typically alluvial deposits of sand, clays, silts and cobbles that are highly stratified with depth due to flood scour and deposition. Highly stratified profiles consist of alternating layers of clay loam and organic material with coarser sand or thin layers of sandy loam over very coarse alluvium. Soils are fine-textured with organic material over coarser alluvium. Some soils are more developed due to a slightly more stable environment and greater input of organic matter.

Key Processes and Interactions: This ecological system contains early-, mid- and late-seral riparian plant associations. It also contains non-obligate riparian species. Cottonwood communities are early-, mid- or late-seral, depending on the age class of the trees and the associated species of the occurrence (Kittel et al. 1999b). Cottonwoods, however, do not reach a climax stage as defined by Daubenmire (1952). Mature cottonwood occurrences do not regenerate in place, but regenerate by "moving" up and down a river reach and regeneration is often associated with flooding events. Over time a healthy riparian area supports all stages of cottonwood communities (Kittel et al. 1999b).

Threats/Stressors: Conversion of this type has commonly come from conversion to agricultural development, road development, changes in hydrology either by flooding reaches under reservoirs or complete draining of reaches by 100% upstream diversion by dams, ditches and other flood-control or translocations activities. Conversion may also come from downcutting of the stream channel where it is susceptible (e.g., wide alluvial bottoms), resulting in desertification or "uplandification" of the former floodplain (J. Tuhy pers. comm. 2013). Historic and contemporary land-use practices have impacted hydrologic, geomorphic, and biotic structure and function of riparian areas in the Rocky Mountains. Human land uses both within the riparian area as well as in adjacent and upland areas have fragmented many riparian reaches which has reduced connectivity between riparian reaches along the same stream as well as a disconnect between riparian areas and their once adjacent upland areas. Adjacent and upstream land uses can contribute excess nutrients and pollutants into riparian areas. Reservoirs, water diversions, ditches, roads, and human land uses in the contributing watershed can have a substantial impact on the hydrology regime. Altered hydrologic regime: reduced frequency and magnitude of flood events, and different timing of flood events, due to upstream dams/diversions, warmer/drier conditions in watersheds (J. Tuhy pers. comm. 2013).

Management effects on woody riparian vegetation can have direct impact, e.g., removal of vegetation by dam construction, roads, logging, or they can be indirect, e.g., removing beavers from a watershed, removing large woody debris, or construction of a weir dam for fish habitat. Continuous heavy livestock grazing can be major influence in altering structure, composition, and function of the community (Elmore and Kauffman 1994, Patten 1998, Flenniken et al. 2001). In general, continuous heavy livestock or native ungulate use leads to less woody cover and an increase in sod-forming grasses particularly on fine-textured soils. Undesirable forb species, such as *Urtica* and *Equisetum*, increase with livestock use. Non-native plants or animals, which can have wide-ranging impacts, also tend to increase with these stressors (Patten 1998). Downcutting is a common side effect of heavy grazing or poor road placement and once a stream starts downcutting the larger floodplain is abandoned and the likelihood of riparian vegetation regeneration is greatly reduced, thus reducing and degrading the size of the riparian area (R. Rondeau pers. comm. 2013).

Invasion and dominance of non-native woody plants (e.g., tamarisk, Russian olive); narrowing and armoring of the channel, and artificial accumulations of sediment adjacent to the channel (levees), caused by the woody invasives, which can lead to reduction in suitable sites for cottonwood regeneration: fewer colonizable sand/mud bars, or available sand/mud bars colonized by woody invasives instead of natives (J. Tuhy pers. comm. 2013).

Average temperature has already increased roughly 1.5°F compared to the 1960-1979 baseline period in the southwestern US, including the southern Rocky Mountains (Karl et al. 2009). Predictions are for 3.5-5.5°F increase in temperatures by mid-century (Karl et al. 2009). Predictions suggest an increase in probability of droughts, and that droughts will be exacerbated by warmer temperatures. Increased temperatures will drive declines in spring snowpack and Colorado River flow (Karl et al. 2009). For the higher elevations, in areas where it snows, a warmer climate means major changes in the timing of runoff: streamflow increases in winter and early spring, and then decreases in late spring, summer, and fall. This shift in streamflow timing has already been observed over the past 50 years (Peterson et al. 2008), with the peak of spring runoff shifting from a few days earlier in some places to as much as 25 to 30 days earlier in others (Stewart et al. 2004). This trend is projected to continue, with runoff shifting 20 to 40 days earlier within this century. Reductions in summer water availability are expected to see reductions of about 10% in colder regions such as the Rocky Mountains (Karl et al. 2009). Moreover, increased flood risk in the southern Rocky Mountains is likely to result from a combination of decreased snow cover on the lower slopes of high mountains, and an increased fraction of winter precipitation falling as rain and therefore running off more rapidly (Knowles et al. 2006). The increase in rain on snow events will also result in rapid runoff and flooding (Bales et al. 2006).

Potential climate change effects could include: a shift away from cottonwood-dominated reaches due to shift in timing of high flows and seed distribution of *Populus* spp. (Merritt and Wohl 2002); and lower streamflows in late summer and early fall leading to earlier senescence of vegetation, which may shift species composition to more drought-tolerant and heat-tolerant species such as tamarix; lower groundwater tables due to less recharge and lower streamflows, which may result in loss of deep-rooted riparian species (Comer et al. 2013a). Warmer summer temperatures may increase the number and strength of thunder storms which may in turn result in increased flash flooding, increasing sediment runoff and scour of stream channels, which may increase stream geomorphology heterogeneity and consequently riparian habitat diversity (Parsons et al. 2005, Stromberg et al. 2010a). The 2000-2012 below-average precipitation pattern in much of the region killed many mature cottonwood trees and with an increase in intensity and frequency of droughts, more die-back is expected (R. Rondeau pers. comm. 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from excessive grazing or heavy recreational use to the point of severe soil erosion and total loss of vegetative cover; dewatering of stream by upstream diversions; channelization and encroachment that armors banks and eliminates any overbank flooding or other flooding processes to occur. Conversion to a different ecosystem type through replacement of non-native species which may be interpreted as very poor condition riparian ecosystem that may still support fish and other species, but it certainly functions differently (J. Tuhy pers. comm. 2013).

Environmental Degradation (from CNHP 2010b and WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: A return to the natural hydrologic regime is not feasible or practical; waterflow has been substantially diminished by human activity. The stream channel and or banks are made of concrete, or artificially hardened, through most of the site. Severe erosion of both banks; Extensively disconnected from floodplain by dikes, tide gates, elevated culverts, etc. The system remains fundamentally compromised despite restoration of some processes. Disturbance is extensive and significant enough to have >70% impact on species composition and soil compaction, causing excessive erosion. Any of these conditions or combination of conditions rates as moderate-severity: Natural hydrologic regime altered by upstream dams, local drainage, diking, filling, digging, or dredging. Alteration is extensive but potentially restorable over several decades. Streambanks may be severely altered. Streambanks are moderately stable with bank held in place by trees and boulders and eroded elsewhere, extensive erosion and bank undercutting. Disturbance is extensive and significant enough to have notable (between 50-70%) impact on soil compaction, causing excessive erosion.

Disruption of Biotic Processes (from CNHP 2010b and WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Non-native species are dominant over significant portions of area, with little potential for control. No perennial vegetation to waterline; recently exposed tree roots common; tree falls and/or severely undercut trees common. No reproduction of native woody species. Any of these conditions or combination of conditions rates as moderate-severity: Non-native species may be widespread but potentially manageable with restoration of most natural processes. Perennial vegetation to waterline sparse (mainly scoured or removed by lateral erosion); recently exposed tree roots and fine root hairs common. Saplings/seedlings of native woody species present but in low abundance; little regeneration by native species.

CES306.833 Rocky Mountain Subalpine-Montane Riparian Woodland

CES306.833 CLASSIFICATION

Concept Summary: This riparian woodland system comprises seasonally flooded forests and woodlands found at montane to subalpine elevations of the Rocky Mountain cordillera, from southern New Mexico north into Montana, and west into the Intermountain West region and the Colorado Plateau. It occurs throughout the interior of British Columbia and the eastern slopes of the Cascade Range. This system contains the conifer and aspen woodlands that line montane streams. These are communities tolerant of periodic flooding and high water tables. Snowmelt moisture in this system may create shallow water tables or seeps for a portion of the growing season. Stands typically occur at elevations between 1500 and 3300 m (4920-10,830 feet), farther north elevation ranges between 900 and 2000 m. This is confined to specific riparian environments occurring on floodplains or terraces of rivers and streams, in V-shaped, narrow valleys and canyons (where there is cold-air drainage). Less frequently, occurrences are found in moderate-wide valley bottoms on large floodplains along broad, meandering rivers, and on pond or lake margins. Dominant tree species vary across the latitudinal range, although it usually includes *Abies lasiocarpa* and/or *Picea engelmannii*; other important species include *Pseudotsuga menziesii, Picea pungens, Picea engelmannii x glauca, Populus tremuloides*, and *Juniperus scopulorum*. Other trees possibly present but not usually dominant include *Alnus incana, Abies concolor, Abies grandis, Pinus contorta, Populus angustifolia, Populus balsamifera ssp. trichocarpa*, and *Juniperus osteosperma*.

1.B.3.Nd. Western North American Interior Flooded Forest

M036. Interior Warm & Cool Desert Riparian Forest

CES206.946 California Central Valley Riparian Woodland and Shrubland

CES206.946 CLASSIFICATION

Concept Summary: This ecological system occurs in the floodplains of rivers of California's Central Valley. Alluvial soils and late winter/early spring flooding (usually every year) from snowmelt typify this system. Communities are predominantly floodplain woodlands, but also include shrublands, wet meadows and gravel/s and flats. Important trees and shrubs include *Populus fremontii, Platanus racemosa, Quercus lobata, Salix gooddingii, Acer negundo, Cephalanthus occidentalis*, and *Vitis californica*. *Juglans nigra* hybrids and *Ailanthus altissima* are problem invasive trees. *Tamarix* spp. extend as far north as Shasta County. Herbaceous components can include *Carex barbarae, Artemisia douglasiana*, and various marsh species along riverbanks and backwater (*Schoenoplectus californicus, Typha* spp.). *Arundo donax* is another common invasive and introduced forage species that often invades degraded areas within the floodplains. Periodic flooding and associated sediment scour are necessary to maintain growth and reproduction of vegetation. Flooding regimes have been significantly altered in all but a few tributaries that support this system.

Related Concepts:

Distribution: Occurs in the floodplains of rivers of California's Central Valley.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.946 CONCEPTUAL MODEL

Environment: This system is found on alluvial soils adjacent to perennial rivers and streams and their associated floodplains and riverbanks below approximately 550 m (1800 feet).

Key Processes and Interactions: Periodic flooding and associated sediment scour are necessary to maintain growth and reproduction of vegetation (Sawyer et al. 2009). Major flood events and consequent flood scour, overbank deposition of water and sediments, and stream meandering are the key fluvial processes that provide new substrates, remove old banks and stimulate renewed growth of cottonwood and willow species (Sawyer et al. 2009). Natural fire-return interval was long or moderate with low-intensity surface fires.

Threats/Stressors: Conversion of this type has commonly come from agricultural conversion and development for urban and housing, loss of the floodplain through levee development, and complete inundation by creation of reservoirs. Flooding regimes have been significantly altered through the reduction of peak spring and winter flows, less frequent and lower magnitude high flows, that result in very rare overbank flooding as well as increased low flows in all but a few tributaries that support this system (Sawyer et al. 2009). Invasive species alter composition and support different guilds of insects and reptiles and can change the fire regime. *Arundo donax* is a common invasive and introduced forage species that often invades degraded areas within the floodplains. *Juglans nigra* hybrids and *Ailanthus altissima* are problem invasive trees. *Tamarix* spp. extend as far north as Shasta County. Changes in fire regime caused by *Tamarix* which shortens the fire-return interval (10-20 years) in Arizona (Ohmart and Anderson 1986) and California (Brooks and Minnich 2006). Surface fuels provided by *Tamarix* also increase fire intensity and the probability of crown fires that result in high mortality rates in *Populus fremontii* (Sawyer et al. 2009). *Arundo donax* has the same effect of increased fuel load and fire intensity and reduced fire interval resulting in mortality of native woody species and increased post-fire dominance of *Arundo* (Coffman 2007).

In the Central Valley, regional climate models project mean annual temperature increases of 1.4-2.0°C (1.8-3.6°F) by 2070. The projected impacts will be warmer winter temperatures; earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 47-175 mm (1-7 inches) by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions. Projections include a decrease in total annual streamflows and earlier snowmelt, with streamflows increasing slightly in January and February but decreasing in all other months. Annual streamflows statewide are projected to decrease by 27%, with inflows from surrounding mountains to the Sacramento Valley projected to decrease by 22%. Today, the flow of the Sacramento River is heavily managed through a series of dams and diversions. As a result, it is likely that flows on the Sacramento River will be more influenced by management decisions than by climate change effects. However, even though the timing of flows may be mediated by hydrological infrastructure, the ability to deal with extreme flow events will likely remain limited. Accidental levee breaks in the Sacramento-San Joaquin River system have occurred in 25% of years during the 20th century. Historical flood control efforts have not reduced the occurrence or frequency of levee breaks. Current climate-change projections suggest that storm patterns and fluvial responses are expected to aggravate future risks of levee breaks (summarized from PRBO Conservation Science 2011).

In the long term, sea-level rise will greatly increase levee breaches in the Sacramento - San Joaquin Delta. Since many of the delta islands and riparian areas lie below sea level currently flooding will ironically reduce areas for riparian and replace them with standing brackish water too deep to support the natural riparian system(T. Keeler-Wolf pers. comm. 2013). Other potential climate change effects could include: further reduction in high flows; perennial streams may become intermittent; phreatophytic species under greater stress and death; drop in groundwater table; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006, Coffman 2007); and increased competition for water from all users, stresses the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse of this type tends to result from severe hydrologic alteration in that spring and summer flooding no longer occurs, rivers can no longer meander across the floodplain, flooding, scour and sediment deposition no longer occurs. Riverbanks covered in cement or other hard material.

Environmental Degradation: Any of these conditions or combination of conditions rates as high-severity: The system is confined to narrow bands between riverbanks and levees. The system is no longer hydrologically connected to its floodplain. Non-native species such as tamarisk has nearly completely replaced native tree species, thereby increasing the fire frequency within in conjunction with reduced flooding, maintains the dominance of non-native species such as tamarisk and *Arundo donax* (Sawyer et al. 2009). Any of these conditions or combination of conditions rates as moderate-severity: Some flooding occurs but at a lower frequency, invasives may be present to abundant but native species still form at least 50% of the overhead and ground layer canopies.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: There is no longer sexual regeneration of cottonwoods due to loss of flooding and sand bar creation. While no longer new stand formation along point bars of cottonwoods, there will still be individuals which seed in, as long as there is water and also an increase in the presence of hybrid *Juglans regia X hindsii* (product of native and non-native walnuts) and increase of *Ailanthus, Ficus carica*, and other invasive trees, which don't require regular scouring and meander changes (T. Keeler-Wolf pers. comm. 2013). Any of these conditions or combination of conditions rates as moderate-severity: Cottonwoods reproduction reduced, non-native invasive species are present but native species are still at least 50% relative cover of the overstory and ground canopies (or one or the other if not both) (Sawyer et al. 2009).

CES206.944 Mediterranean California Foothill and Lower Montane Riparian Woodland and Shrubland

CES206.944 CLASSIFICATION

Concept Summary: This system is found throughout Mediterranean California within a broad elevation range from near sea level up to 300 m (900 feet) in the Coast Ranges and inland to 1500 m (4545 feet). This system often occurs as a mosaic of multiple communities that are tree-dominated with a diverse shrub component and open shrublands. This system includes open channels and bare alluvial bars as well. The variety of plant associations connected to this system reflects elevation, stream gradient, floodplain width, and flooding events. Dominant trees and shrubs may include *Alnus rhombifolia, Acer negundo, Alnus rubra* (in Coast Ranges), *Populus fremontii, Salix laevigata, Salix gooddingii, Pseudotsuga menziesii, Platanus racemosa, Quercus agrifolia*, and *Acer macrophyllum* (in central and south coast). Dominant shrubs include *Salix exigua* and *Salix lasiolepis*. Exotic trees *Ailanthus altissima, Eucalyptus* spp., and herbs such as *Arundo donax* occur. These are disturbance-driven systems that require flooding, scour and deposition for germination and maintenance.

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.944 CONCEPTUAL MODEL

Environment: This system occurs adjacent to perennial or intermittent streams, streams with at least seasonal channel flow, usually associated with a subsurface groundwater level that is shallower than surrounding uplands. Winter peak and summer discharges can be quite variable. The impact of seasonal high and low flows can be characterized as three regimes: (1) intense disturbances/minimal summer drought (close to channel, or narrow constricted floodplains); (2) moderate disturbances/summer drought (mid distance to channel, or moderate-sized floodplain); and (3) minimal disturbance/summer drought (greatest distance from channel, or wide floodplains). Type and extent of riparian vegetation are dependent upon the balance between the degree of summer drought as controlled by ground and surface water availability and the intensity of disturbance determined by discharge magnitudes and channel morphology (Ross and Swift 2001). This "distance from channel" can dictate the age and size of the riparian woody species.

Key Processes and Interactions: These are disturbance-driven systems that require flooding, scour and deposition for germination and maintenance.

Threats/Stressors:

Ecosystem Collapse Thresholds:

CES206.945 Mediterranean California Serpentine Foothill and Lower Montane Riparian Woodland and Seep

CES206.945 CLASSIFICATION

Concept Summary: This ecological system is found mostly in the central and inner northern Coast Ranges of California and Sierra Nevada foothills. It includes springs, seeps, and perennial and intermittent streams in serpentine substrates (true serpentinite but also other related substrates). Characteristic species include *Salix breweri, Hesperocyparis sargentii, Frangula californica ssp. tomentella, Umbellularia californica, Cirsium fontinale, Stachys albens, Solidago* spp., *Packera clevelandii, Mimulus glaucescens, Mimulus guttatus, Aquilegia eximia*, and *Carex serratodens*. Riparian portions of this system are disturbance-driven and require limited flooding, scour and deposition for germination and maintenance.

Related Concepts:

- Riparian Woodland (203) (Shiflet 1994) **>**

Distribution: This system occurs in the central and inner northern Coast Ranges of California and Oregon and Sierra Nevada foothills.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.945 CONCEPTUAL MODEL

Environment: This system is found in creek bottoms and stream terraces with serpentine-derived alluvium. Elevations range from 300-3000 m. Soils are saturated to moist throughout the growing season (Sawyer et al. 2009).

Key Processes and Interactions: Steady groundwater flow and fire primarily disturb stands of this ecosystem. Plants resprout after flooding disturbance. Most serpentine riparian areas have moderate rather than large flooding events, and most serpentine riparian has low perennial flows not subject to vacillating events as non-serpentine areas. Serpentine riparian are less likely to be susceptible to drought and drying since the serpentine geology tends to release water slowly over time (T. Keeler-Wolf pers. comm. 2013). *Frangula californica* resprouts vigorously after fire (Sawyer et al. 2009). However, it is not known how often fires historically occurred in *Frangula californica*-dominated systems. Fire is less of a disturbance issue in willow-dominated systems, but fire does occur, and *Salix* generally resprouts after fires (Stromberg and Rychener 2010). Fires probably occur relatively frequently even though serpentine chaparral surrounding the riparian has lower fuels than typical non-serpentine chaparral (T. Keeler-Wolf pers. comm. 2013).

Threats/Stressors: Conversion of this type has commonly come from direct impacts of mine development and road building. Conversion to agriculture is not a factor as the soil types are not conducive to agricultural use. Surrounding watershed dewatering due to climate change and water diversion for agriculture in the North Coast Ranges is a real threat. Mining and agriculture (legal and illegal) have altered stream hydrology in several parts of the range (Sawyer et al. 2009).

Riparian areas and their aquatic communities are directly affected by concentrated grazing, cutting of woody vegetation for timber and firewood, residential development, river channelization, regulation or diversion of flows, wildfire suppression, trapping (principally beaver), exotic species (both terrestrial and aquatic plants and animals), unregulated recreation (both motorized and nonmotorized), road building, mining, pollution, farming, channel dredging, bank armoring, and construction of dams and levees. These same communities are indirectly affected by human activities across their surrounding watersheds that alter watershed runoff and groundwater recharge and discharge via altered ground cover and water diversions and withdrawals, or cause pollution, including from atmospheric deposition. Although some serpentine areas are not as heavily used as they once were, including the Clear Creek area of San Benito County (CNPS and CDFG 2006). Currently threats to serpentine riparian areas may be reduced as mineral use is down, ORV use is down, and water levels in streams are low but relatively constant (T. Keeler-Wolf pers. comm. 2013). Invasive plant species that are often treats to riparian areas may be less of threat in serpentine ecosystems; however, some invasives are finding their way into serpentine soils (Batten et al. 2006).

The projected impacts of climate change on thermal conditions in northwestern California will be warmer winter temperatures, earlier warming in the spring, and increased summer temperatures. Currently, there is greater uncertainty about the precipitation projections than for temperature in northwestern California, but with some evidence for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Potential climate change effects could include: perennial streams may become intermittent; phreatophytic species under greater stress and death; drop in groundwater table; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006, Coffman 2007); and increased competition for water from all users, stresses the already overtaxed water allocation of California agricultural system (PRBO Conservation Science RBO 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from dewatering of streams by diversions and groundwater pumping lowering the water table, continued heavy grazing by domestic livestock that completely removes all native vegetation and results in severe erosion and streambank collapse. Continued heavy trampling by recreational uses, especially motorized recreation, within the riparian area that compacts the soil and tears up vegetation. Cutting of woody vegetation to the point of compete upper canopy removal.

Environmental Degradation: Any of these conditions or combination of conditions rates as high-severity: Streamflow is severely modified with very few high flows and increase flows in late summer and fall. Stream channel is extensively disconnected from floodplain by dikes, tide gates, elevated culverts, etc. Banks are very eroded and broken down, no longer overhanging and shading the stream channel, soil compaction is severe, severe erosion evident. Buffer area is lacking. Riparian zone has become highly fragmented where the corridor is no longer continuous, but broken into small segments. Bare soil areas substantially and contribute to altered hydrology or other long-lasting impacts. Deep ruts from ORVs or machinery may be present, or livestock pugging and/or trails are widespread. Water will be channeled or ponded. Any of these conditions or combination of conditions rates as moderate-severity: Streamflow is moderately modified from natural hydrograph, some flushing spring flows occur but not as frequently and in lower magnitudes than historically. Bank collapse and erosion is evident is part of the occurrence. Buffer to riparian zone is less than 50 m in some areas around the occurrence. Fragmentation has occurred in only part of the occurrence.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: Total vegetative canopy is greatly reduced (<20%). Canopy extremely homogeneous, sparse, or absent (<10% cover). No reproduction of native woody species. Any of these conditions or combination of conditions rates as moderate-severity: Invasive species are present to abundant but native species still comprise at least 50% relative cover. Somewhat homogeneous in density and age OR <50% canopy cover. Saplings/seedlings of native woody species (such as *Salix breweri, Frangula, Rhododendron occidentale, Calycanthus* and others) present but in low abundance; little regeneration by native species.

CES302.748 North American Warm Desert Lower Montane Riparian Woodland and Shrubland

CES302.748 CLASSIFICATION

Concept Summary: This ecological system occurs in foothill and mountain canyons and valleys of the warm desert regions of the southwestern U.S. and adjacent Mexico, and consists of mid-to low-elevation (1100-1800 m) riparian corridors along perennial and seasonally intermittent streams. Rivers include upper portions of the Gila, Santa Cruz, Salt, San Pedro, and tributaries of the lower

Colorado River (below the Grand Canyon), the lower Rio Grande and Pecos (up to its confluence with Rio Hondo) that occur in the desert portions of their range. The vegetation is a mix of riparian woodlands and shrublands. Dominant trees include *Acer negundo, Populus deltoides ssp. wislizeni, Populus fremontii, Platanus wrightii, Juglans major, Fraxinus velutina*, and *Sapindus saponaria*. Occasionally *Populus angustifolia* may come in from higher elevations. Shrub dominants include *Salix exigua, Shepherdia argentea, Prunus* spp., *Alnus oblongifolia*, and *Baccharis salicifolia*. Vegetation is dependent upon annual or periodic flooding and associated sediment scour and/or annual rise in the water table for growth and reproduction. In Texas, woody species that may be dominant include *Celtis laevigata var. reticulata, Fraxinus velutina, Juglans major, Juglans microcarpa, Populus deltoides ssp. wislizeni, Populus fremontii, Salix gooddingii, Sapindus saponaria var. drummondii*, and *Ungnadia speciosa*. Shrubs commonly encountered include *Acacia constricta, Acacia greggii, Baccharis salicifolia, Brickellia californica, Cephalanthus occidentalis, Fallugia paradoxa, Mimosa aculeaticarpa var. biuncifera, Prosopis glandulosa, Rhus microphylla*, and *Salix gooddingii*. Some sites with sparse woody overstory may be dominated by grasses such as *Aristida* spp., *Bothriochloa laguroides ssp. torreyana, Bouteloua curtipendula, Bouteloua gracilis, Distichlis spicata, Muhlenbergia porteri, Muhlenbergia rigens, Pleuraphis mutica*, and *Sporobolus airoides*.

Distribution: This system occurs in southern Arizona, New Mexico, and adjacent Mexico, as well as in the desert mountain ranges of southeastern California, at low elevations. It also occurs in southern Nevada and western Texas.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: G. Kittel

CES302.748 CONCEPTUAL MODEL

Environment: This ecological system occurs in foothill and mountain canyons and valleys of the warm desert regions of the southwestern U.S. and adjacent Mexico, and consists of mid- to low-elevation (1100-1800 m) riparian corridors and their associated perennial and seasonally intermittent streams. Some occurrences originate as, or receive flow from, headwater streams supported by surface runoff and shallow groundwater seepage; others originate at montane springs.

Key Processes and Interactions: The hydrologic regime is naturally highly variable temporally and spatially among the streams of this ecosystem. Where present, bedrock formations that force alluvial and basin-fill groundwater to the surface and spring discharges from bedrock aquifers provide flows unaffected by rainfall and snowmelt. Otherwise, stream and river flows are subject to wide fluctuations in where they occur, at what magnitudes, and when and how often as a result of the wide variation in where and when precipitation takes place (cool versus warm season), what form the precipitation takes (rain versus snow), and where and when snowmelt takes place (e.g., Abell et al. 2000, Izbicki and Michel 2004, Levick et al. 2008, Miller et al. 2010a). Intense runoff associated with intense rainfall events are highly erosive, resulting in rapid reconfiguration of aquatic and riparian macrohabitats particularly along reaches with sand and gravel substrates. As a result of this intense regime of fluvial disturbance, occurrences of this ecosystem contain early-, mid- and late-seral riparian plant associations.

Threats/Stressors: Conversion of this type has commonly come from bridge crossings and road installation, agricultural conversion, and drowning by reservoir creation. Dewatering of streams through groundwater pumping and upstream diversions. Conversion to non-native-dominated types such as tamarisk and Russian olive. Common stressors and threats include concentrated grazing, cutting of woody vegetation, development, river channelization, diversion of flows, wildfire suppression, exotic species, unregulated recreation (both motorized and nonmotorized), road building, mining, pollution, channel dredging, bank armoring, and construction of dams. These same communities are indirectly affected by human activities across their surrounding watersheds that alter watershed runoff and groundwater recharge and discharge via altered ground cover and water diversions and withdrawals, or cause pollution, including from atmospheric deposition. Road crossings and dams can constrict flows and cause increased bank erosion. Reductions in flows can reduce the production of gravel and sand bars and thereby limit cottonwood and willow regeneration.

Forecasts for 2060 show monthly maximum temperature to increase at least two standard deviations above the 20th-century baseline values (1900-1979). Increases in July maximum temperature range from 2.5-8.6°F. This result is likely to counter any increase in precipitation via higher evapotranspiration and lower soil moisture levels. The increases in monthly minimum temperature (i.e., night-time temperature) are severe. For every month, 85-99% of the Mojave Basin and Range ecoregion (MBR) is projected to exceed one standard deviation beyond the 20th century baseline. For midcentury summers - July thru October - models predict 80-95% of the region will experience monthly minimum temperatures two standard deviations beyond baseline values; with extremes reaching a 9.6°F increase. This may be related to cloud cover associated with increased precipitation forecasts; in other words, increased night-time cloud cover will reduce radiative cooling at night. Overall, there is no clear spatial pattern to the area that is not expected to experience these changes, although portions of the southern MBR more frequently experience values closer to the range of historic climatic variability (Comer et al. 2013b).

Potential climate change effects could include the following (edited excerpt from Comer et al. 2013b): "The forecasted changes in temperature and precipitation patterns would be expected to result in several effects on riparian resources in the ecoregion, as discussed by Melack et al. (1997), Field et al. (1999), Mote (2006), Christensen and Lettenmaier (2007), Chambers and Pellant (2008), Brown and Mote (2009), Covich (2009), Das et al. (2009), Dettinger et al. (2009), McCabe and Wolock (2009), Cayan et al. (2010), Miller et al. (2010a), USBOR (2011). They include: higher evapotranspiration rates leading to an earlier, more rapid seasonal drying-down of riparian occurrences; earlier snowmelt and a smaller snowpack in watersheds which moves and reduces the height of the peak flood and earlier in the spring; increased water stress in basin-floor phreatophyte communities; shrinkage of areas of perennial flow/open water, coupled with higher water temperatures at locations/times when water temperatures are not controlled by groundwater discharges or snowmelt; persistence of these hydrologic conditions later into the fall or early winter; reduced groundwater recharge in the mountains and reduced recharge to basin-fill deposits along the mountain-front/basin-fill interface; and more erosive mid/late-summer runoff events in those areas experiencing increased July/August precipitation, potentially with associated channel down-cutting and expanded deposition of the eroded sediment in lower-elevation gravel fans.

Based on the ways in which these hydrologic factors affect ecological dynamics in riparian resources, persistence of these hydro-meteorological impacts over multiple decades could result in several long-term impacts at both high and low elevations, as discussed by many of the authors cited above, and also by Harper and Peckarsky (2006), Hultine et al. (2007), Martin (2007), Chambers and Wisdom (2009), Jackson et al. (2009), and Seavy et al. (2009). These include: loss of riparian vegetation at lower elevations where the frequency and spatial extent of seasonal flows determines the spatial limits of this vegetation; loss of basin-floor phreatophyte (deep-rooted plants that obtain water from groundwater sources) communities as a result of lower near-surface ground elevations; declines in the spatial extent and biodiversity of perennial streams and open waters as a result of shrinkage and warmer temperatures; reduced discharge to springs and seeps as a result of reduced aquifer recharge; a continuation of normal "warm-season" aquatic ecological dynamics later into the fall as a result of seasonally normal (baseline) overnight near-freezing temperatures becoming less common in many areas until later in the fall; and a possible de-coupling of the places and timing of emergence of insects, the plants on which they depend, and the animals that feed on the insects, as individual species respond to different cues from air and water temperatures, water availability, and flow conditions."

Ecosystem Collapse Thresholds: Ecological collapse tends to result from dewatering of streams by diversions and groundwater pumping lowering the water table, continued heavy grazing by domestic livestock that completely removes all native vegetation and results in severe erosion and streambank collapse. Continued heavy trampling by recreational uses, especially motorized recreation, within the riparian area that compacts the soil and tears up vegetation. Cutting of woody vegetation to the point of compete upper canopy removal.

Environmental Degradation (from WNHP 2011 and CNHP 2010b): Any of these conditions or combination of conditions rates as high-severity: Streamflow is severely modified with very few high flows and increase flows in late summer and fall. Stream channel is extensively disconnected from floodplain by dikes, tide gates, elevated culverts, etc. Banks are very eroded and broken down, no longer overhanging and shading the stream channel, soil compaction is severe, severe erosion evident. Buffer area is lacking. Riparian zone has become highly fragmented that is the stream corridor is no longer continuous and riparian patches are broken into small segments. Bare soil areas substantially and contribute to altered hydrology or other long-lasting impacts. Deep ruts from ORVs or machinery may be present, or livestock pugging and/or trails are widespread. Water will be channeled or ponded. Any of these conditions or combination of conditions rates as moderate-severity: Streamflow is moderately modified from natural hydrograph, some flushing spring flows occur but not as frequently and in lower magnitudes than historically. Bank collapse and erosion is evident is part of the occurrence. Buffer to riparian zone is less than 50 m in some areas around the occurrence. Fragmentation has occurred in part of the occurrence.

Disruption of Biotic Processes (from WNHP 2011 and CNHP 2010b): Any of these conditions or combination of conditions rates as high-severity: Invasive species dominate the stand, native plants comprise less than 20% of the site, total vegetative canopy is greatly reduced (<20%). Canopy extremely homogeneous, sparse, or absent (<10% cover). No reproduction of native woody species. Any of these conditions or combination of conditions rates as moderate-severity: Invasive species are present to abundant but native species still comprise at least 50% relative cover. Somewhat homogeneous in density and age OR <50% canopy cover. Saplings/seedlings of native woody species (cottonwood/willow) present but in low abundance; little regeneration by native species.

CES302.753 North American Warm Desert Riparian Woodland and Shrubland

CES302.753 CLASSIFICATION

Concept Summary: This ecological system consists of low-elevation (<1200 m) riparian corridors along medium to large perennial streams throughout canyons and desert valleys of the southwestern United States and adjacent Mexico. Rivers include the lower Colorado (into the Grand Canyon), Gila, Santa Cruz, Salt, lower Rio Grande (below Elephant Butte Reservoir in New Mexico to the Coastal Plain of Texas), and the lower Pecos (up to near its confluence with Rio Hondo in southeastern New Mexico). These are disturbance-driven plant communities that require flooding, scour and deposition of sands and gravel, and a periodically elevated water table for germination and maintenance. The aquatic communities, in turn, vary with (1) the frequency, intensity, duration and timing of flow, including its often extreme inter-annual variability; (2) the relative contributions of rainfall, snowmelt, and diffuse groundwater and spring discharges to flow; (3) water temperature and chemistry; (4) channel substrate and form; (5) the extent of the hyporheic zone; and (6) drainage network connectivity. These latter conditions, in turn, vary with elevation, latitude and longitude, channel gradient, floodplain width (a function of topography and geology), and surrounding geology and land cover. The vegetation is a mix of riparian woodlands and shrublands. Species composition varies across the wide range of this system. Dominant trees may include *Celtis laevigata var. reticulata, Fraxinus velutina, Juglans major, Platanus racemosa, Populus fremontii, Populus deltoides ssp. wislizeni, Prosopis glandulosa, Salix amygdaloides, Salix gooddingii, Salix lasiolepis*, and *Sapindus saponaria var. drummondii*. Shrub dominants include *Salix geyeriana* and *Salix exigua*. In Texas, *Baccharis salicifolia, Brickellia laciniata, Celtis ehrenbergiana, Chilopsis linearis, Fallugia paradoxa, Juglans microcarpa*, and *Salix exigua* are present and sometimes patchy. In addition to the woodland and shrubland expression of this system, sparsely vegetated areas also commonly occur. Sparsely vegetated sites may have sparse woody or herbaceous vegetation, including species such as *Brickellia* sp., *Chilopsis linearis, Baccharis* sp., *Prosopis glandulosa*, and *Salvia farinacea*. Vegetation is dependent upon annual or periodic flooding and associated sediment scour and/or annual rise in the water table for growth and reproduction.

- Trans-Pecos: Riparian Woodland (8704) [CES302.753.02] (Elliott 2012) **<**

Distribution: This systems occurs throughout canyons and desert valleys of the southwestern United States and adjacent Mexico. Major rivers and tributaries include the lower Colorado (up into the lower portions of the Grand Canyon), Gila, Salt, Rio Grande (from Elephant Butte Reservoir to the Gulf Coastal Plain), and the lower Pecos (near its confluence with Rio Hondo in southeastern New Mexico).

Description Author: K.A. Schulz, G. Kittel, M. Reid, L. Elliott and J. Teague

CES302.753 CONCEPTUAL MODEL

Environment: These are disturbance-driven plant communities that require flooding, scour and deposition of sands and gravel, and a periodically elevated water table for germination and maintenance. The aquatic communities, in turn, vary with the frequency, intensity, duration and timing of flow, including its often extreme inter-annual variability; the relative contributions of rainfall, snowmelt, and diffuse groundwater and spring discharges to flow; water temperature and chemistry; channel substrate and form; the extent of the hyporheic zone; and drainage network connectivity. These latter conditions, in turn, vary with elevation, latitude and longitude, channel gradient, floodplain width (a function of topography and geology), and surrounding geology and land cover. In Texas, this system occurs on Loamy Bottomland, Salty Bottomland, and Draw Ecological Sites over Quaternary Alluvium, as well as nearby Cretaceous limestones through which drainages flow.

Key Processes and Interactions: From MBR Ecological Condition Assessment (Comer et al. 2013b): The hydrologic regime is naturally highly variable temporally and spatially among the streams of this ecosystem. Where present, bedrock formations that force alluvial and basin-fill groundwater to the surface and spring discharges from bedrock aquifers provide flows unaffected by rainfall and snowmelt. Otherwise, stream and river flows are subject to wide fluctuations in where they occur, at what magnitudes, and when and how often as a result of the wide variation in where and when precipitation takes place (cool versus warm season), what form the precipitation takes (rain versus snow), and where and when snowmelt takes place (e.g., Abell et al. 2000, Izbicki and Michel 2004, Levick et al. 2008, Miller et al. 2010a). Intense runoff associated with intense rainfall events are highly erosive, resulting in rapid reconfiguration of aquatic and riparian macrohabitats particularly along reaches with sand and gravel substrates. As a result of this intense regime of fluvial disturbance, occurrences of this ecosystem contain early-, mid- and late-seral riparian plant associations. Occurrences also contains non-obligate riparian species. Cottonwood communities are early-, mid- or late-seral, depending on the age-class of the trees and the associated species of the occurrence (Kittel et al. 1999b). Cottonwoods, however, do not reach a climax stage as defined by Daubenmire (1952). Mature cottonwood occurrences do not regenerate in place, but regenerate by "moving" up and down a river reach. Over time, a healthy riparian area supports all stages of cottonwood communities (Kittel et al. 1999b). In Texas, the native streamside vegetation along the large drainages is frequently displaced by extensive areas of *Tamarix* sp. and/or *Arundo donax*.

Threats/Stressors: Conversion of this type has commonly come from bridge crossings and road installation, agricultural conversion, and drowning by reservoir creation. Dewatering of streams through groundwater pumping and upstream diversions. Common stressors and threats include concentrated grazing, cutting of woody vegetation, development, river channelization, diversion of flows, lowering of the groundwater table, wildfire suppression, exotic species, unregulated recreation (both motorized and nonmotorized), road building, mining, pollution, channel dredging, bank armoring, and construction of dams. These same communities are indirectly affected by human activities across their surrounding watersheds that alter watershed runoff and groundwater recharge and discharge via altered ground cover and water diversions and withdrawals, or cause pollution, including from atmospheric deposition. Road crossings and dams can constrict flows and cause increased bank erosion. Reductions in flows can reduce the production of gravel and sand bars and thereby limit cottonwood and willow regeneration.

Forecasts for 2060, show monthly maximum (daytime) temperature to increase at least two standard deviations above the 20th-century baseline values (1900-1979). Increases in July maximum temperature range from 2.5-8.6°F. This result is likely to counter any increase in precipitation via higher evapotranspiration and lower soil moisture levels. The increases in monthly minimum temperature (i.e., night-time temperature) are also pervasive and severe. For every month, 85-99% of the Mojave Basin and Range Ecoregion (MBR) is projected to exceed one standard deviation beyond the 20th century baseline. For midcentury summers - July thru October - models predict 80-95% of the region will experience monthly minimum temperatures two standard deviations beyond baseline values; with extremes reaching a 9.6°F increase. This may be related to cloud cover associated with increased precipitation forecasts; in other words, increased night-time cloud cover will reduce radiative cooling at night. Overall, there is no clear spatial pattern to the area that is not expected to experience these changes, although portions of southern MBR more frequently experience values closer to the range of historic climatic variability (Comer et al. 2013b).

Potential climate change effects could include the following (edited excerpt from Comer et al. 2013b): "The forecasted changes in temperature and precipitation patterns would be expected to result in several effects on riparian resources in the ecoregion, as discussed by Melack et al. (1997), Field et al. (1999), Mote (2006), Christensen and Lettenmaier (2007), Chambers and Pellant (2008), Brown and Mote (2009), Covich (2009), Das et al. (2009), Dettinger et al. (2009), McCabe and Wolock (2009), Cayan et al. (2010), Miller et al. (2010a), and USBOR (2011). These include: higher evapotranspiration rates leading to an earlier, more rapid seasonal drying-down of riparian occurrences; increased water stress in basin-floor phreatophyte communities; shrinkage of areas of perennial flow/open water, coupled with higher water temperatures at locations/times when water temperatures are not controlled by groundwater discharges or snowmelt; persistence of these hydrologic conditions later into the fall or early winter; reduced groundwater recharge in the mountains and reduced recharge to basin-fill deposits along the mountain-front/basin-fill interface; and more erosive mid/late-summer runoff events in those areas experiencing increased July/August precipitation, potentially with associated channel down-cutting and expanded deposition of the eroded sediment in lower-elevation gravel fans.

Based on the ways in which these hydrologic factors affect ecological dynamics in riparian resources, persistence of these hydro-meteorological impacts over multiple decades could result in several long-term impacts at both high and low elevations, as discussed by many of the authors cited above, and also by Harper and Peckarsky (2006), Hultine et al. (2007), Martin (2007), Chambers and Wisdom (2009), Jackson et al. (2009), and Seavy et al. (2009). These include loss of riparian vegetation at lower elevations where the frequency and spatial extent of seasonal flows determines the spatial limits of this vegetation; loss of basin-floor phreatophyte (deep-rooted plants that obtain water from groundwater sources) communities as a result of lower near-surface ground elevations; declines in the spatial extent and biodiversity of perennial streams and open waters as a result of shrinkage and warmer temperatures; reduced discharge to springs and seeps as a result of reduced aquifer recharge; a continuation of normal "warm-season" aquatic ecological dynamics later into the fall as a result of seasonally normal (baseline) overnight near-freezing temperatures becoming less common in many areas until later in the fall; and a possible de-coupling of the places and timing of emergence of insects, the plants on which they depend, and the animals that feed on the insects, as individual species respond to different cues from air and water temperatures, water availability, and flow conditions."

Ecosystem Collapse Thresholds: Ecological collapse tends to result from dewatering of streams by diversions and groundwater pumping lowering the water table, continued heavy grazing by domestic livestock that completely removes all native vegetation and results in severe erosion and streambank collapse. Continued heavy trampling by recreational uses, especially motorized recreation, within the riparian area that compacts the soil and tears up vegetation. Cutting of woody vegetation to the point of compete upper canopy removal.

Environmental Degradation (from WNHP 2011 and CNHP 2010b): Any of these conditions or combination of conditions rates as high-severity: Streamflow is severely modified with very few high flows and increase flows in late summer and fall. Stream channel is extensively disconnected from floodplain by dikes, tide gates, elevated culverts, etc. Groundwater levels have dropped so that once perennial reaches are now intermittent. Banks are very eroded and broken down, no longer overhanging and shading the stream channel, soil compaction is severe, severe erosion evident. Buffer area is lacking. Riparian zone has become highly fragmented, corridor is no longer continuous, but broken into small segments. Bare soil areas substantially and contribute to altered hydrology or other long-lasting impacts. Deep ruts from ORVs or machinery may be present, or livestock pugging and/or trails are widespread. Water will be channeled or ponded. Any of these conditions or combination of conditions rates as moderate-severity: Streamflow is moderately modified from natural hydrograph, some flushing spring flows occur but not as frequently and in lower magnitudes than historically. Bank collapse and erosion is evident is part of the occurrence. Buffer to riparian zone is less than 50 m in some areas around the occurrence. Fragmentation has occurred in part of the occurrence.

Disruption of Biotic Processes (from WNHP 2011 and CNHP 2010b): Any of these conditions or combination of conditions rates as high-severity: Invasive species dominate the stand, native plants comprise less than 20% of the site, total vegetative canopy is greatly reduced (<20%). Canopy extremely homogeneous, sparse, or absent (<10% cover). No reproduction of native woody species. Any of these conditions or combination of conditions rates as moderate-severity: Invasive species are present to abundant but native species still comprise at least 50% relative cover. Somewhat homogeneous in density and age OR <50% canopy cover. Saplings/seedlings of native woody species (cottonwood/willow) present but in low abundance; little regeneration by native species.

CES301.716 Rio Grande Delta Thorn Woodland

CES301.716 CLASSIFICATION

Concept Summary: This diverse, usually broad-leaved evergreen woodland is found on resaca banks and old natural levees on the Rio Grande delta in southern Texas. Sites are well-watered, somewhat elevated relative to the surrounding landscape, and tend to occupy loamy or clayey bottomland soils. This system includes evergreen, mixed and deciduous woodlands and shrublands with a typically open upper canopy of broadleaf evergreen species such as *Ebenopsis ebano* and *Ehretia anacua* and a dense shrub layer of numerous species present. Mature occurrences will often support epiphytes such as *Tillandsia recurvata, Tillandsia usneoides*, and rarely *Tillandsia baileyi*.

Description Author: L. Elliott, J. Teague and K.A. Schulz

CES301.716 CONCEPTUAL MODEL

Environment: This system occurs in the historic floodplain of the Rio Grande delta on Quaternary-aged alluvium. It is found on slight rises such as old natural levees or resaca banks often on Clayey or Loamy Bottomland Ecological Sites, but occasionally on Clay Loam or Gray Sandy Loam types. Sites are well-watered, somewhat elevated relative to the surrounding landscape, and tend to occupy loamy or clayey bottomland soils. Occasionally occurrences can be found on clay loams (such as Raymondville or Racombes soils) or gray sandy loams (such as Hidalgo sandy clay loam).

Key Processes and Interactions: The major processes in this system were flooding and drought (Diamond 1998). Freezes can have significant impacts on canopy species such as *Ebenopsis, Sabal* and *Leucaena pulverulenta* in the delta. Hurricanes may not significantly affect dense *Ebenopsis ebano - Ehretia anacua* forest, except through flood effects. Lengthy droughts (lasting ~10 years) can influence this system but most species are drought-tolerant. Infrequent fires may also occur.

This system was modeled as part of the Tamaulipan Riparian Systems group by Landfire (2007a) using three classes: early-, mid- and late-seral. Fire frequency is likely over-emphasized in this model for this system, as other ecologists suggest fire was historically infrequent in the Rio Grande delta (Diamond 1998).

Early-seral class (0-12 years): Herbaceous species dominant where there are high sunlight conditions. Woody species begin establishing in the understory. Duration of this stage is 12 years. Flooding at an interval of 500 years is modeled for this stage (Landfire 2007a).

Mid-seral class (13-33 years): Species composition would contain canopy species of an earlier successional type such as *Acacia farnesiana, Ehretia anacua, Leucaena pulverulenta, Celtis laevigata* and *Celtis ehrenbergiana*. Shrub cover would be increased due to openness of the canopy. Duration of this stage is 20 years. Flooding at an interval of 500 years moves to early-seral class. Surface fires every 30 years maintain this mid-seral class (Landfire 2007a).

The late-seral class (34+ years): Canopy becomes more closed and includes *Ehretia anacua, Ebenopsis ebano, Ulmus crassifolia*, and *Celtis laevigata*. Gap succession does occur as individual tree mortality occurs (maintenance/ every 500 years) and moves class to mid-seral. Freezes will reduce canopy of ebony and other subtropical species. Freezes (every 50 years) and surface fires (every 30 years) occur but do not cause transitions to other structural or floristic states. Flooding at an interval of 500 years takes class to early-seral (Landfire 2007a).

Threats/Stressors: Threats and stressors include river diversion disrupting deltaic processes, invasive species, fragmentation, loss of overbank flooding and nutrient and sediment input. It has been estimated that 99% of this system has been lost to conversion to agriculture and other land uses. Water developments (dams and reservoirs, diversions for irrigation, municipal, and industrial use, and channelization) have significantly altered the hydrological regime. Periodic flooding is a critical factor in maintaining functioning floodplain and riparian ecosystems. Past alterations have impacted species (Editor 1986, as cited in Jahrsdoerfer and Leslie 1988). Pollution from development and agriculture degrade water quality with pesticides and fertilizer-laden sediments, sewage, etc. (Jahrsdoerfer and Leslie 1988).

Other human impacts have greatly converted and altered this floodplain system, including highway, bridge, and homeland security fence construction and maintenance; recreation; industrial and residential development; agriculture; irrigation; livestock grazing; and gravel mining. These areas are often subjected to heavy grazing and/or agriculture and can be heavily degraded. Non-native species, especially forage grasses such as *Bothriochloa ischaemum var. songarica, Bromus catharticus, Cynodon dactylon, Pennisetum ciliare*, and *Urochloa maxima*, are often present to dominant, and sometimes to the exclusion of most other herbaceous species (Elliot 2011).

Conversion of this type has commonly come from water developments/reservoirs, irrigated agriculture. Common stressors and threats include altered hydrologic regime from water development, channel modifications for flood control, urban and industrial effluent discharge, and gravel mining. Excessive livestock use leads to a shift in plant species composition to more grazing- and disturbance-tolerant species including invasive, non-native forage species).

According to Climate Wizard in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5°F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion. Potential climate change effects could also include alterations to the hydrologic regime causing reductions of flows available for natural processes and plant and animal communities, if climate change has predicted effect of less effective moisture with increasing mean temperature (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from conversion to other land uses and groundwater pumping that lowers the base level, causing the stream to become a losing reach, which dries up the stream and lowers the groundwater table and/or is the result from major disturbances such development or brush removal using herbicides or mechanical treatments resulting in conversion to agriculture.

High-severity environmental degradation appears where occurrences tend to be relatively short (<0.5 mile long). Natural hydrologic regime is severely altered and is considered not restorable (system remains fundamentally compromised despite restoration of some processes). Large upstream dams and numerous water diversions may occur in watershed. Streambank may be severely altered with riprap or gravel mining in floodplain may be extensive. Fire regime has been altered by fire suppression so no fires have burned in >100 years resulting in higher cover of trees and shrubs than occurred under natural conditions. Moderate-severity environmental degradation appears where occurrences are moderate (0.5-1 mile long) in length. Natural hydrologic regime altered by upstream dams, local drainage, diking, filling, digging, or dredging. Alteration is extensive but potentially restorable over several decades. Local or moderate human-caused alteration of hydrology may be present in watershed, for example small dams, irrigation ditches, and gravel mines. Groundwater pumping has produced noticeable changes from historic hydrologic patterns. Streambanks are altered. Disturbance is significant enough to have notable impact on species composition and soil compaction, causing significant erosion. Fire regime has been altered by fire suppression so no fires have burned in >100 years resulting in higher cover of trees and shrubs than occurred under natural conditions.

High-severity disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species may be dominant over significant portions of area, with little potential for control. Connectivity is severely hampered and severely restricts or prevents natural ecological processes from occurring, creating barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low. Moderate-severity disruption appears where occurrences have moderate cover of native grassland species (30-60% relative cover). Non-native invasive species may be widespread but potentially manageable with restoration of most natural processes. Connectivity is moderately hampered and severely restricts some natural ecological processes from occurring, creating some barriers to the natural movement of some animal and plant populations.

CES302.759 Sonoran Fan Palm Oasis

CES302.759 CLASSIFICATION

Concept Summary: This ecological system occurs on highly localized, spring-fed depressions along canyon waterways and tectonic fault lines below 900 m in elevation in the Sonoran and Mojave deserts. Permanent subsurface water is required to maintain *Washingtonia filifera*, a relict species. Salinity is low in the root zone, but increases near the surface where evaporation leaves salt accumulations. These oases woodlands are distinctively dominated by *Washingtonia filifera* with variable understory conditions. Other trees that may be present include *Platanus racemosa, Quercus chrysolepis, Populus fremontii*, and *Fraxinus velutina*. A subcanopy of *Salix lasiolepis, Salix gooddingii, Salix exigua*, or *Prosopis glandulosa* is often present. Reproduction of *Washingtonia filifera* is limited by water supply, surface salinity, rainfall, and fire. Fan palms are fire-tolerant, while the understory species are not, and fires open up the understory allowing palm seedlings to establish. Removal of the understory also decreases competition for water. There are currently 80 known occurrences in California and probably 100 throughout its range including Arizona and Nevada.

Related Concepts:

Distribution: Below 900 m in elevation in the Sonoran and Mojave deserts.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: G. Kittel

CES302.759 CONCEPTUAL MODEL

Environment: Desert springs in canyon waterways or along fault lines where underground water is continuously available. Salinity is low in the root zone, but increases near the surface where evaporation leaves salt accumulations.

Key Processes and Interactions: Reproduction of *Washingtonia filifera* is limited by water supply, surface salinity, rainfall, and fire. Fan palms are fire-tolerant, while the understory species are not, and fires open up the understory allowing palm seedlings to establish. Removal of the understory also decreases competition for water. Fire is essential in the regeneration of *Washingtonia* *filifera* (Sawyer et al. 2009). Natural fires started by lighting as well as those set by Native Americans prior to 1900s created favorable germination sites and increased the flow of springs. Flash floods probably had similar effect (Sawyer et al. 2009).

Threats/Stressors: Conversion of this type has commonly come from agricultural and urban development, raising or lowering of the groundwater table has eliminated many known spring locations (Sawyer et al. 2009). Common stressors and threats include fire suppression, lowering of water table, recreation pressure from hikers and ORV use, vandalism, and vegetation disturbance (Sawyer et al. 2009).

In the Sonoran Desert, regional climate models project mean annual temperature increases of 1.8-2.4°C by 2070, as well as a change in mean annual rainfall that ranges from an increase of 3 mm to a decrease of 55 mm by 2070, current model changes to precipitation are highly uncertain (PRBO Conservation Science 2011). Fires may increase with drier air and fuels, while groundwater recharge may be limited with decreased rainfall, further stressing the water supply in a region where there is high demand for water by agricultural, urban, and industrial users as well as ecosystem and wildlife needs (PRBO Conservation Science 2011). Springs will disappear if groundwater levels drop.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from dewatering of the springs, vegetative damage from cutting, vandalism, and soil compaction, lack of regeneration of palms.

Environmental Degradation (criteria is from literature cited above, thresholds are by the author: Any of these conditions or combination of conditions rates as high-severity: Significant drop in the groundwater table reducing spring flows by more than 50%. Any of these conditions or combination of conditions rates as moderate-severity: Some to moderate drop in the groundwater table reducing spring flows by 10-50%. Disruption of Biotic Processes (criteria is from literature cited above, thresholds are by the author: Any of these conditions or combination of conditions rates as high-severity: No regeneration of the Washington palm for more than 2 decades, buildup of surrounding vegetation such that any resulting fire may burn too hot and kill the palm trees (Sawyer et al. 2009). Any of these conditions or combination of conditions rates as moderate-severity: Little to no regeneration of the Washington palm for 5-10 years, vegetation disturbance by recreationalists, undergrowth beginning to get too thick, causing increased competition and risk of wildfire (Sawyer et al. 2009).

CES301.990 Tamaulipan Floodplain

CES301.990 CLASSIFICATION

Concept Summary: This ecological system is limited to riparian areas of the lower Rio Grande Valley and Rio Corona in southern Texas and northeastern Mexico. Stands occur on riverbanks, floodplains and deltas. Stands are generally deciduous woodlands or forests with tree height reaching to 15 m. Canopy cover is variable, but sometimes reaches near 100%. The canopy may have a conspicuous (sometimes dominant to codominant) evergreen component of species such as *Ebenopsis ebano* and *Ehretia anacua*. Dominant species of the overstory canopy often include one or more of the following: *Celtis laevigata, Ulmus crassifolia, Fraxinus berlandieriana, Prosopis glandulosa, Vachellia farnesiana, Diospyros texana, Leucaena pulverulenta, Celtis ehrenbergiana, Sapindus saponaria var. drummondii, Ebenopsis ebano, Ehretia anacua*, and *Parkinsonia aculeata*. These woodlands are a unique mix of species from southeastern North America and subtropical Central America and are often dominated by *Vachellia farnesiana,* *Diospyros texana, Ebenopsis ebano, Ehretia anacua, Fraxinus berlandieriana*, or *Ulmus crassifolia*, and many other tree species present to locally dominant. The highly variable understory is dependent on canopy density and may include dense shrub or herbaceous layers.

Description Author: J. Teague, M. Pyne, L. Elliott

CES301.990 CONCEPTUAL MODEL

Environment: Stands of this ecological system occur on riverbanks, floodplains, deltas and other riparian areas of the lower Rio Grande Valley and Rio Corona in southern Texas and northeastern Mexico. The geology is Quaternary alluvium. Landforms are floodplains of rivers and large creeks where sediment is deposited. The topography is relatively level with some relief associated with levees and depressions developed from meanders of the waterway, or historical meanders of the Rio Grande (Resaca). It is typically found on alluvial soils of the Bottomland Ecological Sites, including loamy, clayey, and sandy. The Lowland Ecological Site type also supports this system. This ecological system occurs along rivers and major drainages in south Texas from the central portion of the Nueces River south to northeastern Mexico and west to the vicinity of Del Rio, Texas.

Key Processes and Interactions: Stands occur as linear patches along much of the lower Rio Grande and occupy large patches on the delta (Landfire 2007a). Key ecological processes are succession and disturbance. Disturbance was primarily flooding and, to a lesser extent, fire may have occurred within these woodlands and forests. Occurrence of patches of *Phragmites* spp. may have provided adequate fuel to carry fire to the canopy. Floods may have been annual and were primarily depositional floods rather than scouring floods (Landfire 2007a). Long-term succession would occur due to deposition and development of this system into more upland characteristics of another system (Landfire 2007a). Extreme floods may have occurred in association with hurricanes. Freezes would have had significant impacts on the largely tropical/subtropical species, though these impacts more directly affect riparian woodlands where tropical species are more common. Drought would also affect this system, and may provide the unusual opportunity for fire to carry in the system (Landfire 2007a).

This system was modeled as part of the Tamaulipan Riparian Systems group by Landfire (2007a) using three classes: early-, mid- and late-seral. Fire frequency may be over-emphasized in this model for this system, as other ecologists suggest fire less frequent historically.

The early-seral class (0-12 years): Herbaceous cover following 1000-year scouring flood and replacement fire in mid-seral class. Herbaceous cover of sedges and rushes develops as sedimentation produces an adequate substrate not continually flooded to allow development of cover. Areas of *Phragmites* spp. may occur in areas where fires would have occurred. Replacement fire-return interval is approximately 10 years in this class due to the fine fuel (Landfire 2007a).

Mid-seral class (13-20 years): Low canopy cover of trees. Shrub layer well-developed, but composition is similar to the understory of late-seral class. Scouring floods associated with river channel migration on the delta is modeled as encountering a site every 1000 years, taking the class back to early-seral. Replacement fire is modeled as occurring at a similar MFRI to surface fires in mid-seral class (30 years). *Celtis laevigata* is developing as a canopy but still occurs with low cover (Landfire 2007a).

The late-seral class (21+ years): Dominated by *Celtis laevigata* with 60-100% canopy, with *Ulmus crassifolia, Celtis ehrenbergiana, Mimosa pellita*, and *Condalia hookeri* in the midstory, and other shrubs in the understory. Scouring floods modeled as occurring every 1000 years take class back to early-seral. Hurricane of sufficient strength to take out the canopy is modeled as occurring every 50 years, takes class back to mid-seral. Maintenance surface fires occur every 30 years (Landfire 2007a).

Threats/Stressors: Water development (dams and reservoirs, diversions for irrigation, municipal and industrial use, and channelization) has significantly altered the hydrological regime. Periodic flooding is a critical factor in maintaining functioning floodplain and riparian ecosystems. Past alterations have impacted species (Editor 1986, as cited in Jahrsdoerfer and Leslie 1988).

Pollution from development and agriculture degrade water quality with pesticides and fertilizer-laden sediments, sewage, etc. (Jahrsdoerfer and Leslie 1988).

Other human impacts have greatly converted and altered this floodplain system, including highway, bridge, and homeland security fence construction and maintenance; recreation; industrial and residential development; agriculture; irrigation; livestock grazing; and gravel mining. These areas are often subjected to heavy grazing and/or agriculture and can be heavily degraded. Non-native species, especially forage grasses such as *Bothriochloa ischaemum var. songarica, Bromus catharticus, Cynodon dactylon, Pennisetum ciliare*, and *Urochloa maxima*, are often present to dominant, and sometimes to the exclusion of most other herbaceous species (Elliot 2011).

Conversion of this type has commonly come from water developments/reservoirs, irrigated agriculture. Common stressors and threats include altered hydrologic regime from water development, channel modifications for flood control, urban and industrial effluent discharge, and gravel mining. Excessive livestock use leads to a shift in plant species composition to more grazing- and disturbance-tolerant species, including invasive, non-native forage species.

According to Climate Wizard in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5°F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion. Potential climate change effects could also include alterations to the hydrologic regime causing reductions of flows available for natural processes and plant and animal communities, if climate change has predicted effect of less effective moisture with increasing mean temperature (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from groundwater pumping that lowers the base level, causing the stream to become a losing reach, which dries up the stream and lowers the groundwater table and/or is the result from major disturbances such as development or brush removal using herbicides or mechanical treatments resulting in conversion to agriculture.

High-severity environmental degradation appears where occurrences tend to be relatively short (<0.5 mile long). Natural hydrologic regime is severely altered and is considered not restorable (system remains fundamentally compromised despite restoration of some processes). Large upstream dams and numerous water diversions may occur in watershed. Streambank may be severely altered with riprap or gravel mining in floodplain may be extensive. Fire regime has been altered by fire suppression so no fires have burned in >100 years resulting in higher cover of trees and shrubs than occurred under natural conditions. Moderate-severity environmental degradation appears where occurrences are moderate (0.5-1 mile long) in length. Natural hydrologic regime altered by upstream dams, local drainage, diking, filling, digging, or dredging. Alteration is extensive but potentially restorable over several decades. Local or moderate human-caused alteration of hydrology may be present in watershed, for example small dams, irrigation ditches, and gravel mines. Groundwater pumping has produced noticeable changes from historic hydrologic patterns. Streambanks are altered. Disturbance is significant enough to have notable impact on species composition and soil compaction, causing significant erosion. Fire regime has been altered by fire suppression so no fires have burned in >100 years resulting in higher cover of trees and shrubs than occurred under natural conditions.

High-severity disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species may be dominant over significant portions of area, with little potential for control. Connectivity is severely hampered and severely restricts or prevents natural ecological processes from occurring, creating barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low. Moderate-severity disruption appears where occurrences have moderate cover of native grassland species (30-60% relative cover). Non-native invasive species may be widespread but potentially manageable with restoration of most natural processes. Connectivity is moderately hampered and severely restricts some natural ecological processes from occurring, creating some barriers to the natural movement of some animal and plant populations.

CES301.991 Tamaulipan Palm Grove Riparian Forest

CES301.991 CLASSIFICATION

Concept Summary: This ecological system is limited to riparian areas along the lower Rio Grande and Rio Corona in southern Texas and northeastern Mexico. Stands occur on riverbanks and floodplains. The characteristic species are the neotropical *Sabal mexicana* with *Ebenopsis ebano, Ehretia anacua, Leucaena pulverulenta*, and many other riparian species such as *Acacia farnesiana, Diospyros texana, Fraxinus berlandieriana*, or *Ulmus crassifolia*. The understory is dominated by neotropical species.

CES301.991 CONCEPTUAL MODEL

Environment: Stands of this ecological system occur on riverbanks and floodplains in riparian areas along the lower Rio Grande and Rio Corona in southern Texas and northeastern Mexico. The geologic substrate is Quaternary alluvium. It is currently found on levees and resaca margins and adjacent lower sites near the current Rio Grande channel (Elliott 2011). It was historically more widespread within the Rio Grande delta. Soils are Loamy or Clayey Bottomland Ecological Sites. This system is currently limited to relatively small groves (typically less than 20 hectares) of *Sabal mexicana* (sometimes referred to as *Sabal texana*) located on loamy or clayey bottomland soils, such as those of the Rio Grande, Zalla, and Matamoros series, on the Rio Grande Delta and near the Rio Grande itself in Cameron County, Texas, and similar sites in adjacent Mexico. These often occupy slight elevations along the margins of resacas or old river terraces, but may also occur on level sites. The system may have once occurred along the Rio Grande more than 120 km from its mouth, but is now limited to a few sites near the Gulf of Mexico, with a few small stands identified in extreme southern Hidalgo County, Texas (Elliott 2011).

Key Processes and Interactions: Fire may have been an important process in these forests as the sites may become extremely dry and a significant, if patchy, layer of palm thatch may be present. These forests appear to differ from other forests dominated by *Sabal mexicana* further to the south. Martinez-Ojeda and González-Medrano (1977) describe a site of limited distribution in the northern part of the Sierra de San José de las Rusias in the Municipio of Soto La Marina in Tamaulipas, Mexico. It occurs at higher altitudes and on Oligocene geologic formations. Their brief description suggests that this is likely different in composition and process from the presently described system. Lopez and Dirzo (2007) describe a site further south in Vera Cruz that also seems to differ relative to composition. Palm groves were once common in the lower Rio Grande Valley 80 miles from the Gulf of Mexico, but have since largely been converted to agriculture.

The major process in this system was flooding. Freezes can have significant impacts on canopy species such as *Ebenopsis, Sabal* and *Leucaena pulverulenta* in the delta. Hurricanes may not significantly affect dense ebony/anacua forest, except through flood effects. Lengthy droughts (lasting ~10 years) can influence this system, but most species are drought-tolerant. Infrequent fires may also occur (Landfire 2007a).

Threats/Stressors: This ecosystem was once common along the Rio Grande extending from the Gulf of Mexico 130 km inland but has been reduced to scatter remnants (Webster 2001). Development on both sides of the lower Rio Grande and Rio Corona in southern Texas and northeastern Mexico has eliminated much of these riparian forests (Webster 2001). Fragmentation caused by development impacts this ecosystem's habitats for wildlife.

Water development (dams and reservoirs, diversions for irrigation, municipal, and industrial use, and channelization) has significantly altered the hydrological regime. Periodic flooding is a critical factor in maintaining functioning floodplain and riparian ecosystems (Gehlbach 1981). Past alterations have impacted species (Editor 1986, as cited in Jahrsdoerfer and Leslie 1988). Pollution from development and agriculture degrade water quality with pesticides and fertilizer-laden sediments, sewage, etc. (Jahrsdoerfer and Leslie 1988).

Other human impacts have greatly converted and altered this floodplain system, including highway, bridge, and homeland security fence construction and maintenance; recreation; industrial and residential development; agriculture; irrigation; livestock grazing; and gravel mining. These areas are often subjected to heavy grazing and/or agriculture and can be heavily degraded. Non-native species, especially forage grasses such as *Bothriochloa ischaemum var. songarica, Bromus catharticus, Cynodon dactylon, Pennisetum ciliare*, and *Urochloa maxima*, are often present to dominant, and sometimes to the exclusion of most other herbaceous species (Elliot 2011).

Conversion of this type has commonly come from water developments/reservoirs, agriculture and other development such as irrigated agriculture. Common stressors and threats include altered hydrologic regime from water development, channel modifications for flood control and hydroelectric production, and urban and industrial effluent discharge. Excessive livestock grazing leads to a shift in plant species composition to more grazing- and disturbance-tolerant species, including invasive, non-native forage species.

According to Climate Wizard in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5°F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion. Potential climate change effects could also include alterations to the hydrologic regime causing reductions of flows available for natural processes and plant and animal communities, if climate change has predicted effect of less effective moisture with increasing mean temperature (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from groundwater pumping that lowers the base level, causing the stream to become a losing reach, which dries up the stream and lowers the groundwater table and/or is the result from major disturbances such development or brush removal using herbicides or mechanical treatments resulting in conversion to agriculture.

High-severity environmental degradation appears where occurrences tend to be relatively short (<0.5 mile long). Natural hydrologic regime is severely altered and is considered not restorable (system remains fundamentally compromised despite restoration of some processes). Large upstream dams and numerous water diversions may occur in watershed. Streambank may be severely altered with riprap or gravel mining in floodplain may be extensive. Fire regime has been altered by fire suppression so no fires have burned in >100 years resulting in higher cover of trees and shrubs than occurred under natural conditions. Moderate-severity environmental degradation appears where occurrences are moderate (0.5-1 mile long) in length. Natural hydrologic regime altered by upstream dams, local drainage, diking, filling, digging, or dredging. Alteration is extensive but potentially restorable over several decades. Local or moderate human-caused alteration of hydrology may be present in watershed, for example small dams, irrigation ditches, and gravel mines. Groundwater pumping has produced noticeable changes from historic hydrologic patterns. Streambanks are altered. Disturbance is significant enough to have notable impact on species composition and soil compaction, causing significant erosion. Fire regime has been altered by fire suppression so no fires have burned in >100 years resulting in higher cover of trees and shrubs than occurred under natural conditions.

High-severity disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species may be dominant over significant portions of area, with little potential for control. Connectivity is severely hampered and severely restricts or prevents natural ecological processes from occurring, creating barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low. Moderate-severity disruption appears where occurrences have moderate cover of native grassland species (30-60% relative cover). Non-native invasive species may be widespread but potentially manageable with restoration of most natural processes. Connectivity is moderately hampered and severely restricts some natural ecological processes from occurring, creating some barriers to the natural movement of some animal and plant populations.

M660. Mexican Interior Riparian Forest

CES305.279 Mexican Montane Riparian Woodland and Shrubland

CES305.279 CLASSIFICATION

Concept Summary: This riparian system is not well-documented but is likely composed of seasonally flooded woodlands and shrublands found at montane elevations throughout the Sierra Madres and was historically common throughout the Valley of Mexico. This system includes alder woodlands and shrublands that line montane streams. These are communities tolerant of periodic flooding and high water tables. At high elevations, snowmelt moisture in this system may create shallow water tables or seeps for a portion of the growing season. Stands typically occur at elevations between 2500 and 3500 m and are confined to specific riparian environments occurring on floodplains or terraces of rivers and streams, in V-shaped, narrow valleys and canyons (where there is cold-air drainage). Less frequently, occurrences are found in moderate to wide valley bottoms on large floodplains along broad, meandering rivers. The following list of species is diagnostic for this system: *Alnus glabrata, Salix bonplandiana, Fraxinus uhdei, Buddleia cordata, Schinus molle, Populus* spp.

Related Concepts:

Nations: MX

Concept Source: C. Josse

Description Author: C. Josse

CES305.279 CONCEPTUAL MODEL

Environment: These are found along a wide elevational range along moderate to low gradient streams where river scour occurs and floodplains develop.

Key Processes and Interactions: River scour exposes moist soils and supports regeneration of some riparian species. Periodic flooding and disturbance maintains a dynamic vegetative mosaic.

Threats/Stressors:

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

CES403.316 Mexican Lower Montane Riparian Woodland and Shrubland

CES403.316 CLASSIFICATION

Concept Summary: This riparian system comprises seasonally flooded woodlands and shrublands found at lower montane elevations to sea level throughout humid and subhumid portions of Mexico. These are communities tolerant of periodic flooding and high water tables. Stands typically are confined to specific riparian environments occurring on floodplains or terraces of rivers and streams in V-shaped, narrow valleys and canyons (where there is cold-air drainage). Less frequently, occurrences are found in moderate to wide valley bottoms on large floodplains along broad, meandering rivers. The following list of genera is diagnostic for this system: *Platanus, Populus, Ficus, Astianthus, Bambusa, Inga, Carya, Fraxinus, Pachira, Salix*.

1.B.3.Ng. Vancouverian Flooded & Swamp Forest

M035. Vancouverian Flooded & Swamp Forest

CES204.090 North Pacific Hardwood-Conifer Swamp

CES204.090 CLASSIFICATION

Concept Summary: This wetland ecological system occurs from southern coastal British Columbia south into coastal Washington and Oregon, west of the coastal mountain summits (not interior). Treed swamps are common in southeastern Alaska (but are placed into different systems than this one), less so farther south. Forested swamps are mostly small-patch size, occurring sporadically in glacial depressions, in river valleys, around the edges of lakes and marshes, or on slopes with seeps that form subirrigated soils. These are primarily on flat to gently sloping lowlands up to 457 m (1500 feet) elevation but also occur up to near the lower limits of continuous forest (below the subalpine parkland). It can occur on steeper slopes where soils are shallow over unfractured bedrock. This system is indicative of poorly drained, mucky areas, and areas are often a mosaic of moving water and stagnant water. Soils can be woody peat, muck, or mineral. It can be dominated by any one or a number of conifer and hardwood species (*Tsuga heterophylla, Picea sitchensis, Tsuga mertensiana, Callitropsis nootkatensis, Pinus contorta var. contorta, Alnus rubra, Fraxinus latifolia, Betula papyrifera*) that are capable of growing on saturated or seasonally flooded soils. Overstory is often less than 50% cover, but shrub understory can have high cover. In the southern end of the range of this type, e.g., the Willamette Valley, tends to have more hardwood-dominated stands (especially *Fraxinus latifolia*) and very little in the way of conifer-dominated stands. While the typical landscape context for the type is extensive upland forests, for the *Fraxinus latifolia* stands, landscapes were very often formerly

dominated by prairies and now by agriculture. Many conifer-dominated stands have been converted to dominance by *Alnus rubra* due to timber harvest.

CES204.875 North Pacific Intertidal Freshwater Wetland

CES204.875 CLASSIFICATION

Concept Summary: This ecological system occurs throughout the coastal margin and intertidal zone of the Pacific Northwest Coast of Oregon, Washington and north into British Columbia. It may occur in Alaska, but has not been described from there. Intertidal freshwater wetlands occur as narrow strips to more extensive patches along tidally influenced portions of rivers. There has been little vegetation data collection of this type in this region; a few studies indicate dominant species include *Picea sitchensis, Alnus rubra, Cornus sericea, Myriophyllum hippuroides, Typha angustifolia, Athyrium filix-femina*, and *Carex lyngbyei*. This system is driven by daily tidal flooding of freshwater and associated soil saturation. Vegetation structure and composition are varied and depend on substrate characteristics and the tidal flooding regime of particular sites. Where small areas of mudflat occur in tidally influenced

freshwater areas, they are included in this intertidal freshwater wetland and not in ~Temperate Pacific Freshwater Mudflat (CES200.878)$$.

CES204.869 North Pacific Lowland Riparian Forest and Shrubland

CES204.869 CLASSIFICATION

Concept Summary: Lowland riparian systems occur throughout the Pacific Northwest. They are the low-elevation, alluvial floodplains that are confined by valleys and inlets and are more abundant in the central and southern portions of the Pacific Northwest Coast. These forests and tall shrublands are linear in character, occurring on floodplains or lower terraces of rivers and streams. Major broadleaf dominant species are *Acer macrophyllum, Alnus rubra, Populus balsamifera ssp. trichocarpa, Salix sitchensis, Salix lucida ssp. lasiandra, Cornus sericea*, and *Fraxinus latifolia*. Conifers tend to increase with succession in the absence of major disturbance. Conifer-dominated types are relatively uncommon and not well-described; *Abies grandis, Picea sitchensis*, and *Thuja plicata* are important. Riverine flooding and the succession that occurs after major flooding events are the major natural processes that drive this system. Very early-successional stages can be sparsely vegetated or dominated by herbaceous vegetation.

Description Author: G. Kittel and C. Chappell

CES204.869 CONCEPTUAL MODEL

Environment: Stands occur on low-elevation, alluvial floodplains on alluvial soils in valleys and inlets, on riverbanks, outer floodplains or low terraces of rivers and streams.
Key Processes and Interactions: Beaver activity is an important driver of hydrological change and subsequent development of a diversity of habitat patches. The contribution of large woody debris (LWD) from riparian or adjacent upland trees is important to maintaining the hydrological and sediment regimes. LWD has a significant impact on the evolution of channel morphology and also contributes to the spatial distribution and diversity of habitat patches within this system (Naiman and Bilby 1998). Major flood events and consequent flood scour, overbank deposition of water and sediments, and stream meandering are the key fluvial

processes that provide new substrates, remove old banks and stimulate renewed growth of cottonwood and willow species (Sawyer et al. 2009). Natural fire-return interval was long or moderate with low-intensity surface fires.

Threats/Stressors: Conversion of this type has commonly come from agricultural conversion and development of urban areas, loss of the floodplain through levee development, and complete inundation by creation of reservoirs. The greatest threat is the change to the natural hydrologic cycle through dams and water management and use. Other threats are more from direct impact and use. Reservoirs, water diversions, ditches, roads, and human land uses in the contributing watershed can have a substantial impact on the hydrologic and sediment regimes. Alterations to both processes can affect the establishment of new and maintenance of existing riparian vegetation. Management effects on woody riparian vegetation can be obvious, e.g., removal of vegetation by dam construction, roads, logging, or they can be subtle, e.g., removing beavers from a watershed, removing large woody debris, or construction of a weir dam for fish habitat. Logging activities tend to reduce the amounts of large woody debris in streams and remove future sources of that debris. Timber harvest can also alter hydrology, most often resulting in post-harvest increases in peak flows. Mass wasting and related disturbances (stream sedimentation, debris torrents) in steep topography increase in frequency with road building and timber harvest. Roads and other water diversion/retention structures change watershed hydrology with wide-ranging and diverse effects, including major vegetation changes. The most significant of these are the major flood controlling dams, which have greatly altered the frequency and intensity of bottomland flooding. Increases in nutrients and pollutants are other common anthropogenic impacts. *Phalaris arundinacea* is an abundant non-native species in low-elevation, disturbed settings dominated by shrubs or deciduous trees. Many other exotic species also occur. This system has also decreased in extent due to agricultural development, roads, dams and other flood-control activities (WNHP 2011).

In the Pacific Northwest Regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation, averaged over all models, are small (+1 to +2%), but some models project wetter autumns and winters and drier summers. Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models (Littell et al. 2009). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. This change will result in: less winter snow accumulation, higher winter streamflows, earlier spring snowmelt, earlier peak spring streamflow and lower summer streamflows in rivers that depend on snowmelt (most rivers in the Pacific Northwest) (Littell et al. 2009).

Potential climate change effects could include: further reduction in summer flows (Littell et al. 2009); earlier high flow pluses may negatively affect cottonwood species dominance as their seed production is timed for June-July (Boes and Strauss 1994, Merritt and Wohl 2002), so cottonwood-dominated streams may shift to other deciduous trees; however, regional climate model simulations generally predict increases in extreme high precipitation over the next half-century, particularly around Puget Sound (Littell et al. 2009); drop in groundwater table; and increased fire frequency due to warmer temperatures resulting in drier fuels the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from complete removal of flooding and streambanks covered in cobble or cement, entire reach is sent through an underground ditch or canal under city streets. Riparian area is converted to agricultural use (commonly hay meadow), or road embankment. Environmental Degradation (from WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Lack of flooding and ability for stream to meander, create sandbars and point bars and erode riverbanks, channel is straightened. Any of these conditions or combination of conditions rates as moderate-severity: Flooding does occur in a minimal way, large floods due occur but infrequently, channel does meander slightly. Channel retains some sinuosity. Disruption of Biotic Processes (from WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Woody vegetation removed and is not reproducing, herbaceous cover is replaced by non-native species. Any of these conditions or combination of conditions rates as moderate-severity: Woody vegetation is present, at least asexual reproduction occurs, non-natives may be present and abundant but natives still form at least 25-50% of the relative canopy cover.

CES204.866 North Pacific Montane Riparian Woodland and Shrubland

CES204.866 CLASSIFICATION

Concept Summary: This ecological system occurs throughout mountainous areas of the Pacific Northwest coast, both on the mainland and on larger islands. It occurs on steep streams and narrow floodplains above foothills but below the alpine environments, e.g., above 1500 m (4550 feet) elevation in the Klamath Mountains and western Cascades of Oregon, up as high as 3300 m (10,000 feet) in the southern Cascades, and above 610 m (2000 feet) in northern Washington. Surrounding habitats include subalpine parklands and montane forests. In Washington, they are defined as occurring primarily above the *Tsuga heterophylla* zone, i.e., beginning at or near the lower boundary of the *Abies amabilis* zone. Dominant species include *Pinus contorta var. murrayana, Populus balsamifera ssp. trichocarpa, Abies lowiana, Abies magnifica, Populus tremuloides, Alnus incana ssp. tenuifolia, Alnus viridis ssp. crispa, Alnus viridis ssp. sinuata, Alnus rubra, Rubus spectabilis, Ribes bracteosum, Oplopanax horridus, Acer circinatum*, and several *Salix* species. In western Washington, major species are *Alnus viridis ssp. sinuata, Acer circinatum, Salix, Oplopanax horridus, Alnus rubra, Petasites frigidus, Rubus spectabilis*, and *Ribes bracteosum*. This is a disturbance-driven system that requires flooding, scour and deposition for germination and maintenance. It occurs on streambanks where the vegetation is significantly different than surrounding forests, usually because of its shrubby or deciduous character.

1.B.4.Na. North American Boreal Forest & Woodland

M496. West-Central North American Boreal Forest

CES105.800 Montane Boreal White and Black Spruce Forest

CES105.800 CLASSIFICATION

Concept Summary: This ecological system is more common north and west of the Northern Rockies, and is truly a boreal forest type; it is considered only peripheral to the Rocky Mountain Division. The montane *Picea glauca* and *Picea mariana* forests in the Northern Rockies represent the southernmost extent of these expansive boreal forests. The southern limit appears to be related to July mean temperatures exceeding 65°F and maximum of 75°F, and where annual precipitation drops below 38-50 cm (15-20 inches). *Picea glauca* associations found in Banff, Jasper, Kootenay and Yoho national parks occur on gentle to moderate slopes and are generally very mature stands. Canopy ranges from closed to open forests, usually with a shrub understory, although some stands have only an herbaceous carpet. Other tree species that may be codominant in the upper canopy include *Picea mariana, Picea engelmannii x glauca, Pseudotsuga menziesii, Abies lasiocarpa*, and *Larix occidentalis*. Undergrowth components include *Rosa acicularis, Dasiphora fruticosa ssp. floribunda, Shepherdia canadensis, Menziesia ferruginea*, and *Cornus canadensis*. Herbaceous species include *Equisetum arvense* and *Triglochin maritima* and the bryophytes *Abietinella abietina (= Thuidium abietinum)* and *Hylocomium splendens*.

1.B.5.Na. North American Boreal Flooded & Swamp Forest

M299. North American Boreal Conifer Poor Swamp

CES103.724 Boreal-Laurentian Conifer Acidic Swamp and Treed Poor Fen

CES103.724 CLASSIFICATION

Concept Summary: This ecological system extends across the boreal regions of central and western Canada, and east and south into northern New England and the Great Lakes region. The system is primarily weakly to moderately minerotrophic (poor fen), though some stands may approach ombrotrophic (bog) conditions. Decomposition is so slow that fibrous or woody peat accumulates, and the water is slightly to very acidic and nutrient-poor (also called mesotrophic). Acidic (also called poor or transitional) fens have organic soils and are dominated by aquatics, emergents, and dwarf-shrubs, or raised peat dominated by shrubs and trees. Groundwater, the primary water source, is nutrient-rich due to its contact with mineral soils, however, acidic fens have less contact with nutrient-rich waters, as the amount of peat has accumulated to raise the level of the fen, but it remains in contact with groundwater (hence "transitional" on its way to becoming a bog). The water is acidic, with a pH generally between 4.0 and 5.8. This is a forested peatland where the trees form partial to full cover over most or all of the peatland. Stunted to well-developed *Picea mariana* and *Larix laricina* are the dominant trees. Heaths and sedges are common in the understory, but the dwarf-shrub layer is less well-developed than in open acidic peatlands, though it may be prominent in more open parts of the system. *Chamaedaphne calyculata, Kalmia polifolia, Ledum groenlandicum, Vaccinium macrocarpon (= Oxycoccus macrocarpus), Vaccinium vitis-idaea*, and *Salix* spp. are the dominant dwarf-shrubs. Other fen indicators also occur, such as *Betula glandulosa* or *Betula pumila*. Other poor fens are graminoid-dominated with herbaceous indicators such as *Drosera* spp., *Equisetum fluviatile, Maianthemum trifolium, Sarracenia purpurea*, and sedges (*Carex* spp.)

2.A.1.Ea. Caribbean-Mesoamerican Lowland Grassland, Savanna & Shrubland

M671. Caribbean Dry Scrub

CES411.422 Caribbean Coastal Thornscrub

CES411.422 CLASSIFICATION

Concept Summary: This system occurs either on sandy or rocky substrates, along the Caribbean coasts, or higher in areas of low rainfall. Few species of thorny trees and shrubs form an open canopy with a maximum height of 5 m, and the herb (mainly grasses) layer is conspicuous. Vegetation cover by annual plants varies due to large quantitative and seasonal rain fluctuations. Cacti are codominant; columnar and tree-shaped cacti are common. Microphyllous shrubs, small succulent trees, plants in rosettes (such as agaves and terrestrial bromeliads) or evergreen and semi-deciduous shrubs can also be present. In Puerto Rico, the cactus scrub is associated with limestone pavements. In the Bahamas, this type occurs on limestone pavements with sinkholes and "dogtooth" terrain above the water table. In many areas, this vegetation has an open aspect. The following list of species is diagnostic for this system: *Erithalis fruticosa, Plumeria alba, Stenocereus fimbriatus (= Stenocereus hystrix, = Ritterocereus hystrix), Stenocereus griseus (= Ritterocereus griseus, = Ritterocereus deficiens), Opuntia dillenii, Opuntia militaris, Cylindropuntia hystrix, Rhodocactus cubensis, Consolea macracantha, Dendrocereus nudiflorus, Pilosocereus brooksianus, Agave albescens, Agave missionum, Melocactus acunae, Caesalpinia* spp., *Capparis* spp., *Guaiacum officinale, Jacquinia armillaris (= Jacquinia arborea), Gochnatia, Cordia* spp., *Guettarda, Lantana involucrata, Cercidium* sp., and *Bourreria* cumanensis. In Puerto Rico, the Lesser Antilles, and Bahamas, the following species are typical: *Melocactus intortus, Pilosocereus royenii, Stenocereus fimbriatus, Oplonia spinosa, Croton flavens, Eugenia xerophytica, Calliandra purpurea, Comocladia dodonaea, Chrysobalanus icaco, Tabebuia bahamensis, Psidium longipes, Stigmaphyllon sagraeanum, Manilkara jaimiqui ssp. emarginata (= Manilkara bahamensis)*, and *Coccoloba* spp.

Related Concepts:

Distribution: This system is found in the Florida Keys, Puerto Rico, Virgin Islands, and most of the islands of the Greater Antilles and the Lesser Antilles.

Nations: BS, CU, DO, HT, JM, PR, TT, US, VI, XC, XD

Concept Source: C. Josse

Description Author: C. Josse

CES411.422 CONCEPTUAL MODEL

Environment: This system occurs in areas of rainshadows created by mountains in areas of extreme temperatures. Xeric areas generally have low and highly seasonal precipitation with a range of 800-1000 mm annual precipitation, with great inter-annual variation. The rainy season goes from May through November. The driest months are February and March. Common coastal substrates have poor, shallow soils and typically are limestones terraces, dogtooth limestone, or sandy soils. Overall temperature averages at sea level are mostly in the range 25-27°C. Annual precipitation ranges from 600 to 1500 mm for the distribution range of

this macrogroup. The dry season is usually limited to one period that can last for 2-6 months, or divided into two periods together lasting up to 8 months. The main dry period is usually between January and April; there may be a second dry period in more southerly latitudes in July to September. The limestone substrate has low water-retention capacity, and rainfall leaches easily after accumulating in cracks and crevices of variable depth. Other substrates where communities of this macrogroup develop also exhibit actual drought during periods of low rainfall and physiological drought due to impeded drainage and waterlogging during periods of high rainfall.
Key Processes and Interactions:
Threats/Stressors:
Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra. Quedan pocos remanentes, principalmente convertido en pastos.

Ecological collapse tends to occur from direct land conversion. Few remnants exist for understanding the factors (beyond conversion) causing collapse.

CES411.423 Caribbean Dry Karst Shrubland

CES411.423 CLASSIFICATION

Concept Summary: This system occurs on bare rock of limestone terraces and on lowland karstic "dogtooth" terrain. Very dense, 2- to 3-m high shrubland with emergent individual trees or groups of trees. Columnar or tree-shaped cacti may occur but are never dominant. The Cuban scrub on limestone substrate is dominated by the shrubs *Auerodendron cubense, Cordia leucosebestena, Picrodendron macrocarpum, Eugenia cowellii, Polygala guantanamana, Coccothrinax munizii, Jacquinia berteroi , Randia spinifex*, and cacti *Consolea macracantha, Dendrocereus nudiflorus, Pilosocereus brooksianus, Harrisia fernowii, Melocactus acunae*, and *Agave albescens* (Huggins et al. 2007), while this type in Puerto Rico features the endemic *Harrisia portoricensis* and shrubs *Croton discolor, Croton betulinus, Erithalis fruticosa, Plumeria obtusa, Reynosia uncinata* (Rojas-Sandoval and Meléndez-Ackerman 2012, Medina et al. 2014). In the Lesser Antilles typical species of the mixed cactus scrub on limestone pavement include *Pilosocereus royenii, Agave karatto, Pisonia subcordata, Pisonia aculeata, Capparis indica, Capparis cynophallophora, Leucaena leucocephala, Pithecellobium unguis-cati, Haematoxylum campechianum* and *Clerodendrum aculeatum* (Areces-Mallea et al. 1999). In the Bahamas, when the limestone pavement community occurs right above the water table and there is more moisture available, characteristic species include *Pithecellobium bahamense, Guettarda scabra, Tabebuia bahamensis, Bursera simaruba, Psidium longipes, Coccoloba northropiae, Coccoloba tenuifolia, Sideroxylon americanum (= Bumelia americana), Stigmaphyllon sagraeanum, Manilkara jaimiqui ssp. emarginata (= Manilkara bahamensis), Cephalocereus* sp., *Randia aculeata* and *Cladium mariscus ssp. jamaicense* (Areces-Mallea et al. 1999).

CES411.423 CONCEPTUAL MODEL

Environment: [from M671] Overall temperature averages at sea level are mostly in the range 25-27°C. Annual precipitation ranges from 600 to 1500 mm for the distribution range of this macrogroup. The dry season is usually limited to one period that can last for 2-6 months, or divided into two periods together lasting up to 8 months. The main dry period is usually between January and April; there may be a second dry period in more southerly latitudes in July to September. The limestone substrate has low water-retention capacity, and rainfall leaches easily after accumulating in cracks and crevices of variable depth. Other substrates where communities of this macrogroup develop also exhibit actual drought during periods of low rainfall and physiological drought due to impeded drainage and waterlogging during periods of high rainfall.

Key Processes and Interactions: Droughts and hurricanes are the main drivers of the natural dynamics of this system. Low rainfall intensities of 76 mm/d have a recurrence interval of 1 year while high rainfall intensities of >305 mm/d are possible during hurricane conditions or when low-pressure systems become stationary. These events have a recurrence interval of 100 years (Gómez Gómez 1984). Forests and other natural ecosystems of the limestone region recover quickly from hurricanes and storms (Wadsworth and Englerth 1959, cited in Lugo et al. 2001). Moreover, these events transport vast amounts of freshwater to the island and trigger many ecologically beneficial functions such as the reproduction of karst forest plants and animals, and the maintenance of the hydrologic cycle of the karst area.

Threats/Stressors: This shrubland ecosystem may have been impacted either by conversion to urban areas, to some agricultural use, or by harvesting of wood for lumber, fenceposts, firewood and charcoal, as well as by grazing in the understory (Murphy and Lugo 1995). More recently in the Caribbean, significant impact has occurred due to land-use change from historically extensive (selective logging, grazing) to currently intensive (resorts, second homes, and energy development) (Franklin and Steadman 2013 and references therein).

Ecosystem Collapse Thresholds: In spite of changes in composition and structure these shrublands can recover from past agricultural land uses or wood removal. However, given the dependencies of the vegetation on very limited sources of moisture and substrate gradients, the mining of limestone deposits and the transformation of the hydrologic cycle due to human interventions would cause the collapse of this system.

CES411.464 Caribbean Serpentine Dry Scrub

CES411.464 CLASSIFICATION

Concept Summary: This system occurs in gently rolling flatlands or hills up to 450 m elevation. Despite the great variation in substrate, climate, and species composition, the physiognomy of the serpentine scrub is very constant throughout its distribution. It occurs on ferrallitic soils, which are derived from serpentine in isolated locations in the case of Cuba's Cajalbana hills and Holguin area. Examples are dominated by stands of dense, thorny 2- to 4-m high shrubland with emergent palms and evergreen microphyllous trees. The proportion of microphylls and spiny elements is very high, with the exception of cacti which are not common in this type of vegetation. Stands of serpentine scrubs that alternate with small grassy clearings also occur, except for the more humid, higher elevation communities which are dominated by microphylls and do not present grassy clearings. These often develop into dwarf-grass savannas after grazing or human interference. The following list of species is diagnostic for this system:

Neobracea valenzuelana, Phyllanthus orbicularis, Phyllanthus comosus, Annona bullata, Pilosocereus royenii, Thouinia striata var. portoricensis, Rondeletia camarioca, Zanthoxylum dumosum, Passiflora cubensis, Ipomoea cordatotriloba (= Ipomoea carolina), Tabebuia lepidota, Coccothrinax fragrans, Copernicia spp., *Coccothrinax* spp., *Jacaranda cowellii, Jacquinia shaferi, Myrtus cabanesensis, Hemithrinax savannarum, Hemithrinax rivularis, Acrosynanthus minor, Tabebuia linearis, Antirhea abbreviata, Antirhea orbicularis, Exostema purpureum, Spirotecoma apiculata, Byrsonima bucheri, Sideroxylon cubense (= Dipholis cubensis), Coccoloba* spp., *Paepalanthus brittonii*, and many other very restricted endemics.
Related Concepts:
Distribution: This system is found in Cuba and Puerto Rico.
Nations: CU, PR
Concept Source: C. Josse
Description Author: C. Josse

CES411.464 CONCEPTUAL MODEL

Environment: Ferrallitic soils on isolated sites occurring on the coastal zone and up to lower montane places. Annual precipitation ranges from 1000-1900 mm, with one or two dry seasons annually. Due to the plant physiology imposed by the limiting factors of soils derived from serpentines, these communities represent a drier degree than a community living in the same climatic conditions but on non-serpentine rock. Adaptations include xeromorphism or pseudo-xeromorphism, reduced productivity, reduced structure, and advantage of sclerophyllous evergreen shrubs over deciduous trees/shrubs.
Key Processes and Interactions:
Threats/Stressors:
Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra. Quedan pocos remanentes, principalmente convertido en pastos.

Ecological collapse tends to occur from direct land conversion. Few remnants exist for understanding the factors (beyond conversion) causing collapse.

M672. Northern Mesoamerican Pine Savanna

CES402.590 Meso-American Pine Savanna

CES402.590 CLASSIFICATION

Concept Summary: Este sistema representa las sabanas arboladas donde *Pinus caribaea* es la especie distintiva aunque se presenta dispersa y mezclada con otras especies arbustivas y arbóreas. Ocurre en la planicie costera del Caribe de Belice, Honduras y Nicaragua. Esta sabana es del tipo estacional, es decir con deficiencia hídrica durante la estación seca, pero con anegamiento durante la estación lluviosa sobre todo en las partes bajas del terreno. Los suelos son genralmente pobres y ácidos, arcillosos a arcilloso-arenosos. El sistema está sujeto a quemas y a tala selectiva. La siguiente lista de especies es diagnóstica para este sistema: *Axonopus aureus, Fimbristylis paradoxa, Declieuxia fruticosa, Rhynchospora* spp., *Thrasya trinitensis, Thrasya mosquitensis, Blechnum serrulatum, Acoelorraphe wrightii, Orbignya cohune, Pinus caribaea, Pinus tecunumanii, Quercus oleoides, Byrsonima crassifolia, Calliandra houstoniana, Xilopia frutescens, Myrica cerífera, Miconia* spp., *Ilex guianensis*.

CES402.590 CONCEPTUAL MODEL

Environment: Relieve plano a ligeramente ondulado de la planicie costera o en cerros hasta los 600-700 msnm (Mountain Pine Forest of western Belize). Suelos de los tipos ultisoles ácidos e inceptisoles, pueden ser higromórficos y generalmente son pobres, en sectores se presentan bancos de grava cuarzosa. La profundidad de la capa laterítica impermeable es variable y sobre ella ocurren

suelos arenosos o arcilloso-arenosos. Clima tropical húmedo. Totalmente de clima estacional con una marcada estación seca, entre febrero y junio. La temperatura varía entre 16°C y 32°C con una precipitación anual de alrededor de 1.500 mm. Suelos de textura gruesa que son típicos de los climas extremadamente estacionales con alguna evidencia de la inundación prolongada durante los períodos húmedos y estaciones secas afectadas por la quema.
Key Processes and Interactions: Una de las amenazas principales que se ha detectado es los ataques de insectos (*Dendroctonus* spp. e Ips spp.) a los árboles de pino, causando la mortalidad de 60% o mas de los individuos. También son sabanas sujetas a quemas para la producción de pastos, tala y cacería de fauna para subsistencia (Hicks et al. 2011).
Threats/Stressors: Sabana sujeta a quemas y tala.
Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.
Ecological collapse tends to occur from direct land conversion.

Description Author:

CES402.621 CONCEPTUAL MODEL

Environment: [de M672] Sarmiento (1983) reconoce tres tipos de sabanas neotropicales: (1) Sabana Semiestacional que se produce en un clima más húmedo, con una o dos temporadas cortas secas e incendios menos frecuentes (algunas de las sabanas amazónicas y de Guayana), (2) Sabana Estacional se caracteriza por una estación seca severa y los frecuentes incendios (por ejemplo, el Cerrado y los Llanos), (3) Sabana Hyperestacional que es el resultado de la sequía y los incendios excesivos durante la temporada seca y grandes inundaciones durante la estación lluviosa. Este tipo sabana es común en las tierras bajas de mal drenaje del Pantanal, Llanos de Moxos, las sabanas de Roraima-Rupununi, y parte de los Llanos. Rodales de palmeras se encuentran a menudo en las zonas anegadas.

El sistema de la sabana es generalmente heterogéneo, consiste en un mosaico de pastizales puros, parches de árboles o arbustos, bosques secos o semideciduos, bosques de galería y en ocasiones, los humedales. La distribución de las distintas comunidades en un paisaje de sabana a menudo sigue gradientes edáficos (por ejemplo, los tipos de suelo o niveles de la capa freática) (Daly y Mitchell 2000).

Al igual que otras sabanas tropicales, la sabana de pino es un ecosistema estructuralmente simple pero espacialmente irregular. Se caracteriza por una capa de plantas herbáceas -principalmente C 4, pastos y juncos, y herbáceas C3 - con diversos grados de arbustos y / o árboles, es decir, un continuo que va desde pastizales sin árboles hasta parches de bosques densos. Las sabanas se dan en climas cálidos con precipitaciones que varían entre (750) 1.000 mm y 2.000 (-2.500) mm y un período seco de uno a seis meses, ocupan una zona de transición entre el bosque húmedo y la vegetación xerófila. La distribución de las precipitaciones es un factor determinante de los tipos de vegetación de sabana (por ejemplo, pastizales o bosques). La sabana tropical generalmente se desarrolla en suelos deficientes en nutrientes, ácidos con la toxicidad del aluminio y con alteración pronunciada de condiciones húmedas y secas (Fry 1983).

La relación / tallo alto raíz en los ecosistemas de sabana, especialmente en el estrato herbáceo, es una característica que proporciona resistencia al estrés y la perturbación causados por la sequía, el fuego y la herbivoría. Se cree que las sabanas tropicales se han desarrollado bajo factores de perturbación como el fuego, la herbivoría y sequía. La persistencia de las sabanas puede depender de que la perturbación de preservar la estabilización de los componentes y propiedades (Coupland 1992c, Baruch et al. 1996, Silva 1996).

[from M672] Sarmiento (1983) recognizes three types of Neotropical savannas: (1) Semiseasonal savanna which occurs in a rather humid climate with one or two short dry seasons and less frequent fires (some of the Amazonian and Guianan savannas), (2) Seasonal savanna characterized by a severe dry season and frequent fires (e.g., the Cerrado and the Llanos), (3) Hyperseasonal savanna which is the result of excessive drought and fires during dry season and severe flooding during the wet season. This savanna type is common in the poorly drained bottomlands of the Pantanal, Llanos de Moxos, the Roraima-Rupununi savannas, and part of Llanos. Palm stands are often found in water-logged areas.

The savanna system is usually heterogeneous, consisting of a mosaic of pure grasslands, patches of trees or shrubs, dry or semi-deciduous forests, gallery forests, and sometimes wetlands. The distribution of various communities in a savanna landscape often follows edaphic gradients (e.g., soil types or levels of water table) (Daly and Mitchell 2000). Like other tropical savannas, pine savanna is structurally simple but spatially patchy ecosystem. It is characterized by a layer of herbaceous plants- mainly C 4 grasses and sedges, and C3 forbs- with varying degrees of shrubs and/or trees, that is, a continuum from treeless grassland to dense woodland.

Savannas occur in hot climates with rainfall varying between (750-) ,000 mm and 2000 (-2500) mm and a dry period of one to six months, forming a transition zone between moist forest and xerophytic vegetation. Rainfall distribution is a major determinant of the savanna vegetation types (e.g., grassland or woodland). Tropical savanna usually develops on nutrient deficient, acidic soils with aluminum toxicity and pronounced alteration of wet and dry conditions (Fry 1983).

The high root/shoot ratio in savanna ecosystems, especially within the herbaceous layer, is a feature that provides resistance to stress and disturbance from drought, fire, and herbivory. It is believed that tropical savannas have developed under disturbance factors like fire, herbivory and drought. Persistence of savannas may depend on such disturbance to preserve stabilizing components and properties (Coupland 1992, Baruch et al. 1996, Silva 1996).

Key Processes and Interactions: [de M672] Intervalo de incendios: la frecuencia de incendios deben estar dentro de un rango esperado para el tipo (por ejemplo, 5 a 20 años); incendios demasiado frecuentes dan como resultado la pérdida de la diversidad nativa y la supresión de resulta en una densa invasión de especies leñosas (y la pérdida de especies nativas).

La sequía y el régimen de crecidas: Donde están inundadas las sabanas de pino, en general también hay una estación seca de 3-9 meses. La densidad de arboles y arbustos tiende a ser mayor cuando la la inundación es más profunda. La distribución de clases de edad de los pinos forma una curva de J invertida que refleja una amplia gama de diámetros resultantes de perturbaciones periódicas y regeneración exitosa.

[from M672] Fire Return Interval: fire frequency should fall within an expected range for the type (e.g., 5-20 years); too frequent fires result in loss of native diversity and fire suppression results in dense woody species encroachment (and loss of native species).

Drought and Flood Regime: Where pine savannas are inundated, there is generally a 3-9 month dry season. Tree and shrub density tends to be higher with deeper inundation. Age class distribution of pine trees forms an inverted J curve reflecting a full range of diameters resulting from periodic disturbance and successful regeneration.

Threats/Stressors: [de M672] La sobreexplotación y el exceso de pastoreo tienen efectos más directos en la composición biótica de sabanas de pino.
<br /[from M672] >Overharvest and overgrazing have most direct effects on biotic composition of pine savannas.

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.

Ecological collapse tends to occur from direct land conversion.

M691. Mesoamerican Montane Grassland & Shrubland

CES402.610 Talamancan Upper Montane Meadow

CES402.610 CLASSIFICATION

Concept Summary: Este sistema es muy similar al de los páramos andinos, aunque la dominancia de otras especies y en algunos casos, formas de vida diferentes de los pajonales, lo convierten en un sistema distinto. En este caso las herbáceas también son dominantes y entre ellas, una forma bambusoidea del género *Chusquea*. Estos pajonales y herbazales se saturan estacionalmente, especialmente en las partes deprimidas del terreno. La siguiente lista de especies es diagnóstica para este sistema: *Aciachne pulvinata, Lorenzochloa rectifolia, Chusquea subtessellata, Cortaderia apalotricha, Myrrhidendron donnell-smithii, Rumex costaricensis, Calamagrostis, Carex, Azorella, Alchemilla, Acaena, Castilleja, Centropogon, Coriaria, Vaccinium, Cavendishia, Senecio, Diplostephium, Monnina, Miconia, Relbunium, Arcytophyllum, Pentacalia, Hypericum*.

This system is very similar to the Andean páramos, although the dominance of other species and in some cases, different lifeforms, make it a different system. In this case the forbs are also dominant and among them, the bambu-like genus *Chusquea*. This steppe and grassland is seasonally saturated, particularly in low areas. The above list of species is diagnostic for this system.

Related Concepts:

Nations: CR, PA

Concept Source: C. Josse

Description Author: C. Josse

CES402.610 CONCEPTUAL MODEL

Environment: Ocurren sobre suelos inceptisoles y andosoles, en ocasiones sobre histosoles, estacionalmente pueden saturarse, así como también sufrir déficit hídrico. Las pendientes son moderadas y el drenaje es lento.

Occurs on Inceptisols and Andisols, sometimes on Histosols where seasonally it can be saturated and alternatively, experience drought. Slopes are moderate and drainage is generally slow.

Key Processes and Interactions: Frío, la formación de nubes, el viento y la precipitación pesada apoyo developmnet de este ecosistema alpino. El fuego es aparentamente un factor importante en su mantenimiento (League y Horn 2000)

Cold temperature, cloud formation, wind, and heavy precipitation support developmnet of this alpine ecosystem. Fire is apparently an important factor in its maintenance (League and Horn 2000).

Threats/Stressors: El papel relativo del uso humano del fuego en los sitios de Centroamérica es limitado, pero aparentemente hay una larga historia de incendios naturales que ocurren en este sistema. La conversión a la agricultura es limitada, y las cantidades relativamente limitadas de ocurrencias de este sistema han sido en gran parte inalteradas excepto donde se estableció la infraestructura vial (por ejemplo, el sur de Costa Rica, carretera interamericana).

The relative role of human use of fire in Central American sites is limited, but there is apparently an extensive history of natural fire occurring in this system. Conversion for agriculture is limited, but past grazing might have been more common. The relatively limited numbers of examples have been largely undisturbed except where road infrastructure was established (e.g., southern Costa Rica, Inter-American highway).

Ecosystem Collapse Thresholds: Aparte de conversion completa, el pastoreo intensivo y la extinción de incendios naturales podría provocar un cambio importante en la composición de especies. Alteración hidrológica es posible en áreas bajas donde se acumula el agua.

Short of complete conversion, intensive grazing and or fire suppression could result in turnover in species composition. Hydrologic alteration is possible in low areas where water accumulates.

CES305.284 Madrean-Transvolcanic Zacatonal

CES305.284 CLASSIFICATION

Concept Summary: These are high-elevation meadows found primarily along volcanic slopes around the Valley of Mexico. They are dominated by herbaceous species found on wetter sites with very low-velocity surface and subsurface flows. They range in elevation from upper montane to alpine (3000-3300 m). Sites typically are small depressions and flats with deep, poorly drained soils of sandy loam (pH 5.0-6.2) surrounding volcanic craters. This system often occurs as a mosaic of several plant associations, often dominated by graminoids. Often alpine dwarf-shrublands are immediately adjacent to these praderas. These systems are typically not subjected to high disturbance events such as flooding. The following list of species is diagnostic for this system: *Potentilla candicans, Stipa ichu, Astragalus micranthus, Reseda luteola, Bidens triplinervia, Hedeoma piperitum, Vulpia myuros, Gnaphalium seemannii, Salvia* spp.
Related Concepts:
Nations: GT, MX
Concept Source: C. Josse
Description Author: C. Josse

CES305.284 CONCEPTUAL MODEL

Environment: Sites typically are small depressions and flats with deep, poorly drained soils of sandy loam (pH5.0-6.2) surrounding volcanic craders.
Key Processes and Interactions: River scour exposes moist soils and supports regeneration of some riparian species. Periodic flooding and disturbance maintains a dynamic vegetative mosaic.
Threats/Stressors:
Ecosystem Collapse Thresholds:

CES402.601 Petén Littoral Karstic Hills

CES402.601 CLASSIFICATION

Concept Summary: El sistema representa las comunidades casmófitas que se desarrollan en afloramientos cársticos en la costa Caribe y reciben la brisa marina. La vegetación es dispersa y esclerófila y está compuesta de hierbas y arbustos bajos. La siguiente lista de las especies es de diagnóstica para este sistema: *Coccoloba uvifera, Dactyloctenium aegyptium, Gomphrena* spp., *Jacquinia armillaris (= Jacquinia arborea), Phyla nodiflora (= Lippia nodiflora), Neea psychotrioides, Pancratium littorale, Sesuvium portulacastrum, Stachytarpheta jamaicensis, Tridax procumbens*.
Related Concepts:
Nations: BZ
Concept Source: C. Josse
Description Author: C. Josse

CES402.601 CONCEPTUAL MODEL

Environment: Relieve colinado, sustrato rocoso bien drenado, influencia de brisa marina.
Key Processes and Interactions: Dinámico

Threats/Stressors: [from M700] Conversion to urban and tourism uses. Invasion by exotics following disturbance is an ongoing threat to this community.

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.
Ecological collapse tends to occur from direct land conversion.

CES411.271 South Florida Shell Hash Beach

CES411.271 CLASSIFICATION

Concept Summary: This system represents carbonate sand beaches of the Florida Keys and south Florida mangrove islands (after Johnson and Barbour 1990). The vegetation is poorly known but apparently includes at least one endemic species, *Chamaesyce garberi*. Other diagnostic species may include *Piscidia piscipula* and *Pithecellobium keyense*.

Related Concepts:

Distribution: The range of this system includes Cape Sable (the southernmost point of mainland Florida), Ten Thousand Islands (Collier County), Florida Keys, and islands in Biscayne Bay (near Miami).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans

CES411.272 Southeast Florida Beach

CES411.272 CLASSIFICATION

Concept Summary: This beach ecological system is the southernmost of its kind along the mainland coast of North America. Its southerly location distinguishes it from other types along the Atlantic Coast, primarily due to the prevalence of the tropical flora it supports. This type is related to ~Southwest Florida Beach (CES411.276)$$ but is affected directly by much higher wave energy from the Atlantic. This region has some of the highest wave energy along the entire Atlantic Coast.

Related Concepts:

Distribution: Endemic to south Florida.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans and C. Nordman

CES411.272 CONCEPTUAL MODEL

Environment: Its southerly location distinguishes this system from others along the Atlantic Coast, primarily due to the prevalence of the tropical flora it supports. This system is affected directly by much higher wave energy from the Atlantic than the beaches on the southwest coast of Florida. The southeast coastal region has some of the highest wave energy along the entire Atlantic Coast (Tanner 1960).

Key Processes and Interactions: This region has some of the highest wave energy along the entire Atlantic Coastal Plain (Tanner 1960). The process of sand movement due to the forces of wind and water are part of the natural dynamics of beach ecosystems. This includes transport of sand along the coast, and movement of sand by wind or water between the dunes, beach and subtidal areas. If not restricted by infrastructure or engineered hard structures, beaches and dunes can migrate as coastlines change over time in response to the action of wind and water. The beaches of southeast Florida are affected by two tides per day.

Threats/Stressors: Threats include recreation, beach cleaning (removal of wrack), beach renourishment (if not planned and carried in a way compatible with the beach ecosystem), water pollution, sea-level rise, coastal development, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009). Many coastlines are starved of sand due to dams on rivers which restrict the transport of sand to coastal areas. Coastal engineering hard structures reflect wave energy, constrain coastal sand migration and often lead to greater loss of beach sand (Defeo et al. 2009). Structures such as jetties around inlets restrict the natural movement of sand from north to south, starving beaches to the south of sand. The developed residential and tourism infrastructure of coastal areas has restricted natural dune and beach migration. Increasing sea-level rise associated with global climate change will lead to more loss of beach, especially in developed areas where infrastructure such as seawalls, buildings and coastal roads restrict the potential for inland migration of the beach and dunes. Beach renourishment has been carried out on many beaches along the southeast Florida coast. The use of sand for renourishment which does not match the grain size and composition of the beach to be restored can be a threat, especially where sand is applied deeply. The lack of nearby offshore sand compatible with eroded beaches is beginning to restrict beach renourishment activity in southeast Florida.

Invasive exotic plants which are threats include *Colubrina asiatica, Scaevola sericea var. taccada (= Scaevola taccada)*, and *Casuarina equisetifolia* which can alter beach and dune sand vegetation dynamics (FNAI 2010a). Invasive animals include imported red fire ants (*Solenopsis invicta*) and feral hogs (*Sus scrofa*) which prey on the eggs of sea turtles (Defeo et al. 2009). Feral house cats, dogs, and coyotes are a threat to nesting birds and other small animals which occur in coastal habitats. The beaches of the Atlantic coast provide important nesting habitat for sea turtles and shorebirds; certain restrictions on the timing and location of recreational uses may help accommodate nesting wildlife and promote nesting success.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of sand to erosion, especially in conjunction with engineered hard structures, and developed infrastructure on the shore side of the beach which restricts the inland migration of sand and dunes. There are many other threats which can contribute to ecosystem collapse. Ecosystem collapse is characterized by a large reduction of the width of the beach and the degradation and loss of beach ecosystem as habitat for various species, including shorebirds, sea turtles, and many invertebrates.

CES411.276 Southwest Florida Beach

CES411.276 CLASSIFICATION

Concept Summary: This system ranges from Anclote Key southward to Cape Romano, Florida. Within the northern Gulf of Mexico region, these beaches are distinguished by the highest species richness, greatest cover of succulents, and high cover of *Iva imbricata* and several tropical species. Sands are relatively coarse and, unlike other beach systems of the northern Gulf of Mexico, are extremely rich in calcium from an abundance of calcareous shell fragments.

Related Concepts:

Distribution: This system ranges from Anclote Key (border of Pasco and Pinellas counties) southward to Cape Romano, Florida (Collier County) (Johnson and Barbour 1990).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans

M703. Tropical Eastern Pacific Coastal Beach & Dune

CES402.598 Vegetacion de Playas Marinas del Pacifico

CES402.598 CLASSIFICATION

Concept Summary: El sistema incluye tanto a las comunidades que se desarrollan en las playas y sobre dunas, compuestas principalmente por plantas herbáceas esclerófilas, algunas de ellas con hojas suculentas, como los bosques bajos abiertos que se desarrollan sobre los sedimentos costeros muy recientes y moderadamente drenados. Este ambiente está dominado por arbustos y árboles bajos y palmas, tanto nativas como la introducida palma de coco. Las gramíneas están presentes pero no son dominantes en ninguno de los dos ambientes. Generalmente son suelos que no reciben constantemente la influencia de las mareas, salvo aguajes excepcionales, sin embargo por filtración puede haber saturación de capas profundas del suelo. La siguiente lista de especies es diagnóstica para este sistema:*Coccoloba uvifera, Elaeis guianensis, Hibiscus tiliaceus, Caesalpinia bonduc (= Caesalpinia crista), Pithecellobium dulce, Prosopis juliflora, Pithecellobium dulce, Bromelia karatas, Crataeva tapia, Coccoloba floribunda, Pithecellobium oblongum, Hippomane mancinella, Acacia farnesiana, Uniola pittieri, Joubea pilosa, Cenchrus echinatus, Ipomoea pes-caprae, Heliotropium curassavicum, Calotropis gigantea, Canavalia rosea, (= Canavalia maritima), Vigna peduncularis, Crotalaria* spp., *Opuntia lutea, Croton niveus, Caesalpinia bonduc (= Caesalpinia crista)*.

2.B.1.Na. Californian Scrub & Grassland

M045. Californian Annual & Perennial Grassland

CES206.942 California Central Valley and Southern Coastal Grassland

CES206.942 CLASSIFICATION

Concept Summary: This ecological system is found from 10-1200 m (30-3600 feet) elevation, in the Great Central Valley and along the southern coastal regions of California. It receives on average 50 cm (range 25-100 cm) of precipitation per year, mainly as winter rain. It is found with fine-textured soils, moist or even waterlogged in winter, but very dry in summer. Historically, these grasslands were common among oak savanna and woodland and probably experienced similar frequent fire regimes. Characteristic plant species include *Nassella pulchra, Aristida* spp., *Achillea millefolium var. borealis, Achyrachaena mollis, Agoseris heterophylla, Bloomeria crocea, Triteleia ixioides, Chlorogalum pomeridianum, Clarkia purpurea, Dodecatheon jeffreyi, Elymus glaucus, Leymus triticoides, Festuca californica, Melica californica, Castilleja attenuata*, and *Poa secunda*.

Related Concepts:

- Coastal Prairie (214) (Shiflet 1994) **>**
- Valley Grassland (215) (Shiflet 1994) **><**

Distribution: Found from in California from 10-1200 m (30-3600 feet) elevation, in the Great Central Valley and along the southern coastal region.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.942 CONCEPTUAL MODEL

Environment: This ecosystem occurs from 10 to 1200 m (30-3600 feet) in elevation; receiving on average 50 cm (range 25-100 cm) of precipitation per year, mainly as winter rain. It is found with deep fine-textured soils, moist or even waterlogged in winter, but very dry in summer (Sawyer et al. 2009).

Key Processes and Interactions: These grasslands have evolved to survive fire and long seasonal droughts (Keeley 2006). Invasion of non-native annual grasses out-compete natives through prolific seed production and the ability to re-seed quickly after fires, which generally means they maintain themselves at the expense of the native grasses and forbs (Sawyer et al. 2009).

Threats/Stressors: Conversion of this type has commonly come from agricultural and urban development, increased drought and increased fire frequency via Native American ignitions. Common stressors and threats include invasion of non-native annual species, heavy continuous grazing, and more frequent fire that favors the non-native annuals over the native bunch grasses. However, intact native grasslands also are stressed by fire suppression.

Conversion to agriculture and urban development are the greatest change agents to these grasslands rather than invasion by exotic species. Current thinking is that deep ripping and disruption of soil conditions makes way for exotics and if soil structure is in tact it is likely that native species will persist. Persistence of natives is more significant than dominance by natives. Many non-natives are here to stay and do not necessarily supplant or out compete the native species. These grasslands have experienced a long history of variable climate that supports a natural gradient from annual forblands in the southern portion of California to perennial grasslands in the northern portion. Loss of perennial grasses was thought to have been significant throughout the entire range but is now thought to have been over estimated. Many of the most spectacular wildflower fields in the South Coast Ranges and in southern California are the remaining pieces of this annual portion of the annual and perennial grasslands system (T. Keeler-Wolf pers. comm. 2013). There are, however, documented cases in particular where invasives such as *Centaurea solstitialis, Brassica nigra, Taeniatherum*, and others have swamped out the native species through thatch or shading (Stromberg et al. 2007, T. Keeler-Wolf pers. comm. 2013).

In the Central Valley, regional climate models project mean annual temperature increases of 1.4-2.0°C (1.8-3.6°F) by 2070. The projected impacts will be warmer winter temperatures; earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 47-175 mm (1-7 inches) by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). In southwestern California, regional climate models project mean annual temperature increases of 1.7 to 2.2°C by 2070. In southwestern California, regional climate models project a decrease in mean annual rainfall of 51 to 184 mm by 2070. There is relatively little consensus about the projected effects of climate change on precipitation patterns in southwestern California: some projections suggest almost no change, others project decreases of up to 37% (PRBO Conservation Science 2011). Increase in drought length and magnitude will further favor the exotic annual species. Fires may increase with warmer temperatures and drier fuels, which may further favor non-native species, which survive fires through prolific seed production.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from loss of native grasses by complete replacement by non-native annual grass species. Environmental Degradation (from conservation and restoration issues in Bartolome et al. 2007): Any of these conditions or combination of conditions rates as high-severity: Size severely reduced through encroachment, making management actions such as prescribed fire and grazing problematic; heavy continual grazing pressure, or other heavy disturbance to soils, fire return interval is far removed from the historic regime. Any of these conditions or combination of conditions rates as moderate-severity: Size moderately reduced through encroachment, making management actions such as prescribed fire and grazing, problematic; heavy continual grazing pressure at times, or other heavy disturbance to soils, fire return interval is moderately removed from the historic regime.

Disruption of Biotic Processes (from conservation and restoration issues in Bartolome et al. 2007): Any of these conditions or combination of conditions rates as high-severity: Native herbaceous plant diversity very low, abundance of native herbaceous species very low, annual non-native annual grass species dominant. Any of these conditions or combination of conditions rates as moderate-severity: Native herbaceous plant diversity is reduced, native grasses are moderately abundant at lease in some areas, non-native species present and abundant in areas.

CES206.943 California Mesic Serpentine Grassland

CES206.943 CLASSIFICATION

Concept Summary: These grasslands are of very limited distribution in California within the Coast Ranges, Sierra Nevada, and Transverse Ranges on deep soils with serpentine-rich parent material. Not all serpentinite outcrops support distinct vegetation; only those with very low Ca:Mg ratios impact biotic composition. In this system, native bunchgrass dominates, though typically in less dense cover than other perennial bunchgrass types. Characteristic species include *Calamagrostis ophitidis, Eschscholzia californica, Vulpia microstachys var. ciliata (= Festuca grayi), Poa secunda (= Poa scabrella), Hemizonia congesta ssp. luzulifolia (= Hemizonia luzulifolia), Nassella cernua*, and *Nassella pulchra*. Historic fire regimes in this system are not well known.

Related Concepts:

- Valley Grassland (215) (Shiflet 1994) **><**

Distribution: This system is found in the Coast Ranges, Sierra Nevada, and Transverse Ranges of California on deep soils with serpentine-rich parent material. It may also occur on serpentine in the Klamath Mountains of southern Oregon.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.943 CONCEPTUAL MODEL

Environment: This ecosystem occurs on deep soils with serpentine-rich parent material. Not all serpentinite outcrops support distinct vegetation; only those with very low Ca:Mg ratios impact biotic composition.

Key Processes and Interactions: Serpentine soils are relatively infertile soils and mycorrhizal relationships are considered important to plant survival (Jimerson et al. 1995). Hopkins 1986 (as cited in Jimerson et al. 1995) found that 98% of the herbaceous plants in the serpentine grassland communities of the Santa Cruz Mountains were mycorrhizal. Ectomycorrhizae are often associated with members of the Ericaceae family, a well-represented family in the serpentine flora (Jimerson et al. 1995).

Threats/Stressors: Conversion of this type has commonly come from mining and geothermal power development, agricultural and timber development. Common stressors and threats include mining and geothermal power development, agricultural and timber development, shrub-removal land management practices and application of fertilizer, seeding of palatable grasses, and severe erosion following intensive land use (Kruckberg 1984). Nitrogen deposition in serpentine areas adjacent to urban zones like the south Bay Area where N fallout has contributed to the increase of non-native grasses such as *Lolium perenne* which is out competing some of the native species essentially through fertilizing the soil (Weiss 1999).

The projected impacts of climate change on thermal conditions in northwestern California (where most but not all serpentine grasslands are located, but serves as a good representation of the type of projected change for much of California) mean annual temperature increases of 1.7-1.9°C by 2070. For the same time period mean diurnal temperature range will be warmer winter temperatures, earlier warming in the spring, and increased summer temperatures. Regional climate models project a decrease in mean annual rainfall of 101 to 387 mm by 2070. Currently, there is greater uncertainty about the precipitation projections than for temperature in northwestern California, but with some evidence for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Decreased precipitation and higher summer temperature may result in lower biomass production and loss of plant vigor over all of the grassland ecosystem.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from heavy continual grazing that removes all biomass, severe soil disturbance and consequential erosion. Environmental Degradation: The following is based on threats noted in literature cited above, applied through standard criteria of landscape condition, size and physical condition, as described in NatureServe's Ecological Integrity Assessment (Faber-Langendoen et al. 2008b) and Heritage Program Ecological Occurrences Specifications [see WNHP (2011) and CNRA (2009) for example criteria]. Suggested thresholds are by the author. Any of these conditions or combination of conditions rates as high-severity: Area is encroached upon by residential or other development; size of occurrence significantly reduced through development; land use has severely disturbed soils causing severe erosion such as mining (and related road building), continual heavy grazing, logging activity, off-road vehicle activity. Any of these conditions or combination of conditions rates as moderate-severity: Surrounding landscape has residential and/or other development; size of occurrence somewhat reduced through development; land use has disturbed soils in only moderate amounts or intensively in only parts of the occurrence.

Disruption of Biotic Processes: The following is based on threats from literature cited above, applied through standard criteria of landscape condition, size and biotic condition, as described in NatureServe's Ecological Integrity Assessment (Faber-Langendoen et al. 2008b) and Heritage Program Ecological Occurrence Specifications [see WNHP (2011) and CNRA (2009) for example criteria]. Suggested thresholds are by the author. Any of these conditions or combination of conditions rates as high-severity: Total vegetative cover is much reduced, grassland has essential become a serpentine barren, but lacks species typical of serpentine barrens, although this severe case has not been observed (T. Keeler-Wolf pers. comm. 2013). Any of these conditions or combination of conditions rates as moderate-severity: total vegetative cover is moderately reduced, expected serpentine endemics are absent or fewer in number than expected (from undisturbed reference locations).

M043. Californian Chaparral

CES206.929 California Maritime Chaparral

CES206.929 CLASSIFICATION

Concept Summary: This ecological system includes chaparral in patches restricted by edaphic conditions (sands, sandstones, other marine sediments, and stabilized sand dunes) within the fog belt throughout the central and northern California coast. This system is characterized by a combination of locally endemic species of *Arctostaphylos* and *Ceanothus*, species that primarily reproduce by seed rather than resprouting. Shrubs vary in height (up to 3 m tall) and occur in variable densities. More open patches support herbaceous vegetation, while occurrences of high shrub density have no understory. Characteristic species include *Arctostaphylos tomentosa, Arctostaphylos nummularia, Arctostaphylos tomentosa ssp. crustacea, Arctostaphylos hookeri, Arctostaphylos pajaroensis, Arctostaphylos montaraensis* (and others), *Ceanothus masonii, Ceanothus griseus*, and *Ceanothus verrucosus*. In occurrences in southern Oregon, *Arctostaphylos hispidula* is the predominant chaparral shrub. Southernmost stands (San Diego County) can include *Cneoridium dumosum* and *Comarostaphylis diversifolia*. Other common widespread woody taxa can include *Adenostoma fasciculatum, Eriogonum fasciculatum, Salvia mellifera, Frangula californica, Rhamnus crocea*, and *Quercus agrifolia*. Controlled burns have resulted in poor survivorship of the *Arctostaphylos* spp., and current theories are that they need long fire-free intervals to develop a viable seedbank that can reproduce following fire. This system often co-occurs with ~California Coastal Closed-Cone Conifer Forest and Woodland (CES206.922)$$.

Related Concepts:

- Chamise Chaparral (206) (Shiflet 1994) **><**

Distribution: This systems occurs within the fog belt from southern California to the Mendocino coast of northern California. It extends north into coastal Oregon in very small patches.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, M.S. Reid

CES206.929 CONCEPTUAL MODEL

Environment: This system is restricted by edaphic conditions (sands, sandstones, other marine sediments, and stabilized sand dunes) within the summer coastal fog belt throughout the central and northern California coast, usually below 300 m (1000 feet) in elevation (Keeley and Davis 2007, Sawyer et al. 2009). The climate is distinctly Mediterranean, with warm, dry summers and cool, moist winters. Rainfall is rather variable due to the large latitudinal range. Sandy soils with low nutrient levels tend to be the norm, usually within just a few kilometers of the ocean.

Key Processes and Interactions: These shrublands are characterized by species that primarily reproduce by seed rather than resprouting, and are fire-dependent. Infrequent fire results in encroachment of trees and a decline in shrub vigor and seedbank quality. Frequent fire tends to convert the stands to coastal scrub or grassland. Recent studies of many sites that have been fire-free for decades suggest that at least some of the species of *Ceanothus* may be able to germinate without fire and thus sustain populations for long fire-free intervals. Controlled burns have resulted in poor survivorship of the *Arctostaphylos* spp., and current theories are that they need long fire-free intervals to develop a viable seedbank that can reproduce following fire (Keeley and Davis 2007). Most of the dominant shrubs are nitrogen fixers.

Landfire (2007a) model: Chaparral burns in high-intensity, stand-replacing crown fires that burn large acreages in a single event. However, there is a considerable range in the flammability of shrub species (e.g., chamise is "flashier" than manzanita). Large, stand-replacement events can interact with seed availability and, hence, influence post-fire successional pathways differently than for smaller, less severe fires. Mean fire-return intervals are variable and longer than intervals of other chaparral types. Fire intervals can exceed 100 years, and the specimens can grow to large size. Season of burning plays a large part in species composition. Occasionally, frost affects mortality and increases fuel buildup.

Threats/Stressors: Conversion of this type has commonly come from coastal residential development and urbanization, military operations, and fire suppression which eliminates stands (Griffin 1978, Davis and Borchert 2006). Common stressors and threats include fragmentation of the habitat by housing, and agriculture may make utilization of prescribed fire impossible (Van Dyke et al. 2001). Exotic, invasive weeds, including *Cortaderia jubata, Carpobrotus edulis, Carpobrotus chilensis, Genista monspessulana*, and *Eucalyptus globulus* (a tree), also threaten some occurrences where these species are invading nearby vegetation (Griffin 1978, Van Dyke et al. 2001). It was speculated by Davis and Borchert (2006) that this type is more densely invaded by exotics than other chaparrals because it is more densely roaded and thus closer to human disturbance and sources of exotic propagules.

In the west central coast region of California, regional climate models project mean annual temperature increases of 1.6-1.9°C by 2070. The projected impacts will be warmer winter temperatures, earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 61-188 mm by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011).

In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain. Potential climate change effects could include (PRBO Conservation Science 2011): deep-rooted or phreatophytic species under greater stress and death; drop in groundwater table; more and larger fires; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006); increases in the areal extent of grasslands and concomitant reductions in the extent of chaparral, sage scrub, and oak woodlands; and increased competition for water from all users, and stresses on the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from too frequent fires which truncate development of a seedbank; or cessation of fire resulting in dominance of conifers; heavy invasion of exotic plant species, displacing the native grasses and forb; occurrences are small in size (less than 5 acres/2 ha), surrounded by non-natural land uses, and are densely roaded; fragmentation has occurred and connectivity between occurrences is gone.

Environmental Degradation: High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; the surrounding landscape and the occurrence are densely roaded; fire is no longer occurring, or is too frequent, there is severe departure from the historic regime (FRCC = 3). Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2).

Disruption of Biotic Processes: High-severity disruption of biotic processes appears where greater than 30% absolute cover of exotic invasives; non-native species dominate understory with minor native component (native species cover in shrub and herb layers <50%); overall species richness has declined, with fewer than 4 of the expected native species occurring in the shrub or herb layers; adjacent roads or development provide propagules for exotic plants to invade. Moderate-severity appears where exotic invasives prevalent with 5-30% absolute cover; native species have 50-90% of the cover, non-natives can be codominant; overall species richness has declined, but at least 4 to 9 of the expected native species occurring in the shrub or herb layers.

CES206.926 California Mesic Chaparral

CES206.926 CLASSIFICATION

Concept Summary: This ecological system occurs in mesic site conditions, such as north-facing slopes, concavities, or toeslopes, with well-drained soils throughout Mediterranean California away from the coastal fog belt. It occurs most commonly on north-facing slopes up to 1500 m (4550 feet) in elevation and up to 1830 m (6000 feet) in southern California. This system tends to be dominated by a variety of mixed or single-species, evergreen, sclerophyllous shrubs that resprout from lignotubers following fire. Common species include *Quercus berberidifolia, Quercus wislizeni var. frutescens, Cercocarpus montanus var. glaber, Fraxinus dipetala, Garrya flavescens, Garrya elliptica, Heteromeles arbutifolia, Lonicera* spp., *Prunus ilicifolia, Rhamnus crocea, Rhamnus ilicifolia, Toxicodendron diversilobum, Ribes* spp., and *Sambucus* spp. Weakly re-sprouting or obligate seeders that also commonly occur in this system include arborescent *Ceanothus* spp., such as *Ceanothus spinosus, Ceanothus oliganthus, Ceanothus tomentosus*, and *Ceanothus leucodermis*. *Umbellularia californica* and *Aesculus californica* can also occur as shrubs and, lacking disturbance, can grow to tree size, as do some of the other chaparral shrubs (some old-growth stands can reach 10.6 m [35 feet] in height!). Most chaparral species are fire-adapted, resprouting vigorously after burning or producing fire-resistant seeds. This is not a system that requires frequent fire for perpetuation.

Related Concepts:

- Montane Shrubland (209) (Shiflet 1994) **>**
- Scrub Oak Mixed Chaparral (207) (Shiflet 1994) **=**

Distribution: This system occurs throughout Mediterranean California away from the coastal fog belt. It may occur as very small patches in southwestern Oregon, but it isn't clearly documented from there.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.926 CONCEPTUAL MODEL

Environment: Mesic chaparral is extremely drought-tolerant and readily reseeds and resprouts after severe fire. It is highly site-specific; aspect can greatly influence species composition, and the higher elevations of the shrub belt in the Sierra Nevada foothills have greater moisture relative to the chamise-dominated (dry) chaparral found at lower altitudes.

Key Processes and Interactions: TNC fire model information: Chaparral burns in high-intensity stand-replacing crown fires that burn thousands of acres in a single event. However, there is a considerable range in the flammability of shrub species (e.g., chamise is "flashier" than manzanita). Large, stand-replacement events can interact with seed availability and, hence, influence post-fire successional pathways differently than for smaller, less severe fires. Mean fire-return intervals are highly variable across the state depending on species composition and other factors. Sediment cores taken from the Santa Barbara Channel in central California dating from the 16th and 17th centuries indicate that large fires burned the Santa Ynez and Santa Lucia mountains every 40-60 years. Season of burning plays a large part in species composition. Occasionally, frost affects mortality and increases fuel buildup. In the last century, the high frequency of human ignitions has reduced the mean fire-return interval to 30-35 years in southern California.

CES206.927 California Xeric Serpentine Chaparral

CES206.927 CLASSIFICATION

Concept Summary: This ecological system occurs throughout Mediterranean California (excluding far southern California) on thin, rocky, ultramafic (gabbro, peridotite, serpentinite) soils and in areas below winter snow accumulations that typically experience hot and dry summers. Not all ultramafic outcrops support distinct vegetation; only those with very low Ca:Mg ratios impact biotic composition. This system is highly variable and spotty in distribution. Characteristic plant species include *Hesperocyparis macnabiana, Quercus durata, Arctostaphylos viscida, Arctostaphylos pungens*, and *Arctostaphylos glauca*. Common associates include *Adenostoma fasciculatum, Ceanothus cuneatus, Fremontodendron californicum, Quercus sadleriana, Quercus vacciniifolia, Garrya* spp., *Umbellularia californica, Ceanothus pumilus, Frangula californica*, and *Arctostaphylos nevadensis*. California endemics such as *Ceanothus jepsonii* also occur. *Pinus sabiniana* can occur at varying cover from trace to more abundant. Many locally endemic and often rare forbs can occur, such as *Streptanthus* spp., *Hesperolinon* spp., *Eriogonum* spp., *Madia* spp., *Mimulus* spp., *Allium* spp., and *Asclepias solanoana*. This chaparral type tends to have fewer trees than mesic chaparral.

Related Concepts:

- Chamise Chaparral (206) (Shiflet 1994) **><**

Distribution: This system occurs throughout Mediterranean California (excluding far southern California) into Oregon, on thin, rocky, ultramafic soils.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, M.S. Reid

CES206.927 CONCEPTUAL MODEL

Environment: This system occurs on thin, rocky, ultramafic (gabbro, peridotite, serpentinite) soils and in areas below winter snow accumulations that typically experience hot and dry summers. Not all ultramafic outcrops support distinct vegetation; only those with very low Ca:Mg ratios impact biotic composition. Soils on ultramafics are usually shallow and skeletal, with little profile development. Ultramafic soils impose the following stresses on plants: imbalance of calcium and magnesium, magnesium toxicity, low availability of molybdenum, toxic levels of heavy metals, sometime high alkalinity, low concentrations of some essential nutrients, and low soil water storage capacity (Sanchez-Mata 2007). In some cases, the steepness of the slopes and general sparseness of the vegetation result in continual erosion.

Key Processes and Interactions: Landfire (2007a) model: Due to the poor soil nutrient levels, biomass accumulation tends to be significantly lower in these serpentine systems than in neighboring patches of sandstone chaparral. As a result, fire frequency and fire severity are reduced. A study at the McLaughlin Reserve (Safford and Harrison 2008) found that time since last fire was nearly four times longer than on non-serpentine sites, and severity was also significantly reduced. The effects of fire on diversity in these systems are less pronounced than in non-serpentine systems, though they may be longer lasting (Safford and Harrison 2004); these authors found that few species on serpentine depended on fire for germination.

Threats/Stressors: Conversion of this type has commonly come from residential and urban development, mining. Many occurrences have been modified by mining, clearing, or other development activities. *Ericameria nauseosa* colonizes disturbed sites easily, so managers used it in restoration projects. Because shrubs on serpentine are more fire-sensitive and may recruit slowly, they may be especially susceptible to excessively frequent or poorly-timed fires (Parker 1990). Exotic plant species are not a problem in this ecological system because of the nutrient-poor soils.

In the west central coast regions, regional climate models project mean annual temperature increases of 1.6-1.9°C by 2070. The projected impacts will be warmer winter temperatures, earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 61-188 mm by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Potential climate change effects could include (PRBO Conservation Science 2011): deep-rooted or phreatophytic species under greater stress and death; drop in groundwater table; more and larger fires; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006); increases in the areal extent of grasslands and concomitant reductions in the extent of chaparral, sage scrub, and oak woodlands; and increased competition for water from all users, and stresses on the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from too frequent fires; occurrences are small in size (less than 5 acres/2 ha) and surrounded by non-natural land uses; mining activities have impacted much of the occurrences; or mining restoration has introduced undesirable shrubs; fragmentation has occurred and connectivity between occurrences is gone; rare native forbs and grasses have been eliminated from the occurrence.

Environmental Degradation: High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; fire is too frequent or occurs at the 'wrong' season affecting recruitment post-fire, there is severe departure from the historic regime (FRCC = 3); clearing has occurred, removing much of the shrub biomass. Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2); clearing has occurred, removing some of the shrub biomass.

Disruption of Biotic Processes: High-severity disruption of biotic processes appears where overall species richness has declined, with fewer than 4 of the expected native species occurring in the shrub or herb layers; rare plant species have been lost from the occurrence; excessively frequent or poorly timed fire has affected recruitment of the shrubs; fragmentation of occurrences has lead to a loss of seed source for stands that burn. Moderate-severity appears where overall species richness has declined, but at least 4 to 9 of the expected native species occurring in the shrub or herb layers.

CES206.150 Klamath-Siskiyou Xeromorphic Serpentine Savanna and Chaparral

CES206.150 CLASSIFICATION

Concept Summary: This ecological system occurs throughout the Klamath-Siskiyou region below 1500 m (4550 feet) on thin rocky soils below winter snow accumulations and typically experiences hot and dry summers. These savannas and shrublands are almost always found on ultramafic soils (gabbro, peridotite, serpentinite), especially on the Josephine Peridotite Formation in the western Klamaths, with very low Ca:Mg ratio. These systems are highly variable and spotty in distribution. This system represents the most xeromorphic of these environments, generally supporting savannas or shrublands in areas with high rainfall amounts (over 130 cm/year) that would usually support closed-canopy forests. Landforms can include rocky ridges and ridgetops, south-facing slopes and river terraces, or gravelly valley bottomlands. These contain mosaics or patches of open-canopy tree-savannas with chaparral understories or shrub-dominated chaparral. Shrubs will often have higher densities than the trees which are more limited due to the rocky/thin soils and are often stunted in growth-form. These can also be short-duration chaparrals in previously forested areas that have experienced crownfires. When present, trees tend to have a scattered, open canopy or can be clustered, over a usually continuous, dense shrub layer, but sometimes with a grassy understory. *Pinus jeffreyi* or occasionally *Pinus attenuata* can form a scattered tree layer over bunchgrasses. Dense shrub layers can also be present in some stands, or form their own patches without trees, especially on ridges. *Quercus vacciniifolia, Quercus sadleriana* (coastal and wetter climate but found on xeric sties), *Notholithocarpus densiflorus var. echinoides, Quercus garryana var. fruticosa* (drier, inland), *Ceanothus cuneatus, Ceanothus pumilus, Arctostaphylos viscida, Arctostaphylos x cinerea, Arctostaphylos canescens, Arctostaphylos nevadensis, Frangula californica*, and *Garrya buxifolia* represent some of the many chaparral shrubs that can be found in these habitats. Perennial grasses such as *Festuca idahoensis ssp. roemeri, Achnatherum lemmonii, Melica* sp., and *Danthonia californica* may also be characteristic, although a diverse and often endemic forb component (including rare serpentine endemics) is usually present. This system tends to have lower diversity within stands than in the other serpentine woodland and shrubland systems. Locally occurring, stunted and open stands of *Pinus contorta* and *Pinus monticola* on serpentine at low elevation are included in this system. The grassy understory savannas tend to have understory burns, while shrub-dense stands will suffer intense, stand-replacing fires.

Distribution: This system occurs throughout the Klamath-Siskiyou mountains region below 1500 m (4550 feet), but mostly in the western Klamaths on the Josephine peridotite body.

Nations: US

Concept Source: J. Kagan and T. Keeler-Wolf

Description Author: M.S. Reid

CES206.150 CONCEPTUAL MODEL

Environment: This ecological system occurs throughout the Klamath-Siskiyou region below 1500 m (4550 feet) on thin rocky soils below winter snow accumulations and typically experiences hot and dry summers. These savannas and shrublands are almost always found on ultramafic soils (gabbro, peridotite, serpentinite), especially on the Josephine Peridotite Formation in the western Klamaths, with very low Ca:Mg ratio. These systems are highly variable and spotty in distribution. This system represents the most xeromorphic of these environments, generally supporting savannas or shrublands in areas with high rainfall amounts (over 130 cm/year) that would usually support closed-canopy forests. Landforms can include rocky ridges and ridgetops, south-facing slopes and river terraces, or gravelly valley bottomlands.

Key Processes and Interactions: The grassy understory savannas tend to have understory burns, while shrub-dense stands will suffer intense, stand-replacing fires.

CES206.931 Northern and Central California Dry-Mesic Chaparral

CES206.931 CLASSIFICATION

Concept Summary: This ecological system includes chaparral typically located inland from maritime chaparral up to 1500 m (4550 feet) elevation in central and northern California through the northern end of the Central Valley and north into Oregon. This system includes extensive areas on coarse-grained soils with annual precipitation up to 75 cm (winter rain but not snow). Adjacent fine-textured soils support savanna under similar climatic regimes. These areas have supported extensive stand-replacing wildfires. This system is made up of a mixture of mostly obligate seeders. Characteristic species include *Adenostoma fasciculatum, Ceanothus cuneatus, Arctostaphylos viscida, Arctostaphylos manzanita, Arctostaphylos glauca, Arctostaphylos glandulosa, Arctostaphylos stanfordiana, Fremontodendron californicum, Malacothamnus fasciculatus, Dendromecon rigida*, and *Pickeringia montana*. Common shrubs in Oregon include *Arctostaphylos viscida, Cercocarpus montanus var. glaber*, and *Ceanothus cordulatus*. Fire regimes are intense, stand-replacing crown fires. Scattered and young trees may occur, such as *Pinus ponderosa, Pinus sabiniana, Pseudotsuga menziesii*, and *Quercus wislizeni*.

CES206.930 Southern California Dry-Mesic Chaparral

CES206.930 CLASSIFICATION

Concept Summary: This ecological system includes chaparral from sea level up to 1500 m (4550 feet) elevation throughout central and southern California and inland portions of Baja Norte, Mexico. It is found in dry-mesic to mesic site conditions analogous to mesic chaparral. Santa Ana winds drive late-summer, stand-replacing fires in these systems. Characteristic species include *Ceanothus megacarpus, Ceanothus crassifolius, Ceanothus leucodermis, Ceanothus greggii, Adenostoma fasciculatum, Adenostoma sparsifolium, Arctostaphylos glauca, Cercocarpus montanus var. glaber (= Cercocarpus betuloides), Cercocarpus montanus var. minutiflorus (= Cercocarpus minutiflorus), Rhus ovata*, and *Xylococcus bicolor*.

Distribution: This system includes chaparral from sea level up to 1500 m (4550 feet) elevation throughout central and southern California and inland portions of Baja Norte, Mexico.

Nations: MX, US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf

CES206.930 CONCEPTUAL MODEL

Environment: [from M043] This type occurs on a wide variety of settings. It occurs within the fog belt along the coast of central and northern California on generally nutrient-poor edaphic conditions (sands, sandstones, other marine sediments, and stabilized sand dunes), the southern California coast and into the western foothills of the Sierra Nevada. It is typically found on arid, south-facing slopes and ridges, and occasionally on mesic sites, such as north-facing slopes, concavities, or toeslopes, with well-drained soils and mafic soils. The more frost-tolerant species are found at higher, cooler and generally more mesic sites up to approximately 1830 m (6000 feet) elevation. Chaparral is naturally displaced by woodlands on very mesic slopes and by sage scrub on xeric slopes (Keeley and Davis 2007). These shrublands include extensive areas on coarse-grained soils with annual precipitation up to 75 cm (winter rain, and only intermittent snow).

Californian chaparral is mainly linked to three conditions: climate, soil and dynamics. With regard to climate, Mediterranean climate is the norm, regardless of the total amount of precipitations, because within that macroclimate it can be found under a wide range of rainfall. However, when rainfall is low (roughly below 300 mm/year), chaparral constitutes the late-seral vegetation, whereas when rainfall is higher, chaparral plays two ecological roles. First, they constitute the edaphic vegetation living on shallow and rocky soils [see Keeley and Davis (2007)], including deep eolian sands and mafic substrates. Second, in areas with higher rainfall (~>300 mm), they are successional and linked to fire, forming early- and mid-seral stages of bushlands and pyrophytic chaparral that replace oak woodlands and forests, and mixed-coniferous forests (M. Peinado pers. comm. 2014).

Key Processes and Interactions: [from M043] The fire regime ranges from root sprouter-dominated shrubland that survive and regrow after stand-replacing fires. Other stands are dominated by seed reproducers that need long fire-free intervals to develop a viable seedbank that can reproduce following fire (Keeley and Davis 2007). Recent studies of many sites that have been fire-free for decades suggest that at least some of the species of *Ceanothus* may be able to germinate without fire and thus sustain populations during long fire-free intervals. Other stands are stable and do not need frequent fire to persist. Studies show that frost damage to mature plants and drought stress on seedlings may limit the range and distribution of California chaparral species (Keeley and Davis 2007).

Threats/Stressors:

Ecosystem Collapse Thresholds: Colapso ecológico tiende a ocurrir a partir de la conversión directa de la tierra.
Ecological collapse tends to occur from direct land conversion.

M044. Californian Coastal Scrub

CES206.906 Mediterranean California Coastal Bluff

CES206.906 CLASSIFICATION

Concept Summary: Areas of sea bluffs and rocky headlands occur just above the tidal zone throughout rugged portions of coastal Oregon, California, Baja Norte, and off-shore islands (e.g., Channel Islands). Plant communities along these often vertical slopes are typically sparse, with many succulents and prostrate shrubs, and species that readily withstand salt spray and saline soils, as well as seasonal drought. These may include *Baccharis pilularis, Dudleya* spp., *Carpobrotus chilensis, Carpobrotus edulis, Hazardia squarrosa (= Haplopappus squarrosus), Eriogonum parvifolium, Erigeron glaucus, Eriophyllum stoechadifolium*, and *Plantago maritima*. Slope instability and erosion result in severe climate, setting back succession in this system.

Related Concepts:

Distribution: Rugged portions of coastal Oregon, California, and off-shore islands (e.g., Channel Islands), and Baja Norte, Mexico.

CES206.932 Northern California Coastal Scrub

CES206.932 CLASSIFICATION

Concept Summary: This ecological system includes a variety of mixed and single-species-dominated shrublands along a narrow coastal strip with maritime and summer fog influences, on marine sediments, coastal bluffs, terraces, stabilized dunes, and hills below 500 m (1500 feet) elevation from southern Oregon south through central California. It is restricted to coastal plateaus and lower slopes of the Coast Ranges where precipitation ranges from 50-200 cm annually. These are dominated by evergreen, microphyllous-leaved or hemi-sclerophyllous shrub taxa; drought-deciduous species are unimportant or absent in this system. Dense shrublands typically include a well-developed woody and herbaceous understory. Characteristic species include *Baccharis pilularis, Lupinus arboreus, Ceanothus thyrsiflorus, Eriophyllum stoechadifolium, Diplacus aurantiacus, Toxicodendron diversilobum, Rubus* *ursinus, Rubus parviflorus, Rubus spectabilis, Frangula californica, Holodiscus discolor, Gaultheria shallon, Heracleum maximum*, and *Polystichum munitum*. These areas have supported extensive stand-replacing wildfires. This system has direct seral relationships with ~California Northern Coastal Grassland (CES206.941)$$ as, in the absence of fire and grazing, the grassland will usually succeed to this system. In the absence of fire in this system, conifers (*Abies grandis, Pseudotsuga menziesii*) can invade and become prominent.

CES206.933 Southern California Coastal Scrub

CES206.933 CLASSIFICATION

Concept Summary: This ecological system includes mixed coastal shrublands from Monterey, California, south into Baja Norte, Mexico. It is dominated by drought-deciduous shrubs but at times can have characteristic (constant but not dominant) resprouting, deep-rooted sclerophyllous shrubs. It occurs below 1000 m (3000 feet) elevation and may extend inland from the maritime zone in hotter, drier conditions than northern (less fog-drenched) shrublands (e.g., areas with 10-60 cm of annual precipitation). Soils vary from coarse gravels to clays but typically only support plant-available moisture with winter and spring rain. Most predominant shrubs include *Artemisia californica, Salvia mellifera, Salvia apiana, Salvia leucophylla, Encelia californica, Eriogonum fasciculatum, Eriogonum cinereum, Opuntia littoralis, Diplacus aurantiacus, Lotus scoparius* (early seral after fire), and *Baccharis pilularis* (in moister, disturbed sites). Characteristic (constant but not dominant) resprouting, deep-rooted sclerophyllous shrubs include *Malosma laurina, Rhus integrifolia*, and *Rhamnus crocea*. Fire frequency was historically low, but in recent years with adjacency to urban and suburban areas, the fire frequency has increased (a result of arson or cigarette ignition) resulting in type conversion to non-native and ruderal annual grasslands. *Malosma laurina* and *Rhus integrifolia* are also increasing in abundance because they can continually resprout after repeated fires. In places, *Opuntia littoralis* may proliferate and cover entire slopes in dry rocky areas with repeated fires that have killed the scrub taxa, while *Opuntia littoralis* can resprout and spread to cover large patches.

Related Concepts:

- Coastal Sage Shrub (205) (Shiflet 1994) **=**

Distribution: This system is found from Monterey, California, south into Baja Norte, Mexico. It occurs below 1000 m (3000 feet) elevation and may extend inland from the maritime zone.

Nations: MX, US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, M.S. Reid

CES206.933 CONCEPTUAL MODEL

Environment: The most important environmental factors are cool-season precipitation and minimum winter temperature (Rundel 2007, Sawyer et al. 2009). Mean minimum winter temperature is substantially more predictive of southern sage scrub distribution patterns than is mean maximum summer temperature. Southern scrub prefers warm winters and relatively low total precipitation. This means that this system is restricted to low-elevation areas that receive some marine climatic influence; generally it occurs below 1000 m (3000 feet) elevation and receives about 10-60 cm of annual precipitation. The coastal region where it occurs has a longer dry season than further north in California. Southern coastal scrub often responds sensitively to aspect on a local scale (for example, in San Diego County sometimes occurring on south-facing slopes where north-facing slopes are occupied by chaparral types), but occurs on all aspects when viewed at a regional scale (Sawyer et al. 2009). Species composition of stands varies both with distance from the coast and with latitude. Soils vary from coarse gravels to clays but typically only support plant-available moisture with winter and spring rain. Stands often form complex mosaics interdigitated with stands of chaparral and grassland types on scales of 10s-100s of meters.

Key Processes and Interactions: This is not an ecosystem type that requires fire for regeneration of the major shrubs (Landfire 2007a, Rundel 2007). Coastal scrub often occupies sites denuded by landslides, slumps, debris flows, and other mass-wasting events. It sometimes occupies chaparral sites for a number of years after a burn, before the larger, woodier chaparral shrubs reestablish their dominance. The main sage scrub species have seeds that are wind-dispersed, and recovery of sage scrub communities post-disturbance may involve dispersal and germination from plants outside the disturbed area (Rundel 2007). Although *Lotus scoparius* can temporarily occupy chaparral sites, *Artemisia californica* could not have the seedbank necessary to be abundant in post-fire chaparral, except in a case where there were repeated burns over several to many years that opened up the chaparral. Southern coastal scrub can clearly persist on favorable sites for at least a hundred years and probably much longer in the absence of any fire (Rundel 2007).

Threats/Stressors: Conversion of this type has commonly come from urban and suburban expansion/development, agriculture, road-building; reported by Rundel (2007) that some 70 to 90% of the original area of this ecosystem has been lost since European settlement. Common stressors and threats include lack of fire due to exclusion by adjacent urban and agricultural development; or more frequent than historic fire due to human ignition sources (arson or cigarette ignition); invasion by non-native annual grasses and forbs, apparently from a combination of hard grazing by sheep, frequent fire, and possibly N deposition from air pollution (Rundel 2007). Nitrogen deposition downwind of urban areas has raised concentrations of soil inorganic nitrogen, which may favor the annual exotic grasses (Padgett and Allen 1999, as cited in Rundel 2007). Many areas that were historically coastal sage scrub have been completely type-converted to annual grasslands.

Fire frequency was historically low (return intervals >100 years), but in recent years with adjacency to urban and suburban areas, the fire frequency has increased (a result of arson or cigarette ignition) resulting in type conversion to non-native and ruderal annual grasslands. *Malosma laurina* and *Rhus integrifolia* are also increasing in abundance because they can continually resprout after repeated fires. In places, *Opuntia littoralis* may proliferate and cover entire slopes in dry rocky areas with repeated fires that have killed the sage scrub taxa, while *Opuntia littoralis* can resprout and spread to cover large patches (Landfire 2007a, Sawyer et al. 2009). A state-and-transition (VDDT) model reviewer (Landfire 2007a) indicated that coastal sage in Baja California is not being converted to exotic annual grasslands, possibly because livestock grazing (mostly cattle) is removing thatch and actually improves coastal sage scrub recruitment and succession. The modeler stated that the hypothesis that cattle might enhance coastal sage scrub establishment that the reviewer espoused was not consistent with his observations from Alta California. Modeler felt that at a very light stocking rate cattle might not be detrimental to coastal sage scrub, but examples of livestock grazing abetting loss in this type abound.

In the southwest regions of California, regional climate models project mean annual temperature increases of 1.7-2.2°C by 2070. The projected impacts will be warmer temperatures in most months of the year, earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 51-184 mm by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a drier future climate relative to current conditions (PRBO Conservation Science 2011).

In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain. Potential climate change effects could include (PRBO Conservation Science 2011): high temperature events will become more common and species with very narrow temperature tolerance levels may experience thermal stress; change in fire regime is uncertain, as the effects of climate change on the Santa Ana winds does not have any consensus in the models; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006); large increases in the areal extent of grasslands and concomitant reductions in the extent of chaparral and sage scrub; and increased competition for water from all users, and stresses on the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from too frequent fires, or cessation of fire resulting in dominance of chaparral shrub species, cacti, or invasive annual grasses and loss of the characteristic sage scrub species; heavy invasion of exotic plant species, displacing the native grasses and forbs and altering fire regime sometimes to the extent of complete type conversion; occurrences are small in size (less than 5 acres/2 ha) and surrounded by non-natural land uses; fragmentation has occurred and connectivity between occurrences is gone which has lead to a lack of seed source for some stands when they do burn.

Environmental Degradation: High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; fire is no longer occurring, or is too frequent, there is severe departure from the historic regime (FRCC = 3). Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; there is moderate departure from the historic fire regime (FRCC = 2).

Disruption of Biotic Processes: High-severity disruption of biotic processes appears where greater than 30% absolute cover of exotic invasives; non-native species dominate understory with minor native component (native species cover in shrub and herb layers <50%); overall species richness has declined, with fewer than 4 of the expected native species occurring in the shrub or herb layers; cacti may dominate the stand; fragmentation of occurrences has lead to a loss of seed source for stands that burn or for newly formed colonization sites (e.g., after a soil slump/landslide removes chaparral species). Moderate-severity appears where exotic invasives prevalent with 5-30% absolute cover; native species have 50-90% of the cover, non-natives can be codominant; overall species richness has declined, but at least 4 to 9 of the expected native species occurring in the shrub or herb layers.

2.B.2.Na. Western North American Grassland & Shrubland

M048. Central Rocky Mountain Montane-Foothill Grassland & Shrubland

CES304.792 Columbia Basin Palouse Prairie

CES304.792 CLASSIFICATION

Concept Summary: This once-extensive grassland system occurs in eastern Washington and Oregon, and west-central Idaho, though in very small patches there. In much of its range it is characterized by rolling topography composed of loess hills and plains over basalt plains. The climate of this region has warm-hot, dry summers and cool, wet winters. Annual precipitation is high, 38-76 cm (15-30 inches). The soils are typically deep, well-developed, and old. The cool-season bunchgrasses that dominate the vegetation are adapted to this winter precipitation. Characteristic species are *Pseudoroegneria spicata* and *Festuca idahoensis* with *Hesperostipa comata, Achnatherum scribneri, Leymus condensatus, Leymus cinereus, Koeleria macrantha, Pascopyrum smithii*, or *Poa secunda*. Shrubs commonly found include *Amelanchier alnifolia, Rosa* spp., *Eriogonum* spp., *Symphoricarpos albus*, and *Crataegus douglasii*. Excessive grazing, past land use and invasion by introduced annual species have resulted in a massive conversion to agriculture or shrub-steppe and annual grasslands dominated by *Artemisia* spp. and *Bromus tectorum* or *Poa pratensis*. Remnant grasslands are now typically associated with steep and rocky sites or small and isolated sites within an agricultural landscape.

CES304.792 CONCEPTUAL MODEL

Environment: This once-extensive grassland system occurs in eastern Washington and Oregon, and west-central Idaho, though in very small patches there. In much of its range it is characterized by rolling topography composed of loess hills and plains over basalt plains. The climate of this region has warm-hot, dry summers and cool, wet winters. Annual precipitation is high, 38-76 cm (15-30 inches). The soils are typically deep, well-developed, and old. The cool-season bunch grasses that dominate the vegetation are adapted to this winter precipitation.

Key Processes and Interactions: Fire is the primary disturbance factor. Fires were low intensity due to limited fuel and significant internal spacing between fuel patches. Currently, *Bromus tectorum* and other introduced grasses often invade these habitats after fire, building up a dense fuelbed that creates frequent, high-intensity fires that are lethal to native perennial grasses (Landfire 2007a). The historic frequency was 50 years to maintain this grassland (Landfire 2007a). Extending fires frequency to >50 years leads to increased shrub cover and shrub regeneration (Landfire 2007a).

Threats/Stressors: A massive conversion to agriculture resulting in a scattering of remnant grasslands is now typically associated with steep and rocky sites or small and isolated sites within an agricultural landscape. Conversion of this type has commonly come from agriculture (wheat farming) historically and is nearly complete except for remnants on sites too steep or rocky to farm (Landfire 2007a). Conversion of remnants is the result of altered fire regimes with fire suppression (fire frequency >50 years) that has allowed succession (Landfire 2007a) and conversion to deciduous shrublands and/or invasion and domination of non-native species. Common stressors and threats include fragmentation from agriculture and roads, altered fire regime from fire suppression and indirectly from livestock grazing and fragmentation, and introduction of invasive non-native species (Landfire 2007a). Potential climate change effects could include a loss of remnant patches of this ecosystem, if climate change has the predicted effect of less effective moisture with increasing mean temperature (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse will follow continued fragmentation from agriculture and roads, altered fire regime from fire suppression and indirectly from livestock grazing and introduction of invasive non-native species. This tends to result from severe overgrazing where perennial plant cover is reduced enough to allow invasive non-native species to become established and outcompete and replace the dominant native perennial species and/or invasive non-native annual grasses create fine fuels that increase fire frequency and severity lethal to native grasses and shrubs.

High-severity environmental degradation appears where occurrences tend to be relatively small and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval >50 years (Landfire 2007a). Moderate-severity environmental degradation appears where occurrences are moderate in size and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion. Altered fire regime from fire suppression and reduction of fine fuels by grazing increased the fire-return interval from 20-50 years (Landfire 2007a).

High-severity disruption appears where occurrences have low cover of native grassland species cover. There is may be moderate to high cover of shrubs and/or trees (20-50%) because of fire suppression. Invasive non-native species are abundant (>10% absolute cover). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Moderate-severity disruption appears where occurrences have moderate to low cover of native grassland species. There may be significant cover of shrubs and/or trees (10-20%) because of fire suppression. Invasive non-native species are abundant (3-10% absolute cover. Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES204.087 North Pacific Montane Shrubland

CES204.087 CLASSIFICATION

Concept Summary: This system occurs as small to large patches scattered throughout the North Pacific region, but it is largely absent from the windward sides of the coastal mountains where fires are rare due to very wet climates. It is defined as long-lived seral shrublands that persist for several decades or more after major wildfires, or smaller patches of shrubland on dry sites that are marginal for tree growth and that have typically also experienced fire. This system occurs on ridgetops and upper to middle mountain slopes and is more common on sunny southern aspects. It occurs from about 152 m (500 feet) elevation up to the lower limits of subalpine parkland. Vegetation is mostly deciduous broadleaf shrubs, sometimes mixed with shrub-statured trees or sparse evergreen needleleaf trees. It can also be dominated by evergreen shrubs, especially *Xerophyllum tenax* (usually considered a forb). Species composition is highly variable; some of most common species include *Acer circinatum, Arctostaphylos nevadensis, Acer glabrum, Vaccinium membranaceum, Ceanothus velutinus, Holodiscus discolor, Shepherdia canadensis, Sorbus* spp., and *Rubus parviflorus*. On the west side of the Cascades, *Gaultheria shallon* is an important dominant.

CES306.801 Northern Rocky Mountain Avalanche Chute Shrubland

CES306.801 CLASSIFICATION

Concept Summary: This ecological system occurs in the mountains throughout the northern Rockies, from Wyoming north and west into British Columbia and Alberta. It is composed of a diverse mix of deciduous shrubs or trees, and conifers found on steep, frequently disturbed slopes in the mountains. Occurrences are found on the lower portions and runout zones of avalanche tracks, and slopes are generally steep, ranging from 15-60%. Aspects vary, but are more common where unstable or heavy snowpack conditions frequently occur. Sites are often mesic to wet because avalanche paths are often in stream gullies, and snow deposition can be heavy in the run-out zones. The vegetation consists of moderately dense, woody canopy characterized by dwarfed and damaged conifers and small, deciduous trees/shrubs. Characteristic species include *Abies lasiocarpa, Acer glabrum, Alnus viridis ssp. sinuata* or *Alnus incana, Populus balsamifera ssp. trichocarpa, Populus tremuloides*, or *Cornus sericea*. Other common woody plants include *Paxistima myrsinites, Sorbus scopulina*, and *Sorbus sitchensis*. The ground cover is moderately dense to dense forb-rich, with *Senecio triangularis, Castilleja* spp., *Athyrium filix-femina, Thalictrum occidentale, Urtica dioica, Erythronium grandiflorum, Myosotis asiatica, Veratrum viride, Heracleum maximum*, and *Xerophyllum tenax*. Mosses and ferns are often present.

Related Concepts:

Distribution: This ecological system occurs in the mountains throughout the northern Rockies, from Wyoming north and west into British Columbia and Alberta. It is likely to occur in the Colorado Rockies, but no association from that area have been classified as "avalanche chute" communities.

CES306.040 Northern Rocky Mountain Lower Montane-Foothill-Valley Grassland

CES306.040 CLASSIFICATION

Concept Summary: This ecological system of the northern Rocky Mountains is found at lower montane to foothill elevations in the mountains and large valleys of northeastern Wyoming and western Montana, west through Idaho into the Blue Mountains of Oregon, and north into the Okanagan and Fraser plateaus of British Columbia and the Canadian Rockies. They also occur to the east in the central Montana mountain "islands," foothills, as well as the Rocky Mountain Front and Big and Little Belt ranges. These grasslands are floristically similar to ~Inter-Mountain Basins Big Sagebrush Steppe (CES304.778)$$, ~Columbia Basin Foothill and Canyon Dry Grassland (CES304.993)$$, and ~Columbia Basin Palouse Prairie (CES304.792)$$, but are defined by shorter summers, colder winters, and young soils derived from recent glacial and alluvial material. These grasslands reflect a shift in the precipitation regime from summer monsoons and cold snowy winters found in the Southern Rockies to predominantly dry summers and winter precipitation. In the eastern portion of its range in Montana, winter precipitation is replaced by a spring peak in precipitation. They are found at elevations from 300 to 1650 m, ranging from small meadows to large open parks surrounded by conifers in the lower montane, to extensive foothill and valley grasslands below the lower treeline. In the southern extent, some of these valleys may have been primarily sage-steppe with patches of grassland in the past, but because of land-use history post-settlement (herbicide, grazing, fire, pasturing, etc.), they have been converted to grassland-dominated areas. Soils are relatively deep, fine-textured, often with coarse fragments, and non-saline, often with a microphytic crust. The most important species are cool-season perennial bunchgrasses and forbs (>25% cover), sometimes with a sparse (<10% cover) shrub layer. *Pseudoroegneria spicata, Festuca campestris, Festuca idahoensis*, or *Hesperostipa comata* commonly dominate sites on all aspects of level to moderate slopes and on certain steep slopes with a variety of other grasses, such as *Achnatherum hymenoides, Achnatherum richardsonii, Hesperostipa curtiseta, Koeleria macrantha, Leymus cinereus, Elymus trachycaulus, Bromus inermis var. pumpellianus, Achnatherum occidentale, Pascopyrum smithii*, and other graminoids such as *Carex filifolia* and *Danthonia intermedia*. Other grassland species include *Opuntia fragilis, Artemisia frigida, Carex petasata, Antennaria* spp., and *Selaginella densa*. Important exotic grasses include *Phleum pratense, Bromus inermis*, and *Poa pratensis*. Shrub species may be scattered, including *Amelanchier alnifolia, Rosa* spp., *Symphoricarpos* spp., *Juniperus communis, Artemisia tridentata*, and in Wyoming *Artemisia tripartita ssp. rupicola*. Common associated forbs include *Geum triflorum, Galium boreale, Campanula rotundifolia, Antennaria microphylla, Geranium viscosissimum*, and *Potentilla gracilis*. A soil crust of lichen covers almost all open soil between clumps of grasses; *Cladonia* and *Peltigera* are the most common lichens. Unvegetated mineral soil is commonly found between clumps of grass and the lichen cover. The fire regime of this ecological system maintains a grassland due to rapid fire return that retards shrub invasion or landscape isolation and fragmentation that limits seed dispersal of native shrub species. Fire frequency is variable but is presumed to be generally less than 20 years to reduce shrub cover and maintain grassland. These are extensive grasslands, not grass-dominated patches within the sagebrush shrub-steppe ecological system. *Festuca campestris* is easily eliminated by grazing and does not occur in all areas of this system.

CES306.040 CONCEPTUAL MODEL

Environment: This system is found at lower montane to foothill elevations in the mountains and large valleys of northeastern Wyoming and western Montana, west through Idaho into the Blue Mountains of Oregon, and north into the Okanagan and Fraser plateaus of British Columbia and the Canadian Rockies. They also occur to the east in the central Montana mountain "islands" and foothills, as well as the Rocky Mountain Front Range and Big and Little Belt ranges. These grasslands are floristically similar to ~Inter-Mountain Basins Big Sagebrush Steppe (CES304.778)$$, ~Columbia Basin Foothill and Canyon Dry Grassland (CES304.993)$$, and ~Columbia Basin Palouse Prairie (CES304.792)$$, but are defined by shorter summers, colder winters, and young soils derived from recent glacial and alluvial material. These lower montane and valley grasslands represent a shift in the precipitation regime from summer monsoons and cold snowy winters found in the Southern Rockies to predominantly dry summers and winter precipitation. In the eastern portion of its range in Montana, winter precipitation is replaced by a huge spring peak in precipitation. They are found at elevations from 300 to 1650 m, ranging from small meadows to large open parks surrounded by conifers in the lower montane, to extensive foothill and valley grasslands below the lower treeline. In the southern extent some of these valleys may have been primarily sage-steppe with patches of grassland in the past, but because of land-use history post-settlement (herbicide, grazing, altered fire regime, pasturing, etc.), they have been converted to grassland-dominated areas. Soils are relatively deep, fine-textured, often with coarse fragments, and non-saline, often with a microphytic crust.

Key Processes and Interactions: These are extensive grasslands, not grass-dominated patches within the sagebrush shrub-steppe ecological system. *Festuca campestris* is easily eliminated by grazing and does not occur in all areas of this system. The most droughty sites produce little and discontinuous fuel and likely have much longer fire regimes. Isolation of grassland patches by fragmentation may also limit seed dispersal of native shrubs leading to persistence of the grassland. Soil drought and herbivory retard shrub and tree invasion resulting in a patchy distribution of shrubs and trees when present.

The high-frequency fire regime of this ecological system maintains a grassland due to rapid fire return that retards shrub invasion or landscape isolation and fragmentation that limits seed dispersal of native shrub species. Fire frequency is presumed to be less than 20 years generally. Johnson and Swanson (2005) presumed fire frequency to be less than 35 years in the Blue and Ochoco mountains of Oregon. Wikeem and Wikeem (2004) compiled average fire intervals for interior grasslands in British Columbia which range from 5-20 years. Klenner et al. (2008) research supports a fire regime of predominantly mixed-severity fires that maintain grasslands in the dry forest and grasslands ecotone in the southern interior of British Columbia.

Biological soil crust cover is important in these grasslands. It alters the composition of perennial species and increases the establishment of native disturbance-increasers and annual grasses, particularly *Bromus tectorum* and other exotic annual bromes (WNHP 2011). Crust cover and diversity are greatest where not impacted by trampling, other soil surface disturbance and fragmentation (Belnap et al. 2001, Rosentreter and Eldridge 2002, Tyler 2006).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has three classes in total (LANDFIRE 2007a, BpS 1911390). These are summarized as:

A) Early Development 1 All Structures (5% of type in this stage): Graminoid cover is 0-10%. Post-fire, early-seral community dominated by bunchgrasses and forbs. Herbs and forbs will generally have higher cover than pre-burn and may include milkvetch, balsamroot, lupine, yarrow and prairie junegrass. Cover ranges from 0-10%. In the absence of fire or heavy animal impact, this condition succeeds to a mid-development condition (class B). Age ranges from 0-2 years. Idaho fescue may be present but will recover more slowly than the bluebunch wheatgrass after fire.

B) Mid Development 1 Closed (25% of type in this stage): Graminoid cover is 11-30%. Mid-development with moderate canopy closure dominated by bunchgrasses with forb cover generally higher than pre-burn. Typically lasts 5 years.

C) Late Development 1 Closed (70% of type in this stage): Tree cover is 31-100%. Late-development, closed canopy of grasses and forbs. Bunchgrasses dominate with low densities of shrubs (<10%) in some areas, particularly where this BpS transitions to shrub- or tree-dominated communities. Shrub species may include big sagebrush, buckwheat, ceanothus, bitterbrush and snowberry.

This type has frequent replacement fires (fire regime group II). Most species in this type are fire-adapted and respond favorably to these fire types. Where these systems occur within forested ecosystems, fire frequency will be strongly influenced by the surrounding forest's fire regime (e.g., 10-20 years). Where these systems occur below lower treeline, fire frequencies may be longer (e.g., 20-30 years) (LANDFIRE 2007a, BpS 1911390).

Threats/Stressors: The primary land uses that alter the natural processes of the system are associated with livestock practices, exotic species, fire regime alteration, direct soil surface disturbance, and fragmentation (WNHP 2011). Excessive grazing stresses the system through soil disturbance increasing the probability of establishment of native disturbance-increasers and annual grasses, particularly exotic annual bromes (*Bromus racemosus, Bromus arvensis, Bromus hordeaceus, Bromus tectorum*) and *Ventenata dubia* on more xeric sites and exotic perennial grasses *Bromus inermis, Phleum pratense*, and *Poa pratensis* on more mesic sites (WNHP 2011). Other exotic species threatening this ecological system through invasion and potential complete replacement of native species include *Hypericum perforatum, Potentilla recta, Euphorbia esula*, and knapweeds, especially *Centaurea stoebe ssp.*

micranthos. Persistent grazing will further diminish native perennial cover, expose bare ground, and increase exotics (Johnson and Swanson 2005). Darambazar et al. (2007) cite Johnston (1962) that when bare ground is approximately 15%, reduced infiltration and increased runoff occurs in *Festuca* grassland ecosystems. Fire further stresses livestock-altered vegetation by increasing exposure of bare ground and consequent increases in exotic annuals and decrease in perennial bunchgrass. Grazing effects are usually concentrated in less steep slopes although grazing does create contour trail networks that can lead to addition slope failures. Fire suppression leads to deciduous shrubs (*Symphoricarpos* spp., *Physocarpus malvaceus, Holodiscus discolor*, and *Ribes* spp.) and in some areas trees (*Pseudotsuga menziesii*) to increase (WNHP 2011).

Festuca campestris is highly palatable throughout the grazing season, and summer overgrazing for 2 to 3 years can result in the loss of *Festuca campestris* in the stand. Although a light stocking rate for 32 years did not affect range condition, a modest increase in stocking rate led to a marked decline in range condition. The major change was a measurable reduction in basal area of *Festuca campestris*. Long-term heavy grazing on moister sites can result in a shift to a *Poa pratensis - Phleum pratense* type. *Pseudoroegneria spicata* shows an inconsistent reaction to grazing, increasing on some grazed sites while decreasing on others. It seems to recover more quickly from overgrazing than *Festuca campestris*. It tolerates dormant-period grazing well but is sensitive to defoliation during the growing season. Light spring use or fall grazing can help retain plant vigor. It is particularly sensitive to defoliation in late spring. Exotic species threatening this ecological system through invasion and potential complete replacement of native species include *Bromus arvensis, Potentilla recta, Euphorbia esula*, and all manner of knapweed, especially *Centaurea stoebe ssp. micranthos*.

Conversion of this type has commonly come from invasive by non-native species such as *Bromus tectorum, Centaurea stoebe ssp. micranthos, Centaurea solstitialis, Hypericum perforatum, Poa pratensis*, and *Prunus cerasifera*. These invasive species increase post disturbance including long-term excessive grazing by livestock, or direct soil disturbance from severe trampling by livestock and roads. Altered fire regimes, primarily fire suppression, has allowed succession and conversion to deciduous shrublands (*Symphoricarpos* spp., *Physocarpus malvaceus, Holodiscus discolor, Rosa* spp., and *Ribes* spp.) and in some areas trees (*Pinus ponderosa* or *Pseudotsuga menziesii*) to increase (Wikeem and Wikeem 2004, LANDFIRE 2007a, WNHP 2011).

Common stressors and threats include fragmentation from roads, altered fire regime from fire suppression and indirectly from livestock grazing and fragmentation, and introduction of invasive non-native species (WNHP 2011). Potential climate change effects could include a shift to species more common on hotter, drier southern aspects, if climate change has the predicted effect of less effective moisture with increasing mean temperature (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<25 acres) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from historic including ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval >100 years (LANDFIRE 2007a) resulting in regeneration of trees and shrubs (>5 % cover). Biological soil crust, if present, is found only in protected areas (WNHP 2011). Moderate-severity environmental degradation appears where occurrences are moderate (25-1250 acres) in size and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion. Altered fire regime from fire suppression and reduction of fine fuels by grazing increased the fire-return interval from 40-100 years (LANDFIRE 2007a) resulting in regeneration of trees and shrubs (5-10 % cover). Biological soil crust is present in protected areas and with a minor component elsewhere (WNHP 2011).

High-severity disruption appears where occurrences have low cover of native grassland species (<50% relative cover) (WNHP 2011). There may be significant cover of shrubs and/or trees (>10%) because of fire suppression. Invasive non-native species are abundant (>10% absolute cover) (WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Moderate-severity disruption appears where occurrences have low cover of native grassland species (50-85% relative cover) (WNHP 2011). There may be significant cover of shrubs and/or trees (5-10%) because of fire suppression. Invasive non-native species are abundant (3-10% absolute cover) (WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES306.994 Northern Rocky Mountain Montane-Foothill Deciduous Shrubland

CES306.994 CLASSIFICATION

Concept Summary: This shrubland ecological system is found in the lower montane and foothill regions around the Columbia Basin, and north and east into the northern Rockies, including Alberta and British Columbia. These shrublands typically occur below treeline, within the matrix of surrounding low-elevation grasslands and sagebrush shrublands. They also occur in the ponderosa pine and Douglas-fir zones, but rarely up into the subalpine zone (on dry sites). The shrublands are usually found on steep slopes of canyons and in areas with some soil development, either loess deposits or volcanic clays; they occur on all aspects. Fire, flooding and erosion all impact these shrublands, but they typically will persist on sites for long periods. These communities develop near talus slopes as garlands, at the heads of dry drainages, and toeslopes in the moist shrub-steppe and steppe zones. *Physocarpus malvaceus, Prunus emarginata, Prunus virginiana, Rosa* spp., *Rhus glabra, Acer glabrum, Amelanchier alnifolia, Symphoricarpos albus, Symphoricarpos oreophilus*, and *Holodiscus discolor* are the most common dominant shrubs, occurring alone or any combination. In the Alberta's Upper and Lower Foothills subregions, common shrubs include *Arctostaphylos uva-ursi, Juniperus communis, Symphoricarpos* spp., *Amelanchier alnifolia*, and *Rosa* spp. *Rubus parviflorus* and *Ceanothus velutinus* are other important shrubs in this system, being more common in montane occurrences than in subalpine situations. Occurrences in central and eastern Wyoming can include *Artemisia tridentata ssp. vaseyana* and *Cercocarpus montanus*, but neither of these are dominant, and where they occur, the stands are truly mixes of shrubs, often with *Amelanchier alnifolia, Prunus virginiana*, and others being the predominant taxa. In moist areas, *Crataegus douglasii* can be common. *Shepherdia canadensis* and *Spiraea betulifolia* can be abundant in some cases but also occur in ~Northern Rocky Mountain Subalpine Deciduous Shrubland (CES306.961)$$. *Festuca idahoensis, Festuca campestris, Calamagrostis rubescens, Carex geyeri, Koeleria macrantha, Pseudoroegneria spicata*, and *Poa secunda* are the most important grasses. *Achnatherum thurberianum* and *Leymus cinereus* can be locally important. *Poa pratensis* and *Phleum pratense* are common introduced grasses. *Geum triflorum, Potentilla gracilis, Lomatium triternatum, Balsamorhiza sagittata*, and species of *Eriogonum, Phlox*, and *Erigeron* are important forbs.

CES306.961 Northern Rocky Mountain Subalpine Deciduous Shrubland

CES306.961 CLASSIFICATION

Concept Summary: This shrubland ecological system is found within the zone of continuous forest in the upper montane and lower subalpine zones of the northern Rocky Mountains. Soils tend to be moist to wet. Stands are typically initiated by fires and will persist on sites for long periods because of repeated burns and changes in the presence of volatile oils in the soil which impedes tree regeneration. *Menziesia ferruginea, Rhamnus alnifolia, Ribes lacustre, Rubus parviflorus, Alnus viridis, Rhododendron albiflorum, Sorbus scopulina, Sorbus sitchensis, Vaccinium myrtillus, Vaccinium scoparium*, and *Vaccinium membranaceum* are the most common dominant shrubs, occurring alone or in any combination. Other shrubs can include *Shepherdia canadensis* and *Ceanothus velutinus*, but these also commonly occur in ~Northern Rocky Mountain Montane-Foothill Deciduous Shrubland (CES306.994)$$. *Rubus parviflorus* and *Ceanothus velutinus* are occasionally present, being more common in montane shrublands than in this subalpine system. Important forbs include *Xerophyllum tenax, Chamerion angustifolium*, and *Pteridium aquilinum*, reflecting the mesic nature of many of these shrublands.

Related Concepts:

Distribution: This system is found in the subalpine and upper montane zones in the northern Rockies, south and west around the Columbia Basin.

CES306.806 Northern Rocky Mountain Subalpine-Upper Montane Grassland

CES306.806 CLASSIFICATION

Concept Summary: This is an upper montane to subalpine, high-elevation, lush grassland system dominated by perennial grasses and forbs on dry sites, particularly south-facing slopes. It is most extensive in the Canadian Rockies portion of the Rocky Mountain cordillera, extending south into western Montana, eastern Oregon, eastern Washington and Idaho. Subalpine dry grasslands are small meadows to large open parks surrounded by conifer trees but lack tree cover within them. In general, soil textures are much finer, and soils are often deeper under grasslands than in the neighboring forests. Grasslands, although composed primarily of tussock-forming species, do exhibit a dense sod that makes root penetration difficult for tree species. Disturbance such as fire also plays a role in maintaining these open grassy areas. Typical dominant species include *Leymus innovatus, Koeleria macrantha, Festuca campestris, Festuca idahoensis, Festuca viridula, Achnatherum occidentale, Achnatherum richardsonii, Bromus inermis var. pumpellianus, Elymus trachycaulus, Phleum alpinum, Trisetum spicatum*, and a variety of Carices, such as *Carex hoodii, Carex obtusata*, and *Carex scirpoidea*. Important forbs include *Lupinus argenteus var. laxiflorus, Potentilla diversifolia, Potentilla flabellifolia, Fragaria virginiana*, and *Chamerion angustifolium*. This system is similar to ~Northern Rocky Mountain Lower Montane-Foothill-Valley Grassland (CES306.040)$$ but is found at higher elevations and is more often composed of species of *Festuca, Achnatherum*, and/or *Hesperostipa* with additional floristic components of more subalpine taxa. Occurrences of this system are often more forb-rich than ~Southern Rocky Mountain Montane-Subalpine Grassland (CES306.824)$$.

M168. Rocky Mountain-Vancouverian Subalpine-High Montane Mesic Meadow

CES206.940 Mediterranean California Subalpine Meadow

CES206.940 CLASSIFICATION

Concept Summary: This ecological system occurs at subalpine and montane elevations where finely textured soils, snow deposition, or windswept dry conditions limit tree establishment. It is typically found above 3000 m (9100 feet) elevation in California, western Nevada and Oregon. The soils in these sites can be seasonally moist to saturated in the spring but, if so, will dry out later in the growing season, and overall these are mesic to dry meadows, not wet. Characteristic plant species include *Achillea millefolium var. occidentalis, Artemisia rothrockii, Oreostemma alpigenum, Calamagrostis breweri, Cistanthe umbellata, Carex exserta, Eriogonum incanum, Horkeliella purpurascens*, and *Trisetum spicatum*. Burrowing mammals can increase the forb diversity. Herbs can include *Carex subnigricans, Carex vernacula, Calamagrostis breweri, Antennaria media, Potentilla drummondii, Lewisia pygmaea, Erigeron algidus, Lupinus lepidus, Dodecatheon alpinum*, and *Solidago multiradiata*. Wet meadows of *Carex, Calamagrostis, Camassia, Eleocharis, Juncus, Veratrum*, etc. from montane to subalpine are treated in ~Temperate Pacific Subalpine-Montane Wet Meadow (CES200.998)$$.

CES204.099 North Pacific Alpine and Subalpine Dry Grassland

CES204.099 CLASSIFICATION

Concept Summary: This high-elevation, grassland system is dominated by perennial grasses and forbs found on dry sites, particularly south-facing slopes, typically imbedded in or above subalpine forests and woodlands. Disturbance such as fire also plays a role in maintaining these open grassy areas, although drought and exposed site locations are primary characteristics limiting tree growth. It is most extensive in the eastern Cascades, although it also occurs in the Olympic Mountains. Alpine and subalpine dry grasslands are small openings to large open ridges above or drier than high-elevation conifer trees. In general, soil textures are much finer, and soils are often deeper under grasslands than in the neighboring forests. These grasslands, although composed primarily of tussock-forming species, do exhibit a dense sod that makes root penetration difficult for tree species. Typical dominant species include *Festuca idahoensis ssp. idahoensis, Festuca viridula*, and *Festuca idahoensis ssp. roemeri* (the latter occurring only in the Olympic Mountains). This system is similar to ~Northern Rocky Mountain Subalpine-Upper Montane Grassland (CES306.806)$$, differing in its including dry alpine habitats, more North Pacific floristic elements, greater snowpack, and higher precipitation.

CES204.100 North Pacific Montane Grassland

CES204.100 CLASSIFICATION

Concept Summary: This ecological system includes open dry meadows and grasslands on the west side of the Cascades Range and northern Sierra Nevada. They occur in montane elevations up to 3500 m (10,600 feet). Soils tend to be deeper and more well-drained than the surrounding forest soils. Soils can resemble prairie soils in that the A-horizon is dark brown, relatively high in organic matter, slightly acidic, and usually well-drained. Dominant species include *Elymus* spp., *Festuca idahoensis*, and *Nassella cernua*. These large-patch grasslands are intermixed with matrix stands of red fir, lodgepole pine, and dry-mesic mixed conifer forests and woodlands.

CES306.829 Rocky Mountain Subalpine-Montane Mesic Meadow

CES306.829 CLASSIFICATION

Concept Summary: This Rocky Mountain ecological system is restricted to sites from lower montane to subalpine where finely textured soils, snow deposition, or windswept dry conditions limit tree establishment. Many occurrences are small patch in spatial character, and are often found in mosaics with woodlands, more dense shrublands, or just below alpine communities. It is typically found above 2000 m in elevation in the southern part of its range and above 600 m in the northern part. These upland communities occur on gentle to moderate-gradient slopes and relatively moist habitats. The soils are typically seasonally moist to saturated in the spring, but if so will dry out later in the growing season. These sites are not as wet as those found in ~Rocky Mountain Alpine-Montane Wet Meadow (CES306.812)$$. Vegetation is typically forb-rich, with forbs often contributing more to overall herbaceous cover than graminoids. Some stands are composed of dense grasslands, these often being taxa with relatively broad and soft blades, but where the moist habitat promotes a rich forb component. Important taxa include *Erigeron* spp., Asteraceae spp., *Mertensia* spp., *Penstemon* spp., *Campanula* spp., *Lupinus* spp., *Solidago* spp., *Ligusticum* spp., *Thalictrum occidentale, Valeriana sitchensis, Rudbeckia occidentalis, Balsamorhiza sagittata*, and *Wyethia* spp. Important grasses include *Deschampsia cespitosa, Koeleria macrantha*, perennial *Bromus* spp., and a number of *Carex* species. *Dasiphora fruticosa ssp. floribunda* and *Symphoricarpos* spp. are occasional but not abundant. Burrowing mammals can increase the forb diversity.

CES306.824 Southern Rocky Mountain Montane-Subalpine Grassland

CES306.824 CLASSIFICATION

Concept Summary: This Rocky Mountain ecological system typically occurs between 2200 and 3000 m elevation on flat to rolling plains and parks or on lower sideslopes that are dry, but it may extend up to 3350 m on warm aspects. Soils resemble prairie soils in that the A-horizon is dark brown, relatively high in organic matter, slightly acidic, and usually well-drained. An occurrence usually consists of a mosaic of two or three plant associations with one of the following dominant bunchgrasses: *Danthonia intermedia, Danthonia parryi, Festuca idahoensis, Festuca arizonica, Festuca thurberi, Muhlenbergia filiculmis*, or *Pseudoroegneria spicata*. The subdominants include *Muhlenbergia montana, Bouteloua gracilis*, and *Poa secunda*. These large-patch grasslands are intermixed with matrix stands of spruce-fir, lodgepole pine, ponderosa pine, and aspen forests. In limited circumstances (e.g., South Park in Colorado), they form the "matrix" of high-elevation plateaus. Small-patch representations of this system do occur at high elevations of the Trans-Pecos where they present as occurrences of ~*Festuca arizonica - Blepharoneuron tricholepis* Grassland (CEGL004508)$$. These occurrences often occupy sites adjacent to ~Madrean Oriental Chaparral (CES302.031)$$.

Related Concepts:

Distribution: This system occurs between 2200 and 3000 m (7200-10,000 feet) elevation in the Colorado Rockies. Where it transitions in Wyoming to ~Northern Rocky Mountain Subalpine-Upper Montane Grassland (CES306.806)$$ still needs to be clarified. Southern outliers of this system also occur in small patches in high elevations of the mountains of the Trans-Pecos of Texas.

Description Author: L. Elliott, J. Teague and K.A. Schulz

CES306.824 CONCEPTUAL MODEL

Environment: This Rocky Mountain ecological system typically occurs between 2200 and 3000 m elevation on flat to rolling plains and parks or on lower sideslopes that are dry, but it may extend up to 3350 m on warm aspects. These are typically grasslands of forest openings and park-like expanses in the montane and subalpine coniferous forests. Although smaller montane grasslands are scattered throughout the southern Rocky Mountains and high plateaus in the Colorado Plateaus, the largest occurrence by far (over a million acres) is on the valley floor of South Park in central Colorado. Soils resemble prairie soils in that the A-horizon is dark brown, relatively high in organic matter, slightly acidic, and usually well-drained.

Key Processes and Interactions: This system is found in areas that inhibit the establishment of woody species. A variety of factors, including fire, wind, cold-air drainage, climatic variation, soil properties, fluctuating summer snowbanks (drought sequences), snow avalanches, competition with graminoids, and grazing, have been proposed as mechanisms that maintain open grasslands and parks in forest surroundings. Observations and repeat photography studies in sites throughout the southern Rocky Mountains indicate that trees do invade open areas, but that the mechanisms responsible for this trend may differ from site to site. Anderson and Baker (2005) discounted fire suppression as the cause of tree invasions in Wyoming's Medicine Bow Mountains, concluding that edaphic conditions were the most likely factor limiting tree establishment. In the San Juan Mountains of southeastern Colorado, Zier and Baker (2006) also found that the probability of tree invasion varied with forest type. Climatic variation, fire exclusion, and grazing appear to interact with edaphic factors to facilitate or hinder tree invasion in these grasslands (Zier and Baker 2006). In the Gunnison Basin, Schauer et al. (1998) identified seedling mortality as the primary factor preventing invasions of Engelmann spruce, but did not determine if this was due to competition from established grassland plants, or to edaphic conditions. The work of Coop and Givnish (2007) in the Jemez Mountains of northern New Mexico suggests that both changing disturbance regimes and climatic factors are linked to tree establishment in some montane grasslands. Pocket gophers (*Thomomys* spp.) are a widespread source of disturbance in montane-subalpine grasslands. The activities of these burrowing mammals result in increased aeration, mixing of soil, and infiltration of water, and are an important component of normal soil formation and erosion (Ellison 1946). In addition, Cantor and Whitham (1989) found that below-ground herbivory of pocket gophers restricted establishment of aspen to rocky areas in Arizona mountain meadows. The interaction of multiple factors indicates that management for the maintenance of these montane and subalpine grasslands may be complex.

Historically, much of the montane grasslands where this system occurs were heavily grazed by livestock, primarily cattle and sheep (also at subalpine elevation) (Shepherd 1975). Under moderate grazing, the shorter grasses such *Muhlenbergia filiculmis* may have had a competitive advantage over the taller and more palatable *Festuca arizonica* (West 1992). Season of use is also important. In stands with cool-season *Festuca arizonica* or *Hesperostipa comata* and warm-season *Muhlenbergia montana*, fall grazing will favor the cool-season grasses over the later-blooming, warm-season *Muhlenbergia montana* (Clary 1978). The reverse is true if grazing is always limited to late summer. Overgrazing will reduce or eliminate *Festuca arizonica, Hesperostipa comata, Muhlenbergia filiculmis, Muhlenbergia montana*, and the other palatable species, leaving the more grazing-tolerant *Bouteloua gracilis* and less palatable plants such as *Hymenoxys, Artemisia*, and *Chrysothamnus* species to dominate the site (West 1992). Clary (1978) reported that complete natural recovery of montane *Festuca arizonica* may require over 100 years, based on areas where recovery had reached only the "half-shrub" stage after 10 years. Because of the long time needed for recovery, much of the range may be in a seral state. If the range is properly managed, *Muhlenbergia* and *Festuca arizonica* grasslands could potentially become more common.

Higher-elevation grasslands are dominated by *Festuca thurberi* and typically have sharp ecotones with adjacent *Picea engelmannii*- and *Abies lasiocarpa*-dominated subalpine forests. There is rarely any invasion by tree seedlings in the adjacent grasslands. These high-elevation meadows are typically dry with southern or western aspects. The soils are deep and well-developed, typical of sites with long histories of being grassland. They may need catastrophic disturbance, such as forest-destroying crown fire, to be created. It is unclear how these grasslands were maintained in the subalpine forest zone; however, it is thought to be by a combination of factors such as herbivory, fire, deep soils, early summer drought and competition from grass species (Moir 1967, Andrews 1983). In addition, south- and west-facing clearcuts are often difficult to reforest because seedlings are damaged by full sun. The ecotones between stands adjacent to *Populus tremuloides*-dominated subalpine forests are not as sharp because the forest understory consists of the same graminoid and forb species (Andrews 1983).

Where the soil is thinner and rockier in these subalpine parks, *Danthonia parryi* becomes the dominant species with *Festuca thurberi* and *Artemisia* spp. subdominant (Andrews 1983). The spread of the exotic species *Poa pratensis* and *Taraxacum officinale* in subalpine parks is likely from heavy grazing by livestock (Moir 1967, Andrews 1983). These species are more common in heavily grazed bottomlands and near trails in the uplands (Moir 1967).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has three classes in total (LANDFIRE 2007a, BpS 2811460). These are summarized as:

A) Early Development 1 All Structures (graminoid-dominated - 10% of type in this stage): Herb cover is 0-30%. Low cover and frequency of Thurber fescue, Arizona fescue, sheep fescue, mountain muhly, timber/Parry's oatgrass, Kentucky bluegrass, nodding brome, tufted hairgrass, and various sedges in moist (concave) sites. Pine dropseed is common.

B) Mid Development 1 Closed (graminoid-dominated - 30% of type in this stage): Herb cover is 31-70%. Thurber fescue, Arizona fescue, sheep fescue, mountain muhly, timber/Parry's oatgrass, Kentucky bluegrass, nodding brome, tufted hairgrass, and various sedges in moist (concave) sites.

C) Late Development 1 Closed (graminoid-dominated - 50% of type in this stage): Tree cover is 71-100%. Thurber fescue, Arizona fescue, sheep fescue, mountain muhly, timber/Parry's oatgrass, Kentucky bluegrass, nodding brome, tufted hairgrass, and various sedges in moist (concave) sites.

Predicted historic stand-replacement fire regime of approximately 30-60 years based upon historic photographic analysis (B. Johnston-R2 pers. comm. 2018) and inference from mean/max and min fire regimes of adjacent forest types (*Pinus ponderosa)* 3-12 years, *Abies concolor/Pseudotsuga menziesii* 14-46 years, *Picea engelmannii / Abies lasiocarpa* 60-180+ years). Anthropogenic (pre-European cf.) fire use ignitions 5-15 years, current regime greater than 60 years in montane and 100 years in subalpine systems (LANDFIRE 2007a, BpS 2811460).

Threats/Stressors: The primary land uses that alter the natural processes of these communities are associated with livestock grazing. Excessive grazing stresses the system through soil disturbance, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and invasive exotic species, particularly *Bromus inermis, Cardaria draba, Cirsium vulgare, Leucanthemum vulgare, Linaria dalmatica*, and *Poa pratensis*. Other concerns are fragmentation from roads and ORVs, altered fire or altered hydrological regimes.

M049. Southern Rocky Mountain Montane Shrubland

CES306.818 Rocky Mountain Gambel Oak-Mixed Montane Shrubland

CES306.818 CLASSIFICATION

Concept Summary: This ecological system occurs in the mountains, plateaus and foothills of the southern Rocky Mountains and Colorado Plateau, including the Uinta and Wasatch ranges and the Mogollon Rim. These shrublands are most commonly found along dry foothills, lower mountain slopes, and at the edge of the western Great Plains from approximately 2000 to 2900 m in elevation and are often situated above pinyon-juniper woodlands. Substrates are variable and include soil types ranging from calcareous, heavy, fine-grained loams to sandy loams, gravelly loams, clay loams, deep alluvial sand, or coarse gravel. The vegetation is typically dominated by *Quercus gambelii* alone or codominant with *Amelanchier alnifolia, Amelanchier utahensis, Artemisia tridentata, Cercocarpus montanus, Prunus virginiana, Purshia stansburiana, Purshia tridentata, Robinia neomexicana, Symphoricarpos oreophilus*, or *Symphoricarpos rotundifolius*. There may be inclusions of other mesic montane shrublands with *Quercus gambelii* absent or as a relatively minor component. This ecological system intergrades with the lower montane-foothills shrubland system and shares many of the same site characteristics. Density and cover of *Quercus gambelii* and *Amelanchier* spp. often increase after fire. In Texas, this system includes high mountain shrublands dominated by the deciduous oak species *Quercus gambelii*. This species often forms nearly monotypic shrublands, but other species present may include *Cercocarpus montanus, Robinia neomexicana, Symphoricarpos oreophilus*, and *Rhus trilobata*. These shrubland patches represent southern outliers of the extensive and diverse system further north.

Related Concepts:

CES306.818 CONCEPTUAL MODEL

Environment: This ecological system typically occupies the lower slope positions of the foothill and lower montane zones. They may occur on level to steep slopes, cliffs, escarpments, rimrock slopes, rocky outcrops, and scree slopes. Climate is semi-arid and characterized by mostly hot-dry summers with mild to cold winters and annual precipitation of 25 to 70 cm. Precipitation mostly occurs as winter snows but may also consist of some late-summer rains. Soils are typically poorly developed, rocky to very rocky, and well-drained. Parent materials include alluvium, colluvium, and residuum derived from igneous, metamorphic, or sedimentary rocks such as granite, gneiss, limestone, quartz, monzonite, rhyolite, sandstone, schist, and shale. Although this is a shrub-dominated system, some trees may be present. In older occurrences, or occurrences on mesic sites, some of the shrubs may acquire tree-like sizes. Adjacent communities often include woodlands or forests of *Abies concolor, Pinus ponderosa, Pseudotsuga menziesii*, or *Populus tremuloides* at higher elevations, and *Pinus edulis* and *Juniperus osteosperma* on the lower and adjacent elevations. Shrublands of *Artemisia tridentata* or grasslands of *Festuca* sp., *Stipa* sp., or *Pseudoroegneria* sp. may also be present at the lower elevations. In Texas, this system primarily occurs on limestone formations on slopes and rolling landforms of the Trans-Pecos mountains, on Limestone Hill and Mountain and High Montane Conifer Ecological Sites.
Key Processes and Interactions: Fire typically plays an important role in this system, causing die-back of the dominant shrub species in some areas, promoting stump sprouting of the dominant shrubs in other areas, and controlling the invasion of trees into the shrubland system. Natural fires typically result in a system with a mosaic of dense shrub clusters and openings dominated by herbaceous species. In some instances, these associations may be seral to the adjacent *Pinus ponderosa, Abies concolor*, and *Pseudotsuga menziesii* woodlands and forests. Ream (1964) noted that on many sites in Utah, Gambel oak may be successional and replaced by bigtooth maple (*Acer grandidentatum*).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has four classes in total (LANDFIRE 2007a, BpS 2311070). These are summarized as:

A) Early Development 1 All Structures (shrub-dominated - 5% of type in this stage): Shrub cover is 0-20%. Post-replacement sprouts to approximately 2 feet high. Dense resprouting with high number of stems/acre. Abundant grass and forb cover.

B) Mid Development 1 Closed (tree-dominated - 50% of type in this stage): Tree cover is 21-70%. Oak 3-6 feet tall to 3 inches dbh. There will be some stem mortality due to competition and self-thinning, with slight decrease in understory species due to shading. Grasses and forbs declining.

C) Mid Development 1 Open (tree-dominated - 15% of type in this stage): Tree cover is 51-70%. This class has >6 feet tall and >3 inches dbh oak. Small stands <30 m across usually scattered throughout a grassland or shrub type (Brown 1958).

D) Late Development 1 Closed (shrub-dominated - 30% of type in this stage): Tree cover is 71-100%. This class has >6 feet tall and 3 inches dbh. Nearly continuous stand two or more hectares in size with only occasional openings (Brown 1958).

Fire regime group IV or III. The primary disturbance mechanism is replacement fire, resulting in >75% top-kill. Gambel oak responds to fire with vigorous sprouting from the root crown. Larger forms may survive low-intensity surface fire. Extended drought also contributes to disturbance (LANDFIRE 2007a, BpS 2311070).
Threats/Stressors: Threats and stressors to this shrubland system include altered fire regime, fragmentation from roads and development near urban areas, mining, invasive species, livestock grazing disturbance or other human disturbances (CNHP 2010). These disturbances can cause significant soil loss/erosion and negatively impact the water quality within the immediate watershed. Invasive exotic species such as *Bromus tectorum* can become abundant in disturbed areas and alter floristic composition and provide fine fuels that many increase fire frequency and severity beyond the natural range of variation.

CES306.822 Rocky Mountain Lower Montane-Foothill Shrubland

CES306.822 CLASSIFICATION

Concept Summary: This ecological system is found in the foothills, canyon slopes and lower mountains of the Rocky Mountains and on outcrops and canyon slopes in the western Great Plains. It ranges from southern New Mexico, extending north into Wyoming, and west into the Intermountain West region. These shrublands occur between 1500 and 2900 m elevation and are usually associated with exposed sites, rocky substrates, and dry conditions, which limit tree growth. It is common where *Quercus gambelii* is absent, such as the northern Colorado Front Range and in drier foothills and prairie hills. This system is generally drier than ~Rocky Mountain Gambel Oak-Mixed Montane Shrubland (CES306.818)$$ but may include mesic montane shrublands where *Quercus gambelii* does not occur. *Cercocarpus montanus* dominates pure stands in parts of Wyoming and Colorado. Scattered trees or inclusions of grassland patches or steppe may be present, but the vegetation is typically dominated by a variety of shrubs, including *Amelanchier utahensis, Cercocarpus montanus, Purshia tridentata, Rhus trilobata, Ribes cereum, Symphoricarpos oreophilus*, or *Yucca glauca*. Grasses are represented as species of *Muhlenbergia, Bouteloua, Hesperostipa*, and *Pseudoroegneria spicata*. Fires play an important role in this system as the dominant shrubs usually have a severe die-back, although some plants will stump sprout. *Cercocarpus montanus* requires a disturbance such as fire to reproduce, either by seed sprout or root-crown sprouting. Fire suppression may have allowed an invasion of trees into some of these shrublands, but in many cases sites are too xeric for tree growth. In Wyoming, stands where *Cercocarpus montanus* is a component of mixed shrublands are placed in ~Northern Rocky Mountain Montane-Foothill Deciduous Shrubland (CES306.994)$$.

CES306.822 CONCEPTUAL MODEL

Environment: This ecological system is found in the foothills, canyon slopes and lower mountains of the Rocky Mountains and on outcrops and canyon slopes in the western Great Plains. It ranges from southern New Mexico, extending north into Wyoming, and west into the Intermountain West region. These shrublands occur between 1500 and 2900 m elevation and are usually associated with exposed sites, rocky substrates, and dry conditions, which limit tree growth. It is common where *Quercus gambelii* is absent, such as the northern Colorado Front Range and in drier foothills and prairie hills.

Key Processes and Interactions: Fires play an important role in this system as the dominant shrubs usually have a severe die-back, although some plants will stump sprout. *Cercocarpus montanus* requires a disturbance such as fire to reproduce, either by seed sprout or root-crown sprouting. Fire suppression may have allowed an invasion of trees into some of these shrublands, but in many cases sites are too xeric for tree growth.

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2810860). These are summarized as:

A) Early Development 1 All Structures (grass-dominated - 15% of type in this stage): Grass cover is 0-10%. Early succession, usually after moderately frequent stand-replacement fires; grasses and forbs dominant.

B) Mid Development 1 Closed (shrub-dominated - 15% of type in this stage): Shrub cover is 11-80%. Greater than 10% shrub cover (i.e., line intercept method) by weakly sprouting and seed-producing shrubs; grasses/forbs dominant in scattered openings.

C) Mid Development 1 Open (10% of type in this stage): Shrub cover is 0-10%, with grasses/forbs dominant in extensive openings.

D) Late Development 1 Open (10% of type in this stage): Shrub cover is 0-10%, with over-matured shrubs as patchy dominant overstory (e.g., in rock outcrops); grasses/forbs dominant in extensive openings.

E) Late Development 1 Closed (shrub-dominated - 50% of type in this stage): Shrub cover is 11-80%. Greater than 10% shrub cover; all age classes present but dominated by over-matured shrubs (e.g., in rocky draws).

Historically, this type may have been in a Fire Regime IV or II -- primarily moderate-interval (e.g., 20-50 years) stand-replacement fires in the shrub-dominated layer. Nearly all the dominant species in this BpS have the capability to resprout after disturbance (LANDFIRE 2007a, BpS 2810860).

Threats/Stressors: Threats and stressors to this shrubland system include altered fire regime, fragmentation from roads and development near urban areas, mining, invasive species, livestock grazing disturbance or other human disturbances (CNHP 2010). These disturbances can cause significant soil loss/erosion and negatively impact the water quality within the immediate watershed. Invasive exotic species such as *Bromus tectorum* can become abundant in disturbed areas and alter floristic composition and provide fine fuels that many increase fire frequency and severity beyond the natural range of variation.

M050. Southern Vancouverian Lowland Grassland & Shrubland

CES206.941 California Northern Coastal Grassland

CES206.941 CLASSIFICATION

Concept Summary: This ecological system is found in discontinuous patches below 300 m (1000 feet) elevation from San Francisco Bay north into Oregon, on coastal terraces and ridgeline balds in the Coast Ranges and Klamath Mountains. Small patches have been documented as far south as Santa Barbara and San Luis Obispo counties. It has a similar distribution to coastal shrublands (~Northern California Coastal Scrub (CES206.932)$$) in areas that receive more rainfall than other California grasslands of the interior or southern coastal California. In recent centuries, these were fire-dominated systems, and there is a known history of Native American use of fire in these areas. While still present, annual grasses and forbs are not as prevalent in these grasslands as elsewhere in California. With fire suppression, *Baccharis pilularis* and other shrub components of north coastal scrub often invade and can replace these grasslands with scrub-dominated systems. *Agrostis* spp., *Bromus carinatus, Calamagrostis nutkaensis, Danthonia californica, Festuca rubra, Festuca idahoensis, Deschampsia cespitosa, Koeleria macrantha, Trisetum canescens*, and perennial forbs such as *Iris douglasiana, Sisyrinchium bellum, Grindelia hirsutula*, and *Sanicula arctopoides* are characteristic.

Related Concepts:

- Coastal Prairie (214) (Shiflet 1994) **>**

Distribution: This system is found below 300 m (1000 feet) elevation from San Francisco Bay (and possibly farther south) north into Oregon, on coastal terraces and ridgeline balds in the Coast Ranges and Klamath Mountains.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.941 CONCEPTUAL MODEL

Environment: This ecosystem occurs on coastal terraces and ridgeline balds in the Coast Ranges in small patches in areas that receive more rainfall than the Central Valley grasslands or those of southern coastal California (south of Santa Barbara County), and wherever the cooling influence of the Pacific Ocean moderates summer drought (Ford and Hayes 2007). Soils are rich and moist, on terraces on the coast line and balds on inland ridges and hilltops (Sawyer et al. 2009).

Key Processes and Interactions: Coastal prairies are maintained by salt spray that limits woody growth, and burning, likely annual ignitions by Native Americans (Stuart and Stephens 2006). Historical frequent fire, salt-laden wind, and windy ridgetops inhibit forest development in these areas (Franklin and Dyrness 1973, as cited in Sawyer et al. 2009). Fire is a useful management tool for control of non-native invasive species (Sawyer et al. 2009).

Threats/Stressors: Conversion of this type has commonly come from road building and residential development. Common stressors and threats include urban and agricultural development, succession of woody plant communities, intensive continual livestock grazing, non-native grass invasions and fire suppression (Ford and Hayes 2007, Sawyer et al. 2009)

In northwestern California, regional climate models project mean annual temperature increases of 1.7-1.9°C (3.06-3.42°F) by 2070 (PRBO Conservation Science 2011). Currently, there is greater uncertainty about the precipitation projections than for temperature in northwestern California, but with some evidence for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Increased fire frequency with warmer temperatures, lower precipitation may result in drier, more flammable fuels. Less rainfall and higher temperatures may shift species composition, to more drought-tolerant species, which may favor non-native herbaceous species. In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from lack of fire, complete take over by exotic species, and continuous heavy grazing resulting in loss of native bunch grasses. Environmental Degradation (based on conservation and restoration criteria in Ford and Hayes 2007): Any of these conditions or combination of conditions rates as high-severity: Development encroachment into and/or adjacent to occurrence; fire suppression such that no prescribed or natural fires have occurred in several years (>15), or lack of any grazing that may mimic this issue; however fire may not control invasive scrub species once they become established; continual heavy grazing has been known to degrade occurrences. Any of these conditions or combination of conditions rates as moderate-severity: Development encroachment in surrounding landscape, prescribed or natural fires have occurred within least 10 years; grazing has been periodically too heavy.

Disruption of Biotic Processes (based on conservation and restoration criteria in Ford and Hayes 2007): Any of these conditions or combination of conditions rates as high-severity: Native grasses are low in their relative cover (<15% cover), not all expected native species are present (although there is no data on reference condition composition and cover values); non-native species are abundant in their absolute cover; woody species encroachment cover is evident and abundant, and woody species are taller than native herbaceous species. Any of these conditions or combination of conditions rates as moderate-severity: Native grasses are abundant (>15%) in their relative cover but not all expected native species are present (although there is no data on reference condition composition and cover values), non-native species are present and abundant in areas; woody species encroachment is present and woody species are of equal height to the native herbaceous species.

CES204.089 North Pacific Herbaceous Bald and Bluff

CES204.089 CLASSIFICATION

Concept Summary: This system consists of mostly herbaceous-dominated areas located primarily on shallow soils from eastern Vancouver Island and the Georgia Basin south to at least the southern end of the Willamette Valley and adjacent slopes of the Coast Ranges and western Cascades, excluding areas adjacent to the outer coastline (hypermaritime climate). They are largely, if not completely, absent from the windward side of Vancouver Island, the Olympic Peninsula, and the Coast Ranges of Washington and Oregon. Due to shallow soils, steep slopes, sunny aspect, and/or upper slope position, these sites are dry and marginal for tree establishment and growth except in favorable microsites. Rock outcrops are a typical small-scale feature within balds and are considered part of this system. Sites with many favorable microsites can have a "savanna" type structure with a sparse tree layer of *Pseudotsuga menziesii* or, less commonly, *Quercus garryana*. The climate is relatively dry to wet (20 to perhaps 100 inches annual precipitation), always with a distinct dry summer season when these sites usually become droughty enough to limit tree growth and establishment. Seeps are a frequent feature in many balds and result in vernally moist to wet areas within the balds that dry out by summer. Vegetation differences are associated with relative differences in soil moisture. Most sites have little snowfall, but sites in the *Abies amabilis* zone (montane *Tsuga heterophylla* in British Columbia) can have significant winter snowpacks. Snowpacks would be expected to melt off sooner on these sunny aspect sites than surrounding areas. Fog and salt spray probably have some influence (but less than in the hypermaritime) on exposed slopes or bluffs adjacent to saltwater shorelines in the Georgia Basin, where soils on steep coastal bluffs sometime deviate from the norm and are deep glacial deposits. Slightly to moderately altered serpentine soils occur rarely. Fires, both lightning-ignited and those ignited by Native Americans, undoubtedly at least occasionally burn all these sites. Lower elevation sites in the Georgia Basin, Puget Trough, and Willamette Valley probably were burned somewhat more frequently and in some cases intentionally. Because of this fire history, the extent of this system has declined locally through tree invasion and growth, as areas formerly maintained herbaceous by burning have filled in with trees.

Grasslands are the most prevalent vegetation cover, though forblands are also common especially in the mountains. Dwarf-shrublands occur commonly, especially in mountains or foothills, as very small patches for the most part, usually in a matrix of herbaceous vegetation, most often near edges. Dominant or codominant native grasses include *Festuca idahoensis ssp. roemeri, Danthonia californica, Achnatherum lemmonii, Festuca rubra* (near saltwater), and *Koeleria macrantha*. Forb diversity can be high. Some typical codominant forbs include *Camassia quamash, Camassia leichtlinii, Triteleia hyacinthina, Mimulus guttatus* (seeps), *Plectritis congesta, Lomatium martindalei, Allium cernuum*, and *Phlox diffusa* (can be considered a dwarf-shrub). Important dwarf-shrubs are *Arctostaphylos uva-ursi, Arctostaphylos nevadensis*, and *Juniperus communis*. Small patches and strips dominated by the shrub *Arctostaphylos columbiana* are a common feature nested within herbaceous balds. Significant portions of some balds, especially on rock outcrops, are dominated by bryophytes (mosses) and to a lesser degree lichens.

Related Concepts:

Distribution: This system occurs in the Willamette Valley, Puget Trough, Georgia Basin, eastern and northern Olympic Mountains, eastern side of Vancouver Island, western and northwestern Cascades of Washington, probably on the leeward side of the Coast Mountains in British Columbia (submaritime climates)?, Old Cascades of western Oregon, and Oregon Coast Ranges (but not the coast itself).

CES204.088 North Pacific Hypermaritime Shrub and Herbaceous Headland

CES204.088 CLASSIFICATION

Concept Summary: This system consists of herbaceous- and shrub-dominated areas directly adjacent to the outer Pacific Coast from central Oregon north to Vancouver Island. These are very windy sites where wind and salt spray combine to limit tree growth. The climate is very wet, relatively warm in winter, and cool and foggy. In Oregon, fires apparently set by Native Americans also contributed to the open character of many of these sites. The relative prevalence of grasslands versus shrublands increases to the south. Steep slopes on coastal bluffs, headlands, or small islands are typical, though sometimes this system occurs on relatively level tops of headlands or islands. Soils can be shallow to bedrock or of glacial or marine sediment origin. Vegetation is dominated by perennial bunchgrasses or shrubs. Dominant species include *Vaccinium ovatum, Gaultheria shallon, Rubus spectabilis, Calamagrostis nutkaensis*, and *Festuca rubra*. Scattered stunted trees, especially *Picea sitchensis*, are often present.

CES204.858 Willamette Valley Upland Prairie and Savanna

CES204.858 CLASSIFICATION

Concept Summary: This grassland system is endemic to the Puget Trough and Willamette Valley. It formed a complex mosaic of varying patch sizes with wet prairies and riparian forests over much of the Willamette Valley during the pre-European settlement era. In parts of the Puget Trough, it occurred as large patches in more forested landscapes, usually associated with deep, coarse outwash deposits. Historically, it also occurred as large patches on glacially associated soils of variable texture in localized portions of the Georgia Basin in both Washington and British Columbia. It occurs on well-drained deep soils and was maintained historically by frequent anthropogenic burning. Landforms are usually flat, rolling, or gently sloping, and often part of extensive plains. Dominant vegetation is perennial bunchgrasses, especially *Festuca idahoensis ssp. roemeri* and, to a lesser degree, *Danthonia californica*, with abundant and diverse forbs. Scattered deciduous (*Quercus garryana*) and/or coniferous (*Pseudotsuga menziesii, Pinus ponderosa*) trees are rarely found now, but such savannas historically covered about one-third of the total acreage. In the absence of disturbance, many of them have succeeded to forest and others continue to do so.

Related Concepts:
Distribution: This system is endemic to the Puget Trough and Willamette Valley.
Nations: US
Concept Source: C. Chappell
Description Author: C. Chappell and G. Kittel

CES204.858 CONCEPTUAL MODEL

Environment: This ecosystem occurs on well-drained deep soils and was maintained historically by frequent anthropogenic burning. Landforms are usually flat, rolling, or gently sloping, and often part of extensive plains.

Key Processes and Interactions: Fires are thought to have occurred every few years (Chappell and Kagan 2001, as cited in WNHP 2011). Annual soil drought during the summer made it difficult for woody species (especially trees) to establish in these grasslands. However, occasionally *Quercus garryana* and *Pseudotsuga menziesii* would establish and survive long enough to be resistant to frequent fires thereby creating savanna conditions (Chappell and Kagan 2001, as cited in WNHP 2011). Following European settlement of the region, anthropogenic fire became less frequent resulting in widespread encroachment of the prairies and savannas by woody vegetation, especially conifers (WNHP 2011).

Threats/Stressors: Conversion of this type has commonly come from residential and agricultural development (WNHP 2011). Common stressors and threats include exclusion of fire, ground-disturbing activities like grazing or off-road vehicle use, continuous heavy grazing, military activity, and conifer encroachment (WNHP 2011).

In the Pacific Northwest, regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation, averaged over all models, are small (+1 to +2%), but some models project wetter autumns and winters and drier summers. Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models (Littell et al. 2009). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. This change will result in: Less winter snow accumulation, Higher winter streamflows, Earlier spring snowmelt, Earlier peak spring streamflow and lower summer streamflows in rivers that depend on snowmelt (most rivers in the Pacific Northwest) (Littell et al. 2009). Potential climate change effects could include: increased vigor of some non-native species; increased fire frequency which may reduce conifer cover; increase drought length and intensity which may benefit native prairie species; and predicted shifts in vegetation favoring mixed evergreen from moist conifer forests, which may indicate less conifer encroachment (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from exclusion of fire, to the point that conifer encroachment completely invades a prairie, continuous heavy ground-disturbing activities such as grazing, military activity or off-road vehicle use (WNHP 2011). Environmental Degradation (from WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Connectivity is relictual: embedded in <20% natural or semi-natural habitat; connectivity is essentially absent; Bare soil areas substantially and contribute to altered hydrology or other long-lasting impacts. Deep ruts from ORVs or machinery may be present, or livestock pugging and/or trails are widespread. Water will be channeled or ponded. Any of these conditions or combination of conditions rates as moderate-severity: Connectivity is fragmented: embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; Bare soil areas due to human causes are common. There may be pugging due to livestock resulting in several inches of soil disturbance. ORVs or other machinery may have left some shallow ruts.

Disruption of Biotic Processes (from WNHP 2011): Any of these conditions or combination of conditions rates as high-severity: Native species total cover <40%; non-native species dominate; Douglas-fir numerous as seedlings/saplings/small trees and >25% cover. Shrub cover >25%, and <5 native species with high fidelity to prairies. Any of these conditions or combination of conditions rates as moderate-severity: Native species total cover 40 to 90%, Douglas-fir numerous as seedlings/saplings/small trees. Shrub cover <10-25%, 5-10 native species with high fidelity to prairies.

2.B.2.Nb. Great Plains Grassland & Shrubland

M054. Central Lowlands Tallgrass Prairie

CES202.312 Arkansas Valley Prairie and Woodland

CES202.312 CLASSIFICATION

Concept Summary: This system of prairies and associated woodlands is found in the Arkansas River Valley region of Arkansas and adjacent Oklahoma. This region is distinctly bounded by the Boston Mountains to the north and the Ouachita Mountains to the south, although it has been considered part of the Ouachita Ecoregion. The valley is characterized by broad, level to gently rolling uplands derived from shales and is much less rugged and more heavily impacted by Arkansas River erosional processes than the adjacent mountainous regions. In addition, the valley receives annual precipitation total of 5-15 cm (2-6 inches) less than the surrounding regions due to a rainshadow produced by a combination of prevailing western winds and mountain orographic effects. The shale-derived soils associated with the prairies are thin and droughty. The combined effect of droughty soils, reduced precipitation, and prevailing level topography create conditions highly conducive to the ignition and spread of fires. Stands are typically dominated by *Andropogon gerardii, Sorghastrum nutans, Panicum virgatum*, and *Schizachyrium scoparium*. Some extant examples of this system remain, but most are small and isolated. They were common on the western edge of the region bordering or possibly included in the Crosstimbers and Southeastern Great Plains Tallgrass Prairie where precipitation and agriculture conversion were lowest.

Description Author: T. Foti, R. Evans, T. Witsell and M. Pyne

CES202.312 CONCEPTUAL MODEL

Environment: This region is distinctly bounded by the Boston Mountains to the north and the Ouachita Mountains to the south, although it has been considered part of the Ouachita Ecoregion (TNC Ecoregion 39). The valley is characterized by broad, level to gently rolling uplands derived from shales and is much less rugged and more heavily impacted by Arkansas River erosional processes than the adjacent mountainous regions. In addition, the valley receives annual precipitation total of 5-15 cm (2-6 inches) less than the surrounding regions due to a rainshadow produced by a combination of prevailing western winds and mountain orographic effects (T. Foti pers. comm. 2003). The shale-derived soils associated with the prairies are thin and droughty. The combined effect of droughty soils, reduced precipitation, and prevailing level topography create conditions highly conducive to the ignition and spread of fires. Some extant examples of this system remain, but most are small and isolated. They were common on the western edge of the Arkansas Valley region, bordering (or possibly included in) the Crosstimbers (TNC Ecoregion 32) where precipitation and agriculture conversion were lowest (T. Foti pers. comm. 2003). This western portion of the Arkansas Valley region is labeled as part of 231Gc by Cleland et al. (2005) and 37d, 37e by EPA (EPA 2013).

Key Processes and Interactions: These prairies and woodlands were historically maintained by frequent fire. Drought cycles and grazing were also likely important ecosystem processes. Fires were frequent, primarily autumnal and of human origin. As *Quercus-Carya* regeneration becomes established, individuals of these species become largely fire-resistant with age. Surface fires within woodland and forest types occurred every 12 to 15 years, reducing duff layers and allowing recruitment of young individuals of *Quercus* and *Carya* species (Landfire 2007a).

Threats/Stressors: The most critical anthropogenic threat to native grasslands, savannas and barrens is their conversion to human-created land uses, including residential development, quarries, industrial development, infrastructure development, and others (TNC 1996c). Rocky glade areas, if present, may be the last areas to be converted to development and housing due to the unsuitability of the soil to septic tanks. Other common threats and stressors include both the removal of disturbance and the effects of inappropriate or too intensive or constant disturbance. These areas often attract off-road-vehicle use.

Fire plays a critical role in the maintenance of most native grasslands. Without it, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). In landscapes where open grassland or savanna vegetation is part of the matrix, and where woody plants have taken over areas once occupied by open grassland and savanna vegetation, the light-dependent species may only persist on the open edges (roadsides, powerlines) of forested patches (Taft 1997). In southeastern grasslands, complete transition to forest-dominated vegetation can occur in one or two decades (Wiens and Dyer 1975). More information is needed about the particular appropriate ranges of fire-return times and intensities in the various systems, along with factors other than fire (e.g., soil/substrate, aspect, herbivory, hydroperiod and flooding) that help maintain grasslands and related communities. Occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing. Too intensive or frequent application of these disturbances will have deleterious effects on stand structure and species diversity. In general, mosaics of scrub and grassland, produced by light to moderate grazing (or occasional fire) will support the greatest diversity (Duffey et al. 1974). Cutting or mowing is not as favorable to plant diversity as is grazing because it is nonselective and does not result in the same kind of soil disturbance and compaction as do the hooves of grazing animals (DeSelm and Murdock 1993). Fire is a critical disturbance factor for southeastern native grasslands, but the intensity, duration, and timing of the fires are all important in their effect on the vegetation (DeSelm and Murdock 1993). In addition to occasional fire, periodic drought may also be important in regulating woody plant encroachment in native grasslands. It is believed that native grasslands have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. A small isolated patch has a low probability of receiving a lightning strike frequently enough to maintain a grassland condition. In many cases, grassland systems were once extensive on the landscape, but have now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). In other cases, the grassland or glade system naturally occurs in small isolated patches occurring within an otherwise forested matrix.

Many native grassland sites, particularly the more productive ones, have been converted to plantations of exotic grasses and legumes (DeSelm and Murdock 1993). Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, as well as *Ailanthus altissima, Albizia julibrissin, Alliaria petiolata, Lespedeza cuneata, Microstegium vimineum*, and *Miscanthus sinensis*) will fundamentally alter the character of native grasslands, barrens, savannas, and glades. Some of these exotics are allelopathic, thereby presenting a greater threat to native species (N. Murdock pers. comm.). Opportunistic native increaser plant species (e.g., *Juniperus virginiana*) can also shade out light-requiring herbaceous plants (TNC 1996c).

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site to other land uses (e.g., residential development, industrial development, infrastructure development, mining or quarrying of underlying bedrock) or conversion to plantations of exotic grasses and legumes. Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, *Ailanthus altissima, Lespedeza cuneata*, and others) will fundamentally alter the character of native grasslands, barrens, savannas, and glades. Ecological collapse may also result from the removal or lessening of appropriate disturbance (grazing, fire). Without fire, *Juniperus* species, *Quercus* species, and other hardwoods quickly regenerate or invade, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a shift to an alternate stable state and a net loss of species diversity (Taft et al. 1995). In many southeastern grasslands and savannas, complete transition to forest-dominated vegetation can occur in one or two decades (Wiens and Dyer 1975).

CES205.683 Central Tallgrass Prairie

CES205.683 CLASSIFICATION

Concept Summary: This system is found primarily in the Central Tallgrass Prairie ecoregion ranging from eastern Kansas and Nebraska to northwestern Indiana. This system differs from other prairie systems to the north and south by being the most mesic with primarily deep, rich Mollisol soils. These soils are usually greater than 1 meter deep. This system is dominated by tallgrass species such as *Andropogon gerardii, Sorghastrum nutans*, and *Panicum virgatum*. These species typically grow to 1-2 m tall in the rich soils found in this system. Other mid- and shortgrass species, such as *Bouteloua curtipendula, Hesperostipa spartea*, and *Schizachyrium scoparium*, are usually present and can be common or locally dominant on patches of this system, particularly slopes or other areas with drier habitats. Several forb species are also associated with this system making it one of the most diverse grassland systems. As many as 300 herbaceous plant species could occur on a 10-ha high-quality example of this system across its range. Historically, fires limited woody species; however, the current environment and habitat of this system do not prevent invasion by shrubs and trees. High-quality examples of this system have trees and shrubs widely scattered or clustered in areas that are wetter and/or more sheltered from fire than the surrounding grassland. Fire, drought, and grazing are the primary natural dynamics influencing this system and help prevent woody species from invading. However, conversion to agriculture has been the prime disturbance since European settlement. The rich soils and long growing season make this an ideal location for farming row crops, and as a result very few examples of this system remain.

Related Concepts:

CES205.683 CONCEPTUAL MODEL

Environment: This system differs from other prairie systems to the north and south by being the most mesic with primarily deep, rich Mollisol soils. These soils are usually greater than 1 m deep and organic matter is high. Litter can build up if sites are not burned or grazed for several years. This system occurs in a climate that allows the growth of trees and shrubs. These are kept out of the prairies largely by fires and periodic drought, so the prairies tended to be on flat to rolling topography with fewer firebreaks (wetlands, rivers, or steeply dissected topography).

Key Processes and Interactions: Fire, drought, and grazing are the primary natural dynamics influencing this system and help prevent woody species from invading. This system is found in a climate that can support trees and shrubs but woody vegetation is inhibited by frequent fires. Historically, fire-return intervals were short, estimated at between 2 and 5 years (Stambaugh et al. 2006, Landfire 2007a). The frequent but unpredictable hot fires created a patchwork of habitats across the landscape, with recently burned sites having less litter and forb cover and sites with infrequent fires possibly having more woody species and dense stands of grasses (Kucera and Koelling 1964). This system developed in an area with large numbers of native ungulates, notably bison (*Bos bison*) but including other species (elk and deer), and the grazing of these species affected species composition and the patchwork of habitat. Bison were likely more numerous and thus had more effect in the western portion of this system's range. Bison preferentially favor newly burned areas and graminoids over forbs (Vinton et al. 1993, Coppedge and Shaw 1998). Their grazing, trampling, and wallowing were important in creating habitat diversity across the landscape (Knapp et al. 1999). On unburned sites, grazing removes live and dead vegetation, allowing more light and heat to the soil surface and increasing available moisture thus favoring species, forbs or woody plants, in the case of bison grazing, that were resilient to the effects of grazing or avoided by the grazers (Damoureyeh and Hartnett 1997).

Threats/Stressors: Tallgrass prairie has been largely eliminated from the landscape due to conversion to agricultural uses, elimination of the landscape-level processes that maintained the system, and introduction of exotic species. Estimates across the range of all tallgrass prairie systems are that 82-99.9% of tallgrass prairie has been eliminated (reported in Samson and Knopf 1994). This system has fared worst of any tallgrass system due to its range coinciding with the most fertile farmland in the Midwest. In addition to loss through direct conversion to crop fields, farmland development has fragmented the natural landscape and has eliminated the large-scale processes of fire and grazing by native ungulates that were necessary to maintain this system. Lack of fire, grazing, or mowing results in a decrease in productivity due to the soil surface staying cooler and shaded longer in the spring (Rice and Parenti 1978, Hulbert 1988). Lack of fire allows tree cover to increase rapidly, especially on lower, more mesic slopes (Heineman and Bragg 1982). This system is well-adapted to moderate grazing over time or heavy grazing for short periods, but when used as long-term pasture and with high stocking rates, the dominant native grasses are reduced or eliminated. Heavy haying or grazing, or if those are done consistently during the mid-summer months, negatively affects the dominant warm-season grasses by removing their biomass before they have flowered. Cool-season grasses and forbs which set seed earlier are favored by these activities. Native and non-native forbs, woody species, and C3 grasses increase in the absence of fire, especially when combined with grazing by livestock. Drier sites on hilltops or rocky soils persist longer, but mesic sites on lower slopes can be invaded by trees and shrubs after just several years without fire. Non-native grasses have been planted for forage on some sites, as well. Restoration of full species diversity and soil characteristics is slow, even with active management (Kindscher and Tieszen 1998).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the landscape is fragmented and remaining tallgrass prairie patches are small. Although these patches may persist for a time, the removal of the landscape-level processes that maintained this system will result in the eventual conversion to another vegetation type. Lack of fire and the pattern of grazing by native ungulates, as well as the nearby seed sources for non-native species, will result in the elimination of sites over time. Encroachment by woody species, native or non-native, can also destroy sites, transforming them to shrublands or woodlands, often dominated by *Quercus* spp. or *Juniperus virginiana*. Heavy grazing or long-term grazing and haying tends to reduce the native warm-season grasses and degrades the system.

CES202.695 North-Central Interior Sand and Gravel Tallgrass Prairie

CES202.695 CLASSIFICATION

Concept Summary: This system is found in the northern Midwest, particularly in Minnesota, Wisconsin, Michigan, and possibly ranging into Ontario. It is often found on glacial features such as kames, eskers, moraines, lakeplains (though excluding the Great Lakes lakeplain) and sandplains, and along eolian dunes. In contrast to the deeper, richer soils supporting other tallgrass systems in the region, the underlying soils in this system tend to be more shallow, sandy, rocky, and/or gravelly outwash soils. Organic content is significantly lower. Grassland species such as *Schizachyrium scoparium, Andropogon gerardii*, and *Bouteloua* spp., varying in cover from sparse to moderately dense, dominate this system. *Hesperostipa spartea* and *Sporobolus heterolepis* are also common components of this system. Woody species more tolerant of droughty conditions may be found in some examples. The most common trees are *Pinus banksiana, Quercus ellipsoidalis, Quercus macrocarpa*, and *Populus tremuloides*. Fire and drought are the major dynamics influencing this system. If fire and periodic drought are not present, woody species begin to invade this system, especially in the eastern parts of its distribution. Wind can also play a role, especially on examples found on sandplains and/or eolian dunes.

Related Concepts:

Distribution: This system is found in the northern Midwest possibly ranging into Ontario.

Nations: CA, US

Concept Source: S. Menard

Description Author: S. Menard and J. Drake

CES202.695 CONCEPTUAL MODEL

Environment: This system is often found on glacial features such as kames, eskers, moraines, lakeplains (though excluding the Great Lakes lakeplain), and sandplains, and along eolian dunes and river deltas. In contrast to the deeper, richer soils supporting other tallgrass systems in the region, the underlying soils in this system tend to be more shallow, sandy, rocky, and/or gravelly soils. Soil texture is sand or sandy loam. Organic content and soil moisture retention are significantly lower than the more mesic grasslands.

Key Processes and Interactions: Fire and drought are the major dynamics influencing this system. If fire and periodic drought are not present, woody species begin to invade this system, especially in the eastern parts of its distribution. Fire-return intervals were likely

1-8 years (Landfire 2007a). Drier examples of this system likely could not be maintained in the presence of long-term short fire-return intervals due to the lower fertility of the soils. The typical dominant perennial grasses would not have time to recover from repeated burning and shorter-lived opportunistic species could dominate (Loucks et al. 1985). These sites were maintained as grasslands by the dry soil conditions possibly supplemented by low-frequency fires, while other areas required fire to eliminate invasion by woody species. Wind can also play a role, especially on examples found on sandplains and/or eolian dunes or during droughts when vegetation cover is low. Blowouts can form, exposing bare sand (Burgess 1965). Productivity is lower on this system than on other tallgrass prairies, so vegetation responds more slowly to disturbance. This system can not persist with the same frequency of reductions in vegetation cover by fire, grazing, drought, or mowing as richer prairies can.

Threats/Stressors: Tallgrass prairie has been largely eliminated from the landscape due to conversion to agricultural uses, elimination of the landscape-level processes that maintained the system, and introduction of exotic species. Estimates across the range of all tallgrass prairie systems are that 82-99.9% of tallgrass prairie has been eliminated (reported in Samson and Knopf 1994). This system occurs in a region that is generally very fertile and suitable for crops. The soils on which this system occurs are less fertile than the general region and so more of this system has escaped outright conversion to cropland than richer prairie systems. In addition to loss through direct conversion to crop fields, farmland development has fragmented the natural landscape and has eliminated the large-scale processes of fire and grazing by native ungulates that were necessary to maintain some examples of this system. Those examples have been invaded by woody species and non-native forbs and cool-season grasses. Many examples of this system can tolerate moderate grazing over time or heavy grazing for short periods, but when used as long-term pasture and with high stocking rates, the dominant native grasses are reduced or eliminated. Heavy haying or grazing, or if those are done consistently during the mid-summer months, negatively affects the dominant warm-season grasses by removing their biomass before they have flowered. Cool-season grasses and forbs which set seed earlier are favored by these activities. Native and non-native forbs, woody species, and C3 grasses increase in the absence of fire, especially when combined with grazing by livestock. Drier sites on hilltops or rocky soils persist longer but more mesic sites on lower slopes can be invaded by trees and shrubs after just several years without fire. Non-native grasses have been planted for forage on some sites, as well.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the landscape is fragmented and remaining tallgrass prairie patches are small. Although these patches may persist for a time, the removal of the landscape-level processes that maintained this system will result in the eventual conversion to another vegetation type. Lack of fire, as well as the nearby seed sources for non-native species, will result in the elimination of sites over time. Encroachment by woody species, native or non-native, can destroy sites, transforming them to shrublands or woodlands, often dominated by *Quercus* spp. or *Juniperus virginiana*. Heavy grazing or long-term grazing and haying tends to reduce the native warm-season grasses and degrades the system.

CES205.686 Northern Tallgrass Prairie

CES205.686 CLASSIFICATION

Concept Summary: This system is found primarily in the Northern Tallgrass ecoregion ranging along the Red River basin in Minnesota and the Dakotas to Lake Manitoba in Canada. It constitutes the northernmost extension of the "true" prairies. Similar to ~Central Tallgrass Prairie (CES205.683)$$, this system is dominated by tallgrass species such as *Andropogon gerardii, Sorghastrum nutans*, and *Panicum virgatum*. However, the soils in this region are not as rich nor deep, the growing season length and precipitation are less, and thus this system does not have as much species diversity as grasslands to the south. This system is often found on well-drained, drier soils and can grade into ~Eastern Great Plains Tallgrass Aspen Parkland (CES205.688)$$ to the north and east. Grazing and fire influenced this system historically. Much of this system has been converted to agriculture with very few unaltered and highly fragmented examples remaining.

CES205.686 CONCEPTUAL MODEL

Environment:

Key Processes and Interactions: Fire plays an important role in the maintenance of this prairie system (Curtis 1959, Vogl 1964, Anderson 1990b). Fire promotes seed production and flowering necessary for plant regeneration. Because environmental conditions are suitable for tree growth, without recurrent fire (every 2-10 years), succession to forest or woodland will occur rapidly (Minnesota DNR 2005b). From Landfire BpS: Frequent fires impacted this prairie system every 1-3 years, maintaining grass and forb vegetation. Fire could occur throughout the year with larger, less frequent fires occurring during the dormant season and smaller, more frequent fires occurring during the growing season. Native American burning, essential to maintaining the eastern tallgrass prairie, was bimodal in distribution, peaking in April and October with lightning ignition occurring primarily during July and August (Higgins 1986).

Bison grazing as a major disturbance was likely much more limited than prairies further west. Elk probably contributed to the impact of grazing and browsing as well, but it is assumed that the total contributions of these two species was still considerably less than to the west. The elk may have contributed to the reduction of young woody saplings invading prairie adjacent to protected woody areas. Prior to European settlement, episodic grazing by large, native mammals was common and encouraged the persistence of several native grass and forb species (Minnesota DNR 2005b). Insect and small mammal herbivory impacts composition and dominance. From Landfire BpS: Bison, with peripheral help from grasshoppers, elk, antelope and a myriad of smaller animals made herbivory one of the dominating factors of the northern tallgrass prairie (Severson and Sieg 2006). With estimates of 30-60 million bison in the Northern Great Plains (Isenberg 2000), herbivory by large mammals also was a significant disturbance to the grasslands. Bison herbivory occurred in a mob-grazing or flash-grazing method, with extensive herds migrating across the prairie as they graze. Modern rotational grazing systems simulate this by resting areas after intensive grazing. Elk, too, may have played an important role than generally believed, particularly in the eastern portion of the zone. Whether bison or elk, large mammals preferentially grazed recently burned sites.

Threats/Stressors: The northern tallgrass system has been significantly transformed since European settlement largely into an agricultural landscape. Remaining patches are highly fragmented. Woodland acreage has increased appreciably due to fire suppression, extirpation of native grazers, and human disturbance. Many areas that were not cultivated are subject to intensive grazing which has resulted in most native species being replaced by introduced ones (Minnesota DNR 2005b). Without heavy intervention and intense management and restoration efforts, it is highly unlikely that many remaining northern tallgrass prairie patches will be self-sustaining or persist over time (Koper et al. 2010).

Ecosystem Collapse Thresholds: *Landscape Context:* Much of the area surrounding remaining patches of northern tallgrass prairie are heavily managed for agriculture or subject to intensive grazing. *Size:* Patch size was somewhat variable historically, but current distribution shows many smaller patches. Smaller patches of northern tallgrass are subject to edge effects such as an increase in invasive and exotic species. Conversely, patches at least 21 ha in size tend to be self-sustaining and may increase in size with proper fire and grazing management (Koper et al. 2010). *Condition:* The majority of this system has been converted to agriculture. Many remaining patches are found in areas not easily plowed or in protected areas. These patches are surrounded by intensive agriculture and will be impacted by that land use. Other remaining patches are being used for season-long grazing which has resulted in a significant increase in introduced species. Fire suppression in other areas has resulted in woody species invasion into other remaining patches.

CES205.685 Southeastern Great Plains Tallgrass Prairie

CES205.685 CLASSIFICATION

Concept Summary: This system of tallgrass prairies ranges from Kansas, Missouri, and Oklahoma south into Arkansas and Texas. It includes several subregional units or variants, which are defined biogeographically but with much overlap in floristics and ecological processes. This range includes the Flint Hills (EPA 28a) and portions of the Northern Cross Timbers (EPA 29a) of Kansas and Oklahoma, the Osage Plains (EPA 40b, 40c, 40d) of Kansas, Missouri, and Oklahoma, the southeastern Springfield Plateau (EPA 39a, 39b? of Arkansas and Missouri, the Arkansas Valley Plains (EPA 37d, 37e) of Arkansas and Oklahoma, and the "Grand Prairie" or "Fort Worth Prairie" (EPA 29d) of Texas,; where it is the primary natural system. It is also scattered in the rest of the Cross Timbers (EPA 29b. 29c, 29e, 29f, 29g, 29h), ranging south into the Lampasas Cutplain of Texas (EPA 29e). It is distinguished from ~Central Tallgrass Prairie (CES205.683)$$ by having more species with southwestern geographic affinities and the presence of a thin soil layer over limestone beds ranging to more acidic substrates, although some areas of deeper soil are found within the region, especially on lower slopes, draws, and terraces. Because of the presence of the rocky substrate close to the surface and the rolling topography, this area is relatively unsuitable for agriculture. The Flint Hills contain one of the largest remaining, relatively intact pieces of Southeastern Great Plains Tallgrass Prairie. The vegetation in this system is typified by tallgrass species such as *Andropogon gerardii, Panicum virgatum, Schizachyrium scoparium*, and *Sorghastrum nutans,* which typically form a dense cover. A moderate to high density of forb species also occurs. Species composition varies geographically, with *Oligoneuron rigidum, Liatris punctata, Symphyotrichum ericoides, Lespedeza capitata*, and *Viola pedatifida* commonly occurring in the Flint Hills and Osage Plains. Areas of deeper soil, especially lower slopes along draws, slopes and terraces, can include *Baptisia alba var. macrophylla, Liatris pycnostachya*, and *Vernonia baldwinii*. Shrub and tree species are relatively infrequent and, if present, constitute less than 10% cover. Fire and grazing constitute the major dynamic processes for this region. Although many of the native common plant species still occur, grazing does impact this region. Poor grazing practices can lead to soil erosion and invasion by cool-season grasses such as *Bromus inermis* within its range.

In the Arkansas Valley Plains (EPA 37d, 37e) the prairies are interspersed with oak or pine-dominated woodlands. This region is distinctly bounded by the Boston Mountains to the north and the Ouachita Mountains to the south. The valley is characterized by broad, level to gently rolling uplands derived from shales and is much less rugged and more heavily impacted by Arkansas River erosional processes than the adjacent mountainous regions. In addition, the valley receives annual precipitation total of 5-15 cm (2-6 inches) less than the surrounding regions due to a rainshadow produced by a combination of prevailing western winds and mountain orographic effects. The shale-derived soils associated with the prairies are thin and droughty. The combined effect of droughty soils, reduced precipitation, and prevailing level topography create conditions highly conducive to the ignition and spread of fires. Stands are typically dominated by *Andropogon gerardii, Sorghastrum nutans, Panicum virgatum*, and *Schizachyrium scoparium*. Some extant examples of this system remain, but most are small and isolated. They were common on the western edge of the region where precipitation was lower and agriculture conversion was less extensive.

CES205.685 CONCEPTUAL MODEL

Environment: This system is typified by a thin soil layer over limestone beds or acidic substrates such as chert or granite, although areas of deeper soils are possible along lower slopes, draws, and terraces. The topography is rolling and mostly unsuitable for agriculture. In Texas, the typical geology is Lower Cretaceous formations, including various limestones, sands (such as from the Paluxy and Antlers formations), and clays (such as from the Walnut Formation). In contrast to Blackland Prairie, landform surfaces are flat rather than undulating, and valley slopes are angular rather than rounded. The "cuesta" landforms with gentle slopes leading up to relatively abrupt escarpments are characteristic of the Grand Prairie portion of the Southeastern Great Plains Tallgrass Prairie in Texas. Much of the region occupied by this prairie in Texas is included in the Blackland Ecological Site, though Clay Loam, Sandy Loam, Shallow, and Claypan Prairie Ecological Sites are also significant. Soils of this area are more frequently characterized as Mollisols, as opposed to the Vertisols more characteristic of the Blackland Prairie. Calcareous clays are commonly encountered (Elliott 2011).

The Arkansas Valley is characterized by broad, level to gently rolling uplands derived from shales and is much less rugged and more heavily impacted by Arkansas River erosional processes than the adjacent mountainous regions. In addition, the valley receives annual precipitation total of 5-15 cm (2-6 inches) less than the surrounding regions due to a rainshadow produced by a combination of prevailing western winds and mountain orographic effects (T. Foti pers. comm. 2003). The shale-derived soils associated with the prairies are thin and droughty. The combined effect of droughty soils, reduced precipitation, and prevailing level topography create conditions highly conducive to the ignition and spread of fires.
Key Processes and Interactions: Fire and grazing are the prevalent dynamic processes in examples of this system. This system is found in a climate that can support trees and shrubs but woody vegetation is inhibited by frequent fires. Historically, fire-return intervals were short, estimated at between 2 and 15 years (Abrams 1986, Landfire 2007a). The frequent but unpredictable fires created a patchwork of habitats across the landscape, with recently burned sites having less litter and forb cover, and sites with infrequent fires possibly having more woody species and dense stands of grasses. This system developed in an area occupied by vast numbers of native ungulates, notably bison (*Bos bison*) but including other species, and the grazing of these species affected species composition and the patchwork of habitat. Bison preferentially favor newly burned areas and graminoids over forbs (Vinton et al. 1993, Coppedge and Shaw 1998). Their grazing, trampling, and wallowing were important in creating habitat diversity across the landscape (Knapp et al. 1999). On unburned sites, grazing removes live and dead vegetation, allowing more light and heat to the soil surface and increasing available moisture thus favoring species, forbs or woody plants, in the case of bison grazing, that were resilient to the effects of grazing or avoided by the grazers (Damoureyeh and Hartnett 1997).
Threats/Stressors: Tallgrass prairie has been largely eliminated from the landscape due to conversion to agricultural uses, elimination of the landscape-level processes that maintained the system, and introduction of exotic species. Estimates across the range of all tallgrass prairie systems are that 82-99.9% of tallgrass prairie has been eliminated (reported in Samson and Knopf 1994). This system has fared relatively better and is in the lower end of those estimates due to its tendency to be found on shallow, rocky soils less suited to tillage for crops. In addition to loss through direct conversion to crop fields, farmland development has fragmented the natural landscape and has eliminated the large-scale processes of fire and grazing by native ungulates that were necessary to maintain this system. Lack of fire, grazing, or mowing results in a decrease in productivity due to the soil surface staying cooler and shaded longer in the spring (Rice and Parenti 1978, Hulbert 1988). Lack of fire allows tree cover to increase rapidly, especially on lower, more mesic slopes (Bragg and Hulbert 1976, Briggs and Gibson 1998). This system is well-adapted to moderate grazing over time or heavy grazing for short periods, but when used as long-term pasture and with high stocking rates, the dominant native grasses are reduced or eliminated. Heavy haying or grazing, or if those are done consistently during the mid-summer months, negatively affects the dominant warm-season grasses by removing their biomass before they have flowered. Cool-season grasses and forbs set seed earlier are favored by these activities. Native and non-native forbs, woody species, and C3 grasses increase in the absence of fire, especially when combined with grazing by livestock. Drier sites on hilltops or rocky soils persist longer, but mesic sites on lower slopes can be invaded by trees and shrubs after just several years without fire. Non-native grasses have been planted

for forage on some sites, as well. Restoration of full species diversity and soil characteristics is slow, even with active management (Kindscher and Tieszen 1998).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the landscape is fragmented and remaining tallgrass prairie patches are small. Although these patches may persist for a time, the removal of the landscape-level processes that maintained this system will result in the eventual conversion to another vegetation type. Lack of fire and the pattern of grazing by native ungulates, as well as the nearby seed sources for non-native species, will result in the elimination of sites over time. Encroachment by woody species, native or non-native, can also destroy sites, transforming them to shrublands or woodlands, often dominated by *Quercus* spp. or *Juniperus virginiana*. Heavy grazing or long-term grazing and haying tends to reduce the native warm-season grasses and degrades the system.

CES205.684 Texas Blackland Tallgrass Prairie

CES205.684 CLASSIFICATION

Concept Summary: This grassland system is found primarily in the Blackland Prairie region of Texas but may range into southern Oklahoma. It is typified by the presence of dark alkaline Vertisol soils over calcareous parent material, although substantial belts of acidic, sandy clay loam Alfisols and loamy or clay loam Mollisols also occur. These soil types relate directly to the underlying surface geology. Microtopography such as gilgai occurs over Vertisols, and mima mounds occur over Alfisols. These create important microhabitats that increase plant diversity in this system. *Schizachyrium scoparium, Sorghastrum nutans*, and *Andropogon gerardii* are the most common dominants. *Tripsacum dactyloides* and *Panicum virgatum* are common associates on the Vertisol soils, especially on the gilgai microtopography. Fire, drought, and possibly grazing were the major natural dynamics influencing this system.

Related Concepts:

- Blackland Prairie: Disturbance or Tame Grassland (207) [CES205.684.9] (Elliott 2011) **<**

Distribution: This system is restricted to the Blackland Prairie region, part of the Crosstimbers and Southeastern Great Plains Tallgrass Prairie Ecoregion, in Texas and possibly adjacent southern Oklahoma.

Nations: US

Concept Source: S. Menard

Description Author: S. Menard, L. Elliott and J. Teague

CES205.684 CONCEPTUAL MODEL

Environment: This system is typified by the presence of dark alkaline Vertisol soils over calcareous parent material interspersed with patches of acidic, sandy loam Alfisols and Mollisols. The detailed geology includes Cretaceous shales, marls and limestones, such as those of the Pecan Gap Chalk, Marlbrook Marl, Eagle Ford, Gober Chalk, Annona Chalk, and Austin Chalk formations, and Taylor and Navarro groups, as well as portions of the Eocene Midway Group and Wilcox Formation. Also, Miocene formations (Fleming and Oakville Sandstone formations) underlie the southern outlier of Blackland prairie recognized as the Fayette Prairie. Landforms are flat to gently rolling and dissected by drainages, with the most significant ridges associated with harder chalk formations. Microtopography such as gilgai and mima mounds can occur and are important microhabitats that lead to an increase in plant diversity in this system (Diamond and Smeins 1990). Soils are typically Vertisols, but this system may occupy Mollisols or Alfisols with the latter more common. The system generally occurs on calcareous clays, but may also occur on loams, clay loams, or even sandy clay loams or silt loams. Annual rainfall averages 890mm, wettest seasons are spring and fall (Harmel et al. 2003).

Key Processes and Interactions: Fire, drought and possibly and grazing constitute the major natural dynamics influencing this system. Frequent fires (mean fire-return interval of 2.5 years) prevent woody species from establishing and favor grassland species adapted to fire for reproduction and vigor (Landfire 2007a) prevent woody species from establishing and favor grassland species adapted to fire for reproduction and vigor. Bison and other ungulates possibly played an important role in the vegetation composition and structure of this system (Eidson and Smeins 1999). Fire suppression and overgrazing have allowed woody species to invade. Heavy grazing has also altered the floristic composition by allowing species such as *Bouteloua dactyloides* and *Bouteloua rigidiseta* to invade. This system is important for a suite of wildlife, many of which are declining, that are dependent on native grasslands (TPWD 2012a).

Threats/Stressors: Historic descriptions of the Blackland Prairie region by early travelers indicate the region was dominated by a tallgrass prairie. Forests were limited to stream valleys, and trees and shrubs sometimes occurred as scattered individuals and clumps in a vast sea of grasses and wildflowers (Diggs et al. 1999). Today, only small remnants (occupying <1% of the original extent) remain (Riskind and Collins 1975, Diggs et al. 1999, Eidson and Smeins 1999). Threats to the remaining remnants include elimination of the landscape-level processes that maintained the system such as fire and native grazers, introduction of exotic species (*Bothriochloa ischaemum, Dichanthium sericeum, Lolium arundinaceum (= Schedonorus arundinaceus)*), woody plant encroachment, overgrazing by livestock, urban and rural development, and infrastructure development (Eidson and Smeins 1999).

Ecosystem Collapse Thresholds: Ecological collapse results from conversion of native prairie to agriculture, exotic pasture, and developed land uses, fragmenting the landscape and disrupting natural processes such as fire. The remaining small remnants of native prairie have a ready seed supply of invasive native and exotic species. Decreases in native grass cover allow for annual grasses and forbs to invade. In addition, much of this system has been impacted by conversion to exotic pasture grasses *Bothriochloa ischaemum* and *Dichanthium annulatum*. Other invasive species issues include *Ligustrum sinense, Melia azedarach, Triadica sebifera, Ailanthus altissima, Lolium arundinaceum (= Schedonorus arundinaceus)*, feral hogs, and red imported fire ants (TPWD 2012a). Ecological collapse is characterized by fragmentation and complete conversion of the system to other land uses, the absence of native grasses and forbs, and encroachment of woody plants.

CES203.550 Texas-Louisiana Coastal Prairie

CES203.550 CLASSIFICATION

Concept Summary: This system encompasses non-saline tallgrass prairie vegetation that developed over Pleistocene terraces flanking the Gulf Coast of Louisiana and Texas. It is sometimes characterized by a ridge-and-swale or mound-and-intermound microtopography and encompasses both upland and wetland plant communities. Upland dominants typically include *Schizachyrium* *scoparium, Paspalum plicatulum*, and *Sorghastrum nutans*. Wetland dominants in undisturbed occurrences include *Panicum virgatum* and *Tripsacum dactyloides*. Fire is an important ecological process in this system.

Related Concepts:

- Gulf Coast: Coastal Prairie (5207) [CES203.550] (Elliott 2011) =

Distribution: This system occurs within 50 to 150 miles of the Gulf Coast from southwestern Louisiana to south-central Texas encompassing approximately 10 million acres.

Nations: US

Concept Source: J. Teague

Description Author: J. Teague, M. Pyne and L. Elliott

CES203.550 CONCEPTUAL MODEL

Environment: This mid- to tallgrass prairie occupies Pleistocene surfaces of the Texas and Louisiana coast, on non-saline soils. The occurrence of this system is generally coincident with the distribution of the Pleistocene Beaumont and Lissie formations in Texas (Prairie and Intermediate allogroups in Louisiana). It is usually found on level to gently rolling landscapes, with slopes generally less than 5%. Microtopography plays an important role in local variation in the system, with ridges, swales, mounds, depressions, mima (or pimple) mounds, and gilgai leading to a mosaic of drier and wetter plant communities. Typical soils are non-saline Vertisols, Alfisols, and (less extensively) Mollisols (Diamond and Smeins 1984, Smeins et al. 1992). Vertisols are often characterized by gilgai, resulting from shrink-swell attributes of the montmorillonitic clays of which they are composed. Historically, rivers and streams dissected this vegetation type, breaking it into large compartments with species composition shifting across the range. A moisture gradient occurs from northeast (average 120 cm/year) to southwest (average 100 cm/year) across the range of this system (Diamond and Smeins 1984).

Key Processes and Interactions: The impacts and interaction of fire, drought, competition, and possibly grazing constitute the major natural dynamics influencing this system (Smeins et al. 1992, USGS 2013). Frequent fires every 2-5 years of both lightning and anthropogenic origins prevent woody species from establishing and favor grassland species adapted to fire for reproduction and vigor. Microtopographic and moisture variability interacted with fire to produce variable fire effects influencing the distribution of flora and fauna. Grazing by bison and other ungulates also played an important role in maintaining the vegetation composition and structure of this system. This system is important for a suite of wildlife, many of which are declining, that are dependent on native grasslands (TPWD 2012a).

Threats/Stressors: This prairie system once covered as much as 9 million acres and less than 1% is thought to remain (Smeins et al. 1992, Bergan 1999, USFWS and USGS 1999, Grace et al. 2000, LDWF 2005, USGS 2013). This loss was caused by conversion to other land uses (primarily rice and sugarcane farming, pasture, and residential and commercial development) and environmental degradation due to the interruption of important ecological processes, such as fire, needed to maintain this system. In the absence of regular fire, this system will be invaded by woody shrubs and trees. Remaining occurrences continue to be threatened by conversion to other land uses (agriculture, pasture, and residential and commercial development), overgrazing, and loss of landscape level natural processes (Smeins et al. 1992, Bergan 1999, USFWS and USGS 1999, Grace et al. 2000, LDWF 2005, USGS 2013). Fire suppression and overgrazing have allowed native and non-native woody species to invade. If changes in regional climate bring about an increase in precipitation, this could lead to an increase in woody encroachment; a decrease in precipitation could lead to loss of the wet prairie components of this system. Due to its proximity to the coast and coastal marshes, sea-level rise could further impact this system by saltwater inundation and increased salinity.

Ecosystem Collapse Thresholds: Ecological collapse results from conversion of native prairie to agriculture, exotic pasture, and developed land uses, fragmenting the landscape and disrupting natural processes such as fire. The remaining small remnants of native prairie have a ready seed supply of invasive native and exotic species (e.g., *Baccharis halimifolia, Bothriochloa ischaemum var. songarica, Cynodon dactylon, Cyperus entrerianus, Dichanthium annulatum, Morella cerifera, Paspalum urvillei, Rosa bracteata, Sorghum halepense*, and Triadica sebifera). Overgrazed examples exhibit a lack of native grass cover and abundance of exotic grasses and forbs. Invasive animal species issues include feral hogs and red imported fire ants (TPWD 2012a). Ecological collapse is characterized by fragmentation and complete conversion of the system to other land uses, including overgrazed pasture, dominance by a single grass species (e.g., *Sporobolus indicus* or even *Schizachyrium scoparium*) and concomitant absence of a diversity of native grasses and forbs, and encroachment of woody plants (USFWS and USGS 1999, Grace et al. 2000, LDWF 2005, USGS 2013).

M158. Great Plains Comanchian Scrub & Open Vegetation

CES303.041 Edwards Plateau Limestone Shrubland

CES303.041 CLASSIFICATION

Concept Summary: This ecological system occurs as a matrix on relatively thin-soiled surfaces of plateaus of the massive limestones such as the Edwards limestone. These short to tall shrublands are variable in density depending on the relative amount of, and depth to, bedrock. *Quercus sinuata var. breviloba* is an important component of the system, with some areas dominated by *Quercus fusiformis*. *Juniperus ashei* is often an important component of this system. Important components in western examples may include *Pinus remota, Quercus mohriana, Quercus vaseyana*, and *Juniperus pinchotii*. Herbaceous cover may be patchy and is generally graminoid with species including *Schizachyrium scoparium, Bouteloua curtipendula, Bouteloua rigidiseta, Bouteloua trifida, Hilaria belangeri, Bothriochloa laguroides ssp. torreyana, Nassella leucotricha, Erioneuron pilosum, Aristida* spp., and others. Disturbances such as fire may be important processes maintaining this system. However, it appears to persist on thin-soiled sites. In the western portions of the Edwards Plateau, more xeric conditions lead to the slow succession of sites to woodlands, resulting in long-persisting shrublands.

Distribution: This system is limited in occurrence to the Edwards Plateau of Texas.
Nations: US
Concept Source: L. Elliott and K.A. Schulz
Description Author: L. Elliott, K.A. Schulz, J. Teague

CES303.041 CONCEPTUAL MODEL

Environment: This system occurs on thin soils over massive limestone such as Edwards or related formations in the Edwards Plateau of Texas. It may occur on plateaus or slopes and may often form a discontinuous band around a plateau edge as it breaks into the adjacent slope. Soils are characterized by Shallow or Very Shallow Ecological Sites, but may also be found on Low Stony Hill Ecological Sites (Elliott 2011).
Key Processes and Interactions: This system occurs in a steady state on thin-soiled xeric sites. Shrub cover can be 100% in patches, but overall cover may be 40-50%. Patches of dense shrubs may be interspersed with bare rock and grasslands over shallow soil. Farther west this system grades into other shallow-soiled shrubland systems. Disturbances such as fire may be important processes maintaining this system. However, it appears to persist on thin-soiled sites. In the western portions of the Edwards Plateau, more xeric conditions lead to the slow succession of sites to woodlands resulting in long-persisting shrublands.

CES303.725 Llano Estacado Caprock Escarpment and Breaks Shrubland and Steppe

CES303.725 CLASSIFICATION

Concept Summary: This ecological system occurs on various surfaces that are sufficiently resistant to erosion to form breaks or escarpments along the eastern edge of the Llano Estacado in Texas. This includes sedimentary deposits such as sandstones, limestones, or shales, or less frequently, igneous formations such as basalt. It is sometimes associated with canyons or drainages, but not always. The system occupies slopes, but may continue over transitions to more level sites upslope and downslope. Soils are variable and this system can occur where there is little soil development. Rough Breaks Ecological Sites are characteristic of this system, but other sites such as Rocky Hill and Gravelly Ecological Sites may also be occupied by this system. The physiognomic character of occurrences ranges from sparsely vegetated to shrubland, to sparse woodland. Bare ground is often conspicuous, and herbaceous cover is usually dominated by mid- to short grasses such as *Aristida purpurea, Bouteloua curtipendula, Bouteloua gracilis, Bouteloua hirsuta*, and *Schizachyrium scoparium*. Forbs, including species such as *Artemisia ludoviciana, Calylophus* sp., *Chaetopappa ericoides, Krameria lanceolata*, and *Melampodium leucanthum*, may also be present. Shrub canopy may be dense, with some species reaching tree stature, and on some sites forming sparse woodland. Shrub and tree species include *Juniperus pinchotii, Juniperus ashei, Quercus mohriana, Rhus trilobata, Dalea formosa, Cercocarpus montanus, Prosopis glandulosa*, and *Gutierrezia sarothrae*.

M051. Great Plains Mixedgrass Prairie & Shrubland

CES303.659 Central Mixedgrass Prairie

CES303.659 CLASSIFICATION

Concept Summary: This mixedgrass prairie system ranges from South Dakota into the Rolling Plains and the western Edwards Plateau of Texas. It is bordered by the shortgrass prairie on its western edge and the tallgrass prairie to the east. The loessal regions in west-central Kansas and central Nebraska, the Red Hills region of south-central Kansas and northern Oklahoma are all located within this system. Because of its proximity to other ecoregions, this system contains elements from both shortgrass and tallgrass prairies, which combine to form the mixedgrass prairie ecological system throughout its range. The distribution, species richness and productivity of plant species within the mixedgrass ecological system is controlled primarily by environmental conditions, in particular soil moisture and topography. Grazing and fire are important dynamic processes in this system. The relative dominance of the various grass and forb species within different associations in the system also can strongly depend on the degree of natural or human disturbance. This system can contain grass species such as *Bouteloua curtipendula, Schizachyrium scoparium, Andropogon gerardii, Hesperostipa comata*, and *Bouteloua gracilis*, although the majority of the associations within the region are dominated by *Pascopyrum smithii* or *Schizachyrium scoparium*. Numerous forb and sedge species (*Carex* spp.) can also occur within the mixedgrass system in the Western Great Plains. Although forbs do not always significantly contribute to the canopy, they can be very important. Some dominant forb species include *Ambrosia psilostachya* (grazing increases dominance), *Psoralidium tenuiflorum, Echinacea angustifolia, Helianthus* species, and *Ratibida columnifera*. Oak species such as *Quercus macrocarpa* can occur also in areas protected from fire due to topographic position (usually moister north-facing slopes). This can cause an almost oak savanna situation in certain areas, although fire suppression may allow for a more closed canopy and expansion of bur oak beyond those sheltered areas. In those situations, further information will be needed to determine if those larger areas with a more closed canopy of bur oak should be considered part of ~Western Great Plains Dry Bur Oak Forest and Woodland (CES303.667)$$. Likewise, within the mixedgrass system, small seeps may occur, especially during the wettest years. Although these are not considered a separate system, the suppression of fire within the region has enabled the invasion of native woody species such as *Juniperus virginiana, Juniperus pinchotii, Ziziphus obtusifolia, Prosopis glandulosa*, and also allowed for the establishment of *Pinus ponderosa* in some northern areas.

Distribution: This system is found throughout the central and southern areas of the western Great Plains ranging from southern South Dakota into the Rolling Plains and western Edwards Plateau of Texas.

Nations: US

Concept Source: S. Menard and K. Kindscher

Description Author: S. Menard, K. Kindscher, L. Elliott and J. Drake

CES303.659 CONCEPTUAL MODEL

Environment: Differences in topography and soil characteristics occur across the range of this system. It is often characterized by gently rolling to extremely hilly landscapes with soils developed from loess, shale, limestone or sandstone parent material, including Pennsylvanian formations of the Red Rolling Plains (Elliott 2011). Mollisol soils are most prevalent and range from silt loams and silty clay loams with sandy loams possible on the western edge of the range. The Red Hills region of Kansas and Oklahoma, which contains examples of this system, contains somewhat unique soil characteristics and has developed from a diversity of sources including red shale, red clay, sandy shale, siltstone, or sandstone. These soils have developed a characteristic reddish color from the primary material. These soils can consist of silt, loam, clay loam, or clay and can have textures ranging from a fine sandy loam to a more clayey surface. Ecological Sites include Clay Slopes, Loamy Prairie, Clayey Upland, Claypan Prairie, Sandy Loam, and Clay Loam (Elliott 2011).

Key Processes and Interactions: Fire, grazing, and drought are the primary processes occurring within the system. The diversity in this mixedgrass system likely reflects both the short- and long-term responses of the vegetation to these often concurrent disturbance regimes (Collins and Barber 1985). Fire is not as common as in more fertile, well-watered tallgrass prairies further east but is still important. Fire-return intervals have been estimated at 5-10 years (K. Kindscher pers. comm.), but fires burn patchily across the landscape, consuming vegetation in some areas and missing others. This combined with the differential responses of species to burning results in greater diversity across the landscape (Wright 1974). Grazing by native ungulates, primarily bison (*Bos bison*) and small mammals, principally prairie dogs (*Cynomys* spp.) added a further degree of patchy disturbance to the mixedgrass prairie (Whicker and Detling 1988, Weltzin et al. 1997). Long-term precipitation variance affects diversity of the mixedgrass prairie, creating conditions more favorable to shortgrass species during droughts while allowing mixedgrass species to spread during wetter years (Albertson and Tomanek 1965).

Threats/Stressors: In addition to loss through direct conversion to crop fields, farmland development has fragmented the natural landscape and has eliminated the large-scale processes of fire and grazing by native ungulates and small mammals that were necessary to maintain this system. Lack of fire, grazing, or mowing results in a decrease in productivity as sites accumulate more litter and native warm-season grasses become more dominant. Lack of fire allows tree cover to increase rapidly, especially on lower, more mesic slopes. This system is well-adapted to moderate grazing over time or heavy grazing for short periods, but when used as long-term pasture and with high stocking rates, many of the dominant native grasses are reduced or eliminated (Branson and Weaver 1953). Heavy haying or grazing, or if those are done consistently during the mid-summer months, negatively affects the dominant warm-season grasses by removing their biomass before they have flowered. Cool-season grasses and forbs which set seed earlier are favored by these activities. Native and non-native forbs, woody species, and C3 grasses increase in the absence of fire, especially when combined with grazing by livestock. Drier sites on hilltops or rocky soils persist longer, but mesic sites on lower slopes can be invaded by trees and shrubs after just several years without fire. Non-native grasses have been planted for forage on some sites, as well.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the landscape is fragmented and remaining mixedgrass prairie patches are small. Although these patches may persist for a time, the removal of the landscape-level processes that maintained this system will result in the eventual conversion to another vegetation type. Lack of fire and the pattern of grazing by native ungulates and small mammals, as well as the nearby seed sources for non-native species, will result in the elimination of sites over time. In the eastern portion of this system's range, encroachment by woody species, native or non-native, can also destroy sites, transforming them to shrublands or woodlands, often dominated by *Quercus* spp. or *Juniperus virginiana*. Heavy grazing or long-term grazing and haying tends to reduce the native warm-season grasses and degrades the system.

CES303.451 Northern Great Plains Fescue Mixedgrass Prairie

CES303.451 CLASSIFICATION

Concept Summary: This fescue-mixed grass ecological system is found in the northern Great Plains of Canada and adjacent areas of the United States, with the main area in Saskatchewan, west to Alberta, east to Manitoba and southward to outlier areas in North Dakota and Montana. This midgrass system is typically dominated by *Festuca hallii*. Other common graminoid species include *Hesperostipa comata, Hesperostipa curtiseta, Avenula hookeri, Koeleria macrantha, Pascopyrum smithii*, and upland sedges such as *Carex obtusata, Carex duriuscula, Carex inops ssp. heliophila*, and others. Common herbaceous species tend to be somewhat restricted. *Symphoricarpos occidentalis* and *Rosa arkansana* are common shrub species but may not be readily visible because of the tall growth of the *Festuca hallii*. Other shrubs that may be present include *Rosa woodsii, Artemisia frigida, Amelanchier alnifolia*, and *Rosa acicularis*. Overgrazing can heavily impact species composition and abundance. It usually occurs on nearly level to undulating terrain at elevations between 650 and 1250 m (2130-4100 feet). Stands tend to be on level sites, hilltops and upper slopes in the southern portion of the range, becoming more restricted to south-facing sites to the north. They may be on uplands, low-relief inclines in valleys or in valley settings. Soils may be solonetzic, with an impervious hardpan layer in the subsoil caused by excess sodium (Na+) or may also be clay, silty clay, or loam.

Related Concepts:

CES303.674 Northwestern Great Plains Mixedgrass Prairie

CES303.674 CLASSIFICATION

Concept Summary: This system extends from northern Nebraska into southern Canada and westward through the Dakotas to the Rocky Mountain Front in Montana and eastern Wyoming, on both glaciated and non-glaciated substrates. Soil texture (which ultimately effects water available to plants) is the defining environmental descriptor; soils are primarily fine and medium-textured and do not include sand, loamy sand, or sandy loam soils. This system occurs on a wide variety of landforms (e.g., rolling uplands stream terraces, ridgetops) and in proximity to a diversity of other systems. Most usually it is found in association with ~Western

Great Plains Sand Prairie (CES303.670)$$ which occupies the coarser-textured substrates. ~Northwestern Great Plains Shrubland (CES303.662)$$ is intermixed on the landscape in draws and ravines which receive more precipitation runoff and are somewhat protected from fires. In various locales generally north and east of the Missouri River, the topography where this system occurs is broken by many glacial pothole lakes, and this system may be proximate to ~Great Plains Prairie Pothole (CES303.661)$$. On the eastern Montana and western Dakota plains, mixedgrass prairie is by far the predominant system. Here it occurred continuously for hundreds of square kilometers, interrupted only by riparian areas or sand prairies, which were associated with gentle rises, eroded ridges, or mesas derived from sandstone. The growing season and rainfall are intermediate to drier units to the southwest and mesic tallgrass regions to the east. Graminoids typically comprising the greatest canopy cover include *Pascopyrum smithii, Nassella viridula*, and *Festuca* spp. In Montana these include *Festuca campestris* and *Festuca idahoensis*. Other commonly dominant species in Montana are *Bouteloua gracilis, Hesperostipa comata*, and *Carex filifolia*, while *Festuca campestris* and *Festuca idahoensis* may be more abundant in the north and foothill/montane grassland transition areas. *Bouteloua curtipendula, Elymus lanceolatus, Muhlenbergia cuspidata*, and *Pseudoroegneria spicata* are common, and sometimes abundant, components of this system. Remnants of *Hesperostipa curtiseta*-dominated vegetation are found in northernmost Montana and North Dakota associated with the most productive sites (largely plowed to cereal grains); this species, usually in association with *Pascopyrum smithii*, is much more abundant in Canada. Sites with a strong component of *Nassella viridula* indicate a more favorable moisture balance and perhaps a favorable grazing regime as well because this is one of the most palatable of the mid-grasses. *Hesperostipa comata* is also an important component and becomes increasingly so as improper grazing practices favor it at the expense of (usually) *Pascopyrum smithii*; progressively more destructive grazing can result in the loss of *Pascopyrum smithii* from the system followed by drastic reduction in *Hesperostipa comata* and ultimately the dominance of *Bouteloua gracilis* (or *Poa secunda* and other short graminoids) and/or a lawn of *Selaginella densa*. *Koeleria macrantha*, at least in Montana and southern Canada, is the most pervasive grass; if it has high cover, past intensive grazing is the presumed reason. In the eastern portion of this system's range, tallgrass species, especially *Andropogon gerardii, Panicum virgatum*, and *Sorghastrum nutans*, are often present to common on more mesic sites. Shrub species such as *Symphoricarpos* spp., *Artemisia frigida*, and *Artemisia cana* occur in the western and central portions while *Symphoricarpos* spp. and *Prunus* spp. can be found in the eastern portion. Sites with slightly to moderately saline soils have small to moderate amounts of salt-tolerant species such as *Distichlis spicata* and *Sporobolus airoides*. Fire, grazing and climate constitute the primary dynamics affecting this system. Drought can also impact this system, in general favoring the shortgrass component at the expense of the mid-grasses. With intensive grazing, cool-season exotics such as *Poa pratensis, Bromus inermis*, and *Bromus tectorum* can increase in dominance; both of the rhizomatous grasses have been shown to markedly depress species diversity. Shrub species such as *Juniperus virginiana* can also increase in dominance with fire suppression. This system is one of the most disturbed grassland systems in Nebraska, North and South Dakota, and Canada.

Distribution: This system is found in the western Great Plains north of the shortgrass prairie and west of the northern tallgrass prairie and extends from northern and western Nebraska into southern Canada, and west to central Montana and eastern Wyoming. The U.S. range corresponds to Bailey et al. (1994) sections 331D, 331E, 331F (mostly), 331G, 332A, 332B, 332D, and perhaps minor extensions into 251B, and in Canada to the Moist Mixed Grassland and Fescue Grassland.

Nations: CA, US

Description Author: S. Menard, K. Kindscher, G. Kittel, S. Cooper, M.S. Reid, K.A. Schulz, J. Drake

CES303.674 CONCEPTUAL MODEL

Environment: This system extends from northern Nebraska into southern Canada and westward through the Dakotas to the Rocky Mountain Front in Montana and eastern Wyoming, on both glaciated and non-glaciated substrates. It occurs on a wide variety of landforms (e.g., rolling uplands, mesatops, stream terraces) and in proximity to a diversity of other systems. Elevations range typically from 430-1220 m, and up to 1980 m in the northwestern extent (LANDFIRE 2007a).

Climate: The climate is cool, continental, ranging from hot summers (mean daily temperature in July of 15°C in the northwest to 25°C in the southeast) to cold winters (mean daily temperature of -16°C in the northeast to -5°C in the southwest). Precipitation increases from west (25 cm) to east (55 cm) with most falling as rain or snow from April through June (LANDFIRE 2007a). Climate and growing season length for the region this system occurs are intermediate to the shortgrass regions to the west and southwest and the tallgrass regions to the east with a shorter growing season and less humid climate compared to the range of ~Central Mixedgrass Prairie (CES303.659)$$. Moisture conditions are generally semi-arid.

Physiography/landform: Given the system's rather extensive geographic range, it is not surprising to find it occurring on a wide variety of landforms (e.g., rolling uplands, mesatops, stream terraces) and in proximity to a diversity of other systems.

Soil/substrate/hydrology: Soils are variable as it occurs on both glaciated and non-glaciated substrates generally with Entisols in the west and Mollisols in the east (LANDFIRE 2007a). Soil texture (which ultimately effects water available to plants) is the defining environmental descriptor; soils are primarily fine- and medium-textured, ranging from silt and clay loams, silty clay loams, silt loams to gravelly loam and do not include sands, sandy soils, or coarse sandy loams (Rolfsmeier and Steinauer 2010). In unglaciated areas, soils are derived primarily from fine-textured sedimentary rocks and deposits, primarily Cretaceous Pierre Shales, and to a lesser extent in Tertiary siltstones and chalky shales (Rolfsmeier and Steinauer 2010). Other rock types are included so long as their weathering products are not coarse-textured, namely not sandy soils. In glaciated areas, this system is found over glacial till and sometimes glacial lakeplains. It is found primarily on planar to gently rolling topography but is found on broken topography hillslopes as well. Some examples may include an impermeable or slowly permeable subsoil claypan layer. Other northern soils may be solonetzic and characterized by a subsoil hardpan layer with an excess of sodium (Adams et al. 2013).

Key Processes and Interactions: This grassland system evolved with fire, grazing, and drought, which constitute the primary dynamics affecting this system. The diversity in this mixedgrass system likely reflects both the short- and long-term responses of the vegetation to these often concurrent disturbance regimes (Collins and Barber 1985). Drought, rather than fire, is the primary driver maintaining the dry mixed grassland because it occurs more frequently than fire, inhibits expansion of woody shrubs and reduces the abundance of tallgrasses and mesophytic forbs, and prevents an accumulation of fuel that would maintain a frequent fire regime (Sala et al. 1996). Although variable in area, severe drought years in the Great Plains tend to occur in clusters periodically (1890s, 1930s, mid-1950s, late 1970s, late 1980s to early 1990s, and early 2000s) and have major ecological impacts.

Historic fire-return intervals have been estimated at 8-12 years (LANDFIRE 2007a), but fires burn patchily across the landscape, consuming vegetation in some areas and missing others because of natural firebreaks such as badlands, break in topography/ridge, and rivers. Fire-return intervals were likely longer in the drier, less vegetated central and western portions of this system's range and shorter in the east, near the transition to tallgrass prairie-dominated landscapes. Grazing and prairie dog towns also reduced fuel loads and fire frequency, size and intensity, with the most substantial impacts in valley bottom shrublands and grasslands, and upland grasslands near water (LANDFIRE 2007a). Historically, the majority of human-caused ignitions were concentrated in spring and fall seasons, while the more common lightning-caused fires were concentrated in late summer (Higgins 1984, 1986, LANDFIRE 2007a). This combined with the differential responses of species to burning results in greater diversity across the landscape (Wright and Bailey 1980).

Grazing by native ungulates, primarily bison (*Bos bison*) and small mammals, principally prairie dogs (*Cynomys ludovicianus*) added a further degree of patchy disturbance to the mixedgrass prairie (Whicker and Detling 1988). Available soil moisture drives species composition in this grassland, with a higher percentage of tall grasses on relatively moist, and cooler north-facing slopes, and mid and short grasses on drier steep and warmer southerly exposures (Rolfsmeier and Steinauer 2010). Long-term precipitation variance affects diversity of the central mixedgrass prairie, creating conditions more favorable to shortgrass species during droughts while allowing mixedgrass species to spread during wetter years (Sims et al. 1978, Singh et al. 1983). Extended drought in similar mixedgrass prairie in central Kansas caused loss of most forbs and cool-season grasses, and severe reductions of warm-season grasses (70-80%) (Albertson 1937) and likely has the same effects on mixedgrass prairie further north.

The absence of grazing and replacement fire for many years (e.g., 50 years) would lead to an increased shrub component (often *Symphoricarpos* spp. and *Fraxinus pennsylvanica*, but also possibly *Prunus* spp., *Amelanchier alnifolia, Elaeagnus commutata, Dasiphora fruticosa ssp. floribunda*, and *Juniperus horizontalis*) in precipitation zones greater than 35 cm, and a buildup of dead grass (LANDFIRE 2007a). Within the semi-arid (25-35 cm) precipitation zones, *Artemisia tridentata ssp. wyomingensis* and *Artemisia cana* may also increase. Productivity of the grasses is decreased, resulting in greater mortality from smoldering fire (LANDFIRE 2007a). Mormon crickets (*Anabrus simplex*), grasshoppers (Orthoptera) and extinct Great Plains locust (*Melanoplus spretus*) probably had more of an impact in this system than currently defined, but the historical impact and frequency are unknown.

LANDFIRE developed a VDDT model for this system which has two classes (LANDFIRE 2007a, BpS 2911410).

A) Early Development 1 All Structures (25% of type in this stage): Herbaceous cover is 0-40%. Class A is the post-fire early-seral stage, combined with the very short-statured vegetation resulting from prairie dog disturbance or repeated high-intensity herbivory or trampling (e.g., watering points or buffalo wallows). This class may also be a short-term response to severe drought, combined with other impacts. This class lasts approximately three years. If in a prairie dog state, then the class would last longer in order to transition out of it; however, this is accounted for by having a prairie dog disturbance in the model, resetting succession and keeping it in this class. The 3-year interval attempts to capture what would happen post-fire or post-drought. Also post-heavy-grazing in current conditions would take longer to transition out of this class. Drought can occur every 30 years, not causing a transition. Replacement fire occurs but not as frequently, due to lack of fuel, every 20 years.

B) Mid Development 1 Closed (75% of type in this stage): Herbaceous cover (41-90%). Class B represents the intact historic plant community functioning under grazing and/or fire, dominated by taller, cool and warm-season rhizomatous perennial grasses, as well as bunchgrasses. This is the all-encompassing mid-to late-development, functioning final stage. Little below-ground mortality occurs after replacement fire, and resprouting of perennial grasses and forbs often occurs within days or weeks, depending on season. Grasses show greater vigor; some forb establishment may occur as a result of exposure of mineral soil. Canopy cover recovers quickly after resprouting. Shrub species could be present at 0-10% cover. Silver sagebrush and winterfat (on deeper soils) are the most common shrub, and would start resprouting. Wyoming big sagebrush can also be a component (on shallower soils) of this BpS, although a small component. Clubmoss might be present in Glaciated Plains at 0-5% cover, but not on shallow clay sites or dense clay sites, sands, saline upland, saline lowland, subirrigated or wet meadow. Replacement fire occurs every 5-15 years. Drought occurs every 30 years and maintains this stage. Native grazing by large ungulates could have occurred, including bison grazing. It is likely heavy locally due to increased succulence of young grasses. It might occur with a probability once every five years or 20% of this class each year. Native grazing by prairie dogs could also occur on a small portion of the landscape, bringing this state to A. Insect/disease occurs very infrequently. Grasshoppers and Mormon crickets might have a larger impact historically; however, there is uncertainty of impact and frequency. With a lack of fire, this class might shift to having more shrubs and tree invasion.

In the LANDFIRE BpS 2011410 model (3 Classes), drought was also thought to occur once every 30 years on average (LANDFIRE 2007a). It was also acknowledged that this system occurs within the very same biotope as ~Inter-Mountain Basins Big Sagebrush Steppe (CES304.778)$$ or ~Inter-Mountain Basins Big Sagebrush Shrubland (CES304.777)$$, the only difference being that fire has not been present where the sagebrush systems occur, a purely stochastic outcome (LANDFIRE 2007a).

Threats/Stressors: Historically, this system covered approximately 61.4 million ha (614,000 square km) in Nebraska, North and South Dakota, and Canada; now it covers approximately 29.9 million ha (299,000 square km) in this region, a 51% reduction in extent. Major threats to this system are loss through direct conversion to crop fields and heavily grazed pastures. Farmland development has fragmented the natural landscape and has eliminated the large-scale processes of fire and grazing by native ungulates and small mammals that were necessary to maintain this system. Lack of fire, grazing, or mowing result in a decrease in productivity as sites accumulate more litter. Lack of fire allows tree cover to increase rapidly, especially on lower, more mesic slopes and in the eastern, more mesic edges of the system's range. Encroachment by *Juniperus virginiana* as a result of fire suppression is problematic in some portions of the system's distribution (Rolfsmeier and Steinauer 2010). This system is well-adapted to moderate grazing over time or heavy grazing for short periods but when used as long-term pasture and with high stocking rates many of the dominant native grasses are reduced or eliminated (Branson and Weaver 1953). Heavy haying or grazing done for extended periods results in a selective reduction in more palatable mid- and tallgrass species. This results in a relative increase in short graminoids, such as *Bouteloua dactyloides, Bouteloua gracilis, Carex* spp., and *Poa secunda* and, where there are nearby seed sources, shrubs such as *Artemisia tridentata, Artemisia cana*, and *Symphoricarpos* spp. or if those are done consistently during the mid-summer months negatively affects the taller warm-season grasses (if present) by removing their biomass before they have flowered. Cool-season grasses and forbs which set seed earlier are favored by these activities as are short and/or less palatable species. Native and non-native forbs, woody species, and C3 grasses increase in the absence of fire, especially when combined with grazing by livestock. Drier sites on hilltops or rocky soils persist longer but mesic sites on lower slopes can be invaded by trees and shrubs after just several years without fire.

Invasion by non-native species degrade the biotic integrity of many stands of this grassland system reducing the abundance of native species (Ogle et al. 2003, Pritekel et al. 2006, Mack et al. 2007, Davies 2011, Fink and Wilson 2011). Exotic grasses (*Agropyron cristatum, Bromus inermis, Poa compressa*, and *Poa pratensis*) have been planted for forage and erosion control on many sites. Invasive upland forb species such as *Acroptilon repens, Centaurea stoebe ssp. micranthos, Linaria* spp., *Melilotus officinalis*, and mesic site species *Cirsium* sp. and *Euphorbia esula* have become naturalized in many areas (LANDFIRE 2007a). Invasion by annual bromes, especially *Bromus arvensis* and *Bromus tectorum*, has impacted many mixedgrass prairie sites, especially those dominated by cool-season grasses *Pascopyrum smithii* and *Nassella viridula* (Ogle et al. 2003).

The natural grazing regime has been replaced with domestic livestock grazing that is targeted toward "moderate" grazing intensity. This is often characterized by grazing each year with removal of herbage over an extended period of the growing season without adequate rest and recovery from grazing. This is contrasted with the expected historic shorter, episodic grazing patterns. One result is more structural homogeneity. Under the current livestock-grazing regime, taller, palatable grasses such as *Nassella viridula* and *Pseudoroegneria spicata* decrease and shorter grasses (*Bouteloua gracilis, Hesperostipa comata, Pascopyrum smithii*, and *Poa secunda*) increase. Only under season-long grazing will warm-season grasses such as *Schizachyrium scoparium* decrease. Season of use and/or twice-over grazing will impact the prevalence of *Schizachyrium scoparium* and other C4 plants. Heavy grazing causes cool-season exotics such as *Poa pratensis* and *Bromus inermis* to increase in dominance.

Shrubs (*Artemisia cana, Artemisia frigida, Artemisia tridentata ssp. wyomingensis, Ericameria* spp., *Symphoricarpos occidentalis*, and *Symphoricarpos oreophilus*) increase greatly over the historic plant community. Compare the ecological site description to avoid using a shrub model for historic plant community when considering a grass site that has changed as a result of uncharacteristic grazing or unnaturally long fire-return intervals. Unnaturally long intervals without fire may contribute to an increased shrub component. Xeric sites will experience an increase in sagebrush (*Artemisia* spp.), whereas western snowberry (*Symphoricarpos* spp.) will increase in mesic areas.

Long-term high-intensity grazing by domestic livestock without periods of rest and recovery can result in a conversion in the vegetation states from a midgrass-dominated community to shortgrass-dominated communities (*Bouteloua gracilis, Bouteloua dactyloides* (in southern portions), *Carex* spp., *Koeleria macrantha*, and *Poa secunda*). This should be distinguished from the class

(class B) that's influenced more by presence of prairie dog towns - which have a higher forb component with less of a midgrass component than the other classes. In species composition, communities grazed by prairie dog versus domestic livestock are very different.

In current conditions, there has also been an increase in the amount of woody vegetation on the plains, particularly increases in *Symphoricarpos* spp. on mesic sites and expansion of *Pinus ponderosa* into grasslands and shrublands which were probably maintained in a grassland state under historic fire frequencies. The lack of fire has shifted grassland systems to shrublands or woodlands.

Conversion to agriculture also impacts this system; however, the degree of agricultural alteration of this system is highly variable by geographic region with Montana and Wyoming having experienced much less impact than the estimated 75% percent of the Nebraska-Dakota-south-central Canada region, where this system has been heavily altered. In Montana, this system is the major sustainer of livestock grazing with overall far less than half of it having been lost to agriculture; several Montana counties have more than 90% of this system remaining intact, though impacted by grazing to varying degrees. The shortgrass *Bouteloua gracilis* is frequently abundant and conspicuous on mowed and heavily grazed sites, but on lightly grazed or spring-burned sites the tall grasses are frequently most conspicuous, creating the appearance of tallgrass prairie.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the landscape is fragmented and remaining mixedgrass prairie patches are small. Although these patches may persist for a time, the removal of the landscape-level processes that maintained this system will result in the eventual conversion to another vegetation type. Lack of fire and the pattern of grazing by native ungulates and small mammals as well as the nearby seed sources for non-native species will result in the elimination of sites over time. In the eastern portion of this system's range, encroachment by woody species, native or non-native, can also destroy sites, transforming them to shrublands or woodlands, often dominated by *Juniperus virginiana*. Heavy grazing or long-term grazing and haying tends to reduce the native cool-season grasses and degrades the system. Invasion and conversion to non-native herbaceous species may occur with increased disturbances.

High-severity environmental degradation appears where occurrences tend to be relatively small (<50,000 acres) in size and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Fragmentation from anthropogenic alterations such as a high density of roads (e.g., oil and gas exploration and development or exurban development) has heavily impacted sites creating barriers to fire and as a source of invasive non-native species. Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval beyond 50 years. This may have resulted in a significant increase in cover (5-10%) and regeneration of trees and shrubs. Alteration of abiotic processes is extensive and restoration potential is low.

Moderate-severity environmental degradation appears where occurrences are moderate (50,000-150,000 acres) in size and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Fragmentation from anthropogenic alterations such as a moderate density of roads (e.g., oil and gas exploration and development or exurban development) has moderately impacted sites creating barriers to fire and as a source of invasive non-native species. Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval beyond 25 years. This may have resulted in a significant increase in cover (>10%) and regeneration of trees and shrubs. Alteration of abiotic processes is moderate and restoration potential is moderate.

High-severity disruption appears where vegetation on the occurrence has little or no structural diversity and is likely to have low species diversity. Cover required for nesting and/or breeding of grassland birds is not sufficient. Plant vigor may be poor and dead or decadent plants are common. Reproductive capability of native perennial plants is severely reduced. There may significant cover of shrubs and trees (>10%) because of fire suppression and invasion from adjacent woodlands. Invasive non-native species may be common to dominant. Connectivity is severely hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low. Grassland bird populations are in sharp decline.

Moderate-severity disruption appears where species richness is reduced in comparison with higher ranked occurrences. Native bunchgrasses are present but may be nearly equal in canopy cover to non-native species. Native species that increase with livestock grazing may be codominant or dominant. Trees and shrubs may have seedlings, juveniles, or saplings present. Plant density and production may be reduced, and litter may be excessive or not present at all. Reproductive capability of native perennial plants is greatly reduced. Species composition has shifted to more early-seral species (grazing-increasers) such as *Aristida* spp., *Elymus elymoides, Sporobolus cryptandrus, Gutierrezia sarothrae, Heterotheca villosa*, or near monocultures of the grazing-tolerant species *Bouteloua gracilis*. Connectivity is moderately hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and reduce the natural movement of some animal and plant populations. Grassland bird populations follow rangewide decline.

CES303.662 Northwestern Great Plains Shrubland

CES303.662 CLASSIFICATION

Concept Summary: This ecological system ranges from South Dakota into southern Canada on moderately shallow to deep, fine to sandy loam soils. These sites are typically more mesic than most of the surrounding area. This system may be located along upper terraces of rivers and streams, gently inclined slopes near breaklands, and upland sandy loam areas throughout its range. This system is dominated by shrub species such as *Amelanchier alnifolia, Rhus trilobata, Symphoricarpos* spp., *Shepherdia argentea, Crataegus douglasii, Elaeagnus commutata, Dasiphora fruticosa ssp. floribunda*, and dwarf-shrubs such as *Juniperus horizontalis*. Midgrasses such as *Festuca* spp., *Koeleria macrantha*, and *Pseudoroegneria spicata* and species such as *Carex filifolia* can co-occur. This system differs from ~Northwestern Great Plains Mixedgrass Prairie (CES303.674)$$ in that it contains greater than 10% cover in conjunction with topographic relief (breaks) of natural shrub species. Fire and grazing constitute the primary dynamics affecting this system; drought can also impact this system. This system may include areas of ~Northwestern Great Plains Mixedgrass Prairie (CES303.674)$$ where fire suppression has allowed for a greater cover of shrub species. This system is similar to ~Northern Rocky Mountain Montane-Foothill Deciduous Shrubland (CES306.994)$$ but occurs in the grassland matrix of the Great Plains, whereas the Rocky Mountain system occurs adjacent to the lower treeline of generally forested mountains and highlands. Floristically their shrub composition is similar, but associated grasses and forbs will differ somewhat given their respective adjacent vegetation types.

CES303.662 CONCEPTUAL MODEL

Environment: Climate and growing season length for the region this system occurs are intermediate to the shortgrass regions to the west and the tallgrass regions to the east with a shorter growing season with semi-arid moisture conditions. This system occurs on sites more mesic than most of the surrounding area such as upper river terraces, gently inclined slopes, and upland sandy areas. Soils range from shallow to deep and fine to sandy loams.

Key Processes and Interactions: Fire and grazing constitute the primary dynamics affecting this system. Drought can also impact this system.

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has three classes in total (LANDFIRE 2007a, BpS 2010850). These are summarized as:

A) Early Development 1 Open (herbaceous-dominated - 35% of type in this stage): Cover is 0-50%. Grasses such as little bluestem, western wheatgrass, stipa, bluebunch wheatgrass, sideoats grama and upland sedges dominate this class. This class is a combination of grasses and very short-statured vegetation resulting also from prairie dog disturbance (maybe only in draws - snowberry). A variety of forb species such as fetid marigold, scarlet globemallow, scarlet gaura, skeleton weed and dotted gayfeather tend to dominate this class. Some sprouting of snowberry, chokecherry and serviceberry. The fuel in this class would be initially too sparse to carry fire, but then fuel increases. This class lasts for 9 years then succeeds to class B, mid-open state. (Although, if it were a dense stand initially and then re-sprouted, might take fewer than 9 years to get to class B.) Replacement fire occurs every 30 years, and sets this class back to its beginning stage. Grazing (0.07 probability or 7% of this class each year), the combination of drought and grazing (0.02 probability or 2% of this class each year) and drought modeled as wind/weather/stress (0.05 probability or 5% of this class each year) all occur and maintain this class but don't set it back to its beginning state. Prairie dog impact occurs with a probability of 0.0035 (0.35% of class each year) and returns this class to its beginning. The only shrub that prairie dogs might impact in this BpS would be the snowberry sites and draws/drainageways.

B) Mid Development 1 Open (shrub-dominated - 25% of type in this stage): Shrub cover is 0-20%. More open community than late stage. Seedling shrubs. Dominant shrubs coming in include snowberry, chokecherry, skunkbush, creeping juniper and buffaloberry. Western wheatgrass, needlegrasses, little bluestem and upland sedges are common grasses - same as in class A. Bluebunch wheatgrass can be locally common with skunkbush. Common forbs include scurfpea, prairie coneflower, Rocky Mountain beeplant, scarlet globemallow and dotted gayfeather. Herbaceous cover is approximately 30-70% and approx. 0.5 m in height. This class lasts 9 years and then succeeds to the late-development stage. Replacement fires occur every 30 years. Grazing (0.02 probability or 2% of this class each year) and the combination of drought and grazing (0.01 probability) occur and cause a transition back to the early stage, class A. Grazing (0.02 probability), the combination of drought and grazing (0.003 probability) and drought modeled as wind/weather stress (0.1 probability) can also occur while maintaining this class in this stage. Prairie dog impact occurs with a probability of 0.0003, taking the class back to class A.

C) Late Development 1 Closed (shrub-dominated - 40% of type in this stage): Tree cover is 21-80%. Denser, higher canopy cover. Mature canopy. Vegetation community is similar to previous class. Forbs are present still. Litter layer tends to be relatively continuous. Herbaceous cover 50-65% and 0.5 m in height. Snowberry average cover could be 65%. Maximum up to 75%, minimum approx. 45%. Skunkbush cover average approximately 25%. Horizontal juniper average 44%, range of 25-65% cover. Each of the shrub species associated with own habitat type with moisture gradient. Skunkbush is dry end, and snowberry/chokecherry is wet end.

The northern mixed-grass prairie and shrublands are strongly influenced by wet-dry cycles. Fire, grazing by large ungulates and small mammals such as prairie dogs and soil disturbances (i.e., buffalo wallows and prairie dog towns) are the major disturbances in this vegetation type. In MZ30, many of these shrubland types occur on moderate to steep slopes (west- to northwest-facing).

From instrumental weather records, droughts are likely to occur about 3 in every 10 years. Historically, there were likely close interactions between fire and grazing since large ungulates tend to be attracted to post-fire communities. Conversely, fire presumably was less likely in areas recently heavily grazed by herbivory, thus contributing to spatial and temporal variation in fire occurrence.

Average fire intervals are estimated at 8-25 years, although in areas with very broken topography fire intervals may have been greater than 30 years. The model for MZ20 reflects a 30-year FRI. This system's FRI should be very similar to 1141 mixedgrass prairie, since this system is just inclusions within 1141. It might be a little less frequent because of moisture; however, it should be similar.

Fires were most common in July and August, but probably occurred from about April to September. Seasonality of fires influences vegetation composition. Early-season fires (April - May) tend to favor warm-season species, while late-season fires (August - September) tend to favor cool-season species. Replacement fire in our model does remove 75% of the above-ground cover as assumed in the literature. However, loss of the above-ground cover by the replacement fire will not necessarily induce a retrogression back to an earlier seral stage from the late stage because the main component of dominant grasses remains unharmed to insure the continuity of the seral stage. The shrub species, however, are sprouters. Fire would remove them, and they would resprout. The exception would be horizontal juniper and skunkbush which would not resprout. It would take longer for them to become re-established.

Different levels of native ungulate grazing intensities were used in LANDFIRE modelling. Light grazing was assumed to not alter the community enough to change classes but increasing grazing intensity would move the community back to earlier stages. Grazing return interval probably occurred every 7-10 years but grazing would only result in a class change maybe once every 80-100 years. Overall, the grazing frequency was modeled at every 20 years - that includes grazing just occurring with no transition resulting, as well as grazing taking the stage back to an earlier class. And, overall, the drought plus grazing impact frequency was modeled as every 70 years - that includes the no-transition plus transition to early stage (LANDFIRE 2007a, BpS 2010850). In addition to fire, drought, grazing and insect outbreaks (Rocky Mountain locust) would have impacted all classes, historically.

Threats/Stressors: Conversion to agriculture can impact this system, and its range has probably been decreased by human activities. Impacts from energy extraction in oil and gas fields in the Dakotas and eastern Montana have recently fragmented large areas with road networks to well pads and pipelines. Livestock grazing and trampling can negatively impact these shrublands, especially during the winter as stands often occur in swales and stream terraces that offer livestock and wildlife some protection from winter storms.

CES303.817 Western Great Plains Foothill and Piedmont Grassland

CES303.817 CLASSIFICATION

Concept Summary: This ecological system typically occurs between 1600 and 2200 m in elevation. It is best characterized as a mixedgrass to tallgrass prairie on mostly moderate to gentle slopes, usually at the base of foothill slopes, e.g., the hogbacks of the Rocky Mountain Front Range where it typically occurs as a relatively narrow elevational band between montane woodlands and shrublands and the shortgrass steppe and mixedgrass prairie, but extends east on the Front Range piedmont alongside the Chalk Bluffs near the Colorado-Wyoming border, out into the Great Plains on the Palmer Divide, and on piedmont slopes below mesas and foothills in northeastern New Mexico. A combination of increased precipitation from orographic rain, temperature, and soils limits this system to the lower elevation zone with approximately 40 cm of precipitation/year. It is maintained by frequent fire and associated with well-drained clay soils. Usually occurrences of this system have multiple plant associations that may be dominated by *Andropogon gerardii, Schizachyrium scoparium, Nassella viridula, Pascopyrum smithii, Sporobolus cryptandrus, Bouteloua gracilis, Hesperostipa comata*, or *Hesperostipa neomexicana*. In Wyoming, typical grasses found in this system include *Pseudoroegneria spicata, Schizachyrium scoparium, Hesperostipa neomexicana, Hesperostipa comata*, and species of *Poa*. Typical adjacent ecological systems include foothill shrublands, ponderosa pine savannas, juniper savannas, as well as shortgrass prairie.

Related Concepts:

- Grama - Feathergrass (716) (Shiflet 1994) **<**
- Sideoats Grama - New Mexico Feathergrass - Winterfat (724) (Shiflet 1994) **<**
- Sideoats Grama - Sumac - Juniper (735) (Shiflet 1994) **><**

Distribution: This mixed grassland ecological system occurs in a transitional band between the Rocky Mountains and the Shortgrass Steppe where increased soil moisture from orographic lifting and local topography favor tall and mid-height grasses. The band is restricted to the Rocky Mountain foothills and piedmont and adjacent plains, extending farther east on the Palmer Divide, north alongside the Chalk Bluffs near the Colorado-Wyoming border, and south on and below mesas and escarpments in southeastern Colorado, northeastern New Mexico, and the panhandles of Oklahoma and Texas. These grasslands also occur around the edges of the Black Hills uplift, where Schizachyrium scoparium is the dominant grass.

CES303.817 CONCEPTUAL MODEL

Environment: This ecological system occurs between 1600 and 2200 m in elevation. It is best characterized as a mixedgrass to tallgrass grassland on mostly moderate to gentle slopes, usually at the base of foothill slopes, e.g., the hogbacks of the Rocky Mountain Front Range where it typically occurs as a relatively narrow elevational band between montane woodlands and shrublands and the shortgrass steppe and mixedgrass prairie, but extends east on the Front Range piedmont alongside the Chalk Bluffs near the Colorado-Wyoming border, out into the Great Plains on the Palmer Divide, and on piedmont slopes below mesas and foothills in northeastern New Mexico. This mixed grassland receives more precipitation than shortgrass steppe or occurs on coarser-textured substrates allowing for increased infiltration and water storage (Noy-Meir 1973). A combination of increased precipitation from orographic rain, temperature, and soils limits this system to the lower elevation zone with approximately 40 cm of precipitation/year. It is maintained by frequent fire and associated with well-drained clay soils. Typical adjacent ecological systems include foothill shrublands, ponderosa pine savannas, juniper savannas, as well as shortgrass prairie.

Key Processes and Interactions: Relatively frequent surface fire (FRI = 20 years -15 years in the southern extent) maintains this ecosystem by reducing seedling survival of shrubs such as *Cercocarpus montanus* and *Rhus trilobata* and trees such as *Pinus ponderosa, Pinus edulis*, and *Juniperus* spp. thus preventing conversion to shrublands and woodlands (Landfire 2007a). There is little information on this natural frequency, size, intensity, or severity of fire in this ecosystem. Ungulate grazing (Landfire 2007a) and herbivory are a key process that includes grazing and browsing by large and small mammals and insects. Soils are naturally disturbed by burrowing mammals such as prairie dogs, rabbits, pocket gophers, ground squirrels, and badgers providing habitat for disturbance-dependent species. Drought occurs periodically (approximately every 20-50 years) and can cause shifts in species compositions to more drought-tolerant species (Landfire 2007a).

Threats/Stressors: This system is one of the most severely altered systems in the Southern Rocky Mountains ecoregion. Alteration is due to fire suppression, housing and water developments, conversion to hay meadows, overgrazing, etc. Fire suppression has allowed for shrub and tree invasion into the grassland and alters the species composition as well (Mast et al. 1997, 1998). Housing and water developments severely fragment and usually destroy the habitat, while agricultural use has converted tall grass prairies into hay meadows dominated by exotic grasses, e.g., *Bromus inermis*. It is very unusual to find excellent occurrences of this system. Threats are very high for this system and, therefore, a premium is set on protecting the existing occurrences (CNHP 2010b).

Conversion of this type has commonly come from urban and exurban development along the Front Range, water developments/reservoirs, and dryland wheat and irrigated agriculture especially hay meadows dominated by non-native forage grasses (CNHP 2010b). Fire suppression has allowed succession and conversion to shrublands and conifer woodlands especially from ponderosa pine, pinyon or juniper tree invasion (Mast et al. 1997, 1998). Common stressors and threats include fragmentation from housing and water developments, altered fire regime from fire suppression and indirectly from livestock grazing and fragmentation, introduction of invasive non-native species (CNHP 2010b). Potential climate change effects could include a change in the current extent of the ecosystem with lower elevation transitional areas converting to shortgrass prairie, if climate change has the predicted effect of less effective moisture with increasing mean temperature (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances that allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<1000 acres) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval from 20 years to 40- 80 years similar to ponderosa pine forest (Landfire 2007a). This has resulted in a significant increase in cover (>10%) and regeneration of trees and shrubs. Alteration of abiotic processes is extensive and restoration potential is low. Moderate-severity environmental degradation appears where occurrences are moderate (5000-1000 acres) in size and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion. Fire suppression and reduction of fine fuels by grazing increased the fire-return interval from >20 years (Landfire 2007a) resulting in regeneration of trees and shrubs (5-10% cover.

High-severity disruption appears where occurrences have low cover of native grassland species (<10% cover and <20% relative cover). There is often significant cover of shrubs and trees (>10%) because of fire suppression. Invasive non-native species may be present to abundant. Other non-native species dominate the herbaceous layer (CNHP 2010b). Connectivity is severely hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low (CNHP 2010b). Moderate-severity disruption appears where occurrences have moderate cover of native grassland species (>10% cover and >20% relative cover) (CNHP 2010b). There is often significant cover of shrubs and trees (5-10%) because of fire suppression. Non-native invasive species are present, but still controllable (CNHP 2010b). Species composition has shifted from dominance of late-seral, palatable midgrasses such as *Bouteloua curtipendula, Hesperostipa comata, Pascopyrum smithii*, and *Schizachyrium scoparium* to more early-seral species (grazing-increasers) such as *Aristida* spp., *Elymus elymoides, Gutierrezia sarothrae, Heterotheca villosa, Sporobolus cryptandrus*, and grazing-tolerant species such as *Bouteloua gracilis*. Connectivity is moderately hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and reduce the natural movement of some animal and plant populations (CNHP 2010b).

CES303.673 Western Great Plains Tallgrass Prairie

CES303.673 CLASSIFICATION

Concept Summary: This system can be found throughout the Western Great Plains Division. It is found primarily in areas where soil characteristics allow for mesic conditions more typical of the Eastern Great Plains Division and thus are able to sustain tallgrass species. This system may be small patches interspersed within ~Northwestern Great Plains Mixedgrass Prairie (CES303.674)$$ or ~Western Great Plains Shortgrass Prairie (CES303.672)$$ and may also be associated with upland terraces above a floodplain system where these more mesic conditions persist. Soils are primarily loamy Mollisols that are moderately deep and rich. Those areas that contain more sandy soils should be considered part of ~Western Great Plains Sand Prairie (CES303.670)$$. This system is dominated primarily by *Andropogon gerardii* and may also include *Sorghastrum nutans, Schizachyrium scoparium, Pascopyrum smithii, Hesperostipa spartea*, and *Sporobolus heterolepis*. *Andropogon gerardii* often dominates the lowland regions, although *Pascopyrum smithii* can be prolific if conditions are favorable. Forbs in varying density may also be present. The primary dynamics for this system include fire, climate and grazing. Fire suppression in these areas has allowed for the invasion of woody species such as *Juniperus virginiana* and *Prunus* spp. Grazing also has contributed to these changes and likewise led to a decrease of this system as overgrazing favors shortgrass and mixedgrass systems. Conversion to agriculture likewise has probably decreased the range of this system. Thus, this system likely only occurs in small patches and in scattered locations throughout the division. Large-patch occurrences are mostly isolated to slopes and swales of rolling uplands where either grazing or cultivation are more problematic.

Concept Source: S. Menard and K. Kindscher

Description Author: S. Menard, K. Kindscher, J. Drake

CES303.673 CONCEPTUAL MODEL

Environment: This system is found primarily on loam, moderately deep, and rich Mollisols throughout the Western Great Plains Division. These soils tend to be more mesic and deep than the majority of soils within the Western Great Plains and are more typical of the Eastern Great Plains Division. This system requires more moisture than is available from precipitation in the Western Great Plains so it occurs in valleys, on lower slopes, and sometimes on floodplains (Albertson 1937, Heitschmidt et al. 1970). Occurrences are usually medium to small.

Key Processes and Interactions: Fire, climate and grazing constitute the primary dynamic processes impacting this system. Fire may have occurred as often as every 5 years, especially in the wetter eastern portions of this system's range (Landfire 2007a). This system occurred in a landscape dominated by mixedgrass and shortgrass vegetation. These systems do not have the rapid build up of litter that occurs in tallgrass prairies further east and thus do not carry fire as readily so there were fewer fires that could affect this system.

This system developed in an area occupied by vast numbers of native ungulates, notably bison (*Bos bison*) but including other species, and the grazing of these species affected species composition and the patchwork of habitat. Bison preferentially favor newly burned areas and graminoids over forbs (Coppedge and Shaw 1998, Vinton et al. 1993). On unburned sites, grazing removes live and dead vegetation, allowing more light and heat to the soil surface and increasing available moisture thus favoring species, forbs or woody plants, in the case of bison grazing, that were resilient to the effects of grazing or avoided by the grazers (Damoureyeh and Hartnett 1997).

Threats/Stressors: Fire suppression can allow for the invasion of woody species such as *Juniperus virginiana* and *Prunus* spp. into the prairie matrix. This is a more serious threat in the eastern portion of this system where the climate is more amenable to trees and shrubs and seed sources are more common.

This system is typically more productive than surrounding vegetation and is preferentially grazed by livestock (Branson and Weaver 1953). Many examples of this system are used for pasture or haying. Overgrazing tends to favor shortgrass and mixedgrass species and can cause the conversion of this system to the Western Great Plains shortgrass or mixedgrass systems. Prolonged haying during the early to mid summer favors cool-season species that set seed before the haying occurs. Also, invasion by introduced species such as *Bromus inermis, Poa pratensis*, and several weedy forbs can become more severe as grazing pressure increases.

Long-term drought will favor midgrass and shortgrass species over the tallgrass species that characterize this system. Changes to climatic patterns that increase average summer temperatures or decrease precipitation will result in a reduction of sites where this system can persist.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when sites are heavily grazed or hayed for several years in a row or, in the eastern portion o this system's range, fire suppression allows woody species to spread and convert sites to shrublands or woodlands. Invasion by exotic species can convert sites to non-native vegetation.

M052. Great Plains Sand Grassland & Shrubland

CES303.670 Western Great Plains Sand Prairie

CES303.670 CLASSIFICATION

Concept Summary: Sand prairies are often considered part of the tallgrass or mixedgrass regions in the western Great Plains but can contain elements from ~Western Great Plains Shortgrass Prairie (CES303.672)$$, ~Central Mixedgrass Prairie (CES303.659)$$, and ~Northwestern Great Plains Mixedgrass Prairie (CES303.674)$$. The largest expanse of sand prairies (approximately 5 million ha) can be found in the Sandhills of north-central Nebraska and southwestern South Dakota. These areas are relatively intact. The primary use of this system has been grazing (not cultivation), and areas such as the Nebraska Sandhills can experience less degeneration than other prairie systems. Although greater than 90% of the Sandhills region is privately owned, the known fragility of the soils and the cautions used by ranchers to avoid poor grazing practices have allowed for fewer significant changes in the vegetation of the Sandhills compared to other grassland systems. Nonetheless, the sustained annual grazing within pastures by cattle has altered the mix of vegetation. The unifying and controlling feature for this system is coarse-textured soils, and the dominant grasses are well-adapted to this condition. Soils in the sand prairies can be relatively undeveloped and are highly permeable. Soil texture and drainage along with a species' rooting morphology, photosynthetic physiology, and mechanisms to avoid transpiration loss are highly important in determining the composition of the sand prairies. In the northwestern portion of its range, stand size corresponds to the area of exposed caprock sandstone, and small patches predominate, but large patches are also found embedded in the encompassing ~Northwestern Great Plains Mixedgrass Prairie (CES303.674)$$. Another important feature is their susceptibility to wind erosion. Blowouts and sand draws are some of the unique wind-driven disturbances in the sand prairies, particularly where there are fine sands, such as in the Nebraska Sandhills (where the rare *Penstemon haydenii* occurs). In most of eastern Montana, substrates supporting this system have weathered in place from sandstone caprock; thus the solum is relatively thin, and the wind-sculpted features present further east, particularly in Nebraska, do not develop. Graminoid species dominate the sand prairies, although relative dominance can change due to impacts of wind disturbance. *Andropogon hallii* and *Calamovilfa longifolia* are the most common species, but other grass and forb species such as *Hesperostipa comata, Schizachyrium scoparium, Carex inops ssp. heliophila*, and *Panicum virgatum* are often present. Apparently only *Calamovilfa longifolia* functions as a dominant throughout the range of the system. In the western extent, *Hesperostipa comata* becomes more dominant, and *Andropogon hallii* is less abundant but still present. Communities of *Artemisia cana ssp. cana* are included here in central and eastern Montana. Patches of *Quercus havardii* can also occur within this system in the southern Great Plains. Fire and grazing constitute the other major dynamic processes that can influence this system. In the Western Great Plains in Texas, prairies on deep sands and sandhills which currently represent far southern outliers of this system, are dominated by species such as *Andropogon gerardii, Andropogon hallii, Calamovilfa gigantea, Cenchrus spinifex, Hesperostipa comata, Paspalum setaceum, Schizachyrium scoparium, Sporobolus cryptandrus*, and *Sporobolus giganteus*. Some woody species may be present, including *Artemisia filifolia* and *Quercus havardii*. Shrub species such as *Artemisia filifolia, Prunus angustifolia, Rhus trilobata*, and *Quercus havardii* may be present but constitute relatively little cover.

Distribution: This system is found throughout the Western Great Plains Division. The largest and most intact example of this system is found within the Sandhills region of Nebraska and South Dakota. However, it is also common (though occurring in predominantly small patches) farther west into central and eastern Montana. Its western extent in Wyoming is still to be determined, but it does occur in mapzone 29 on weathered-in-place sandy soils, where *Calamovilfa longifolia* is found, along with *Artemisia cana*. In addition, outliers have been described from the Western Great Plains in Texas (Monahans Sandhills State Park).

Nations: US

Description Author: S. Menard, K. Kindscher, M.S. Reid, K.A. Schulz

CES303.670 CONCEPTUAL MODEL

Environment: The distribution, species richness and productivity of plant species within the sand prairie ecological system are controlled primarily by environmental conditions, in particular, the temporal and spatial distribution of soil moisture and topography. Soils in the sand prairies can be relatively undeveloped and are highly permeable. Soil texture and drainage along with a species' rooting morphology, photosynthetic physiology, and mechanisms to avoid transpiration loss are highly important in determining the composition and distribution of communities/associations within the sand prairies. Another important aspect of soils in the sand prairies is their susceptibility to wind erosion. Blowouts and sand draws are some of the unique wind-driven disturbances in the sand prairies, particularly the Nebraska Sandhills, which can profoundly impact vegetation composition and succession within this system. This tallgrass prairie is found primarily on sandy and sandy loam soils that can be relatively undeveloped and highly permeable as compared to ~Western Great Plains Tallgrass Prairie (CES303.673)$$, which occurs on deeper loams. This system is usually found in areas with a rolling topography and can occur on ridges, midslopes and/or lowland areas within a region. It often occurs on moving sand dunes, especially within the Sandhills region of Nebraska and South Dakota. In Montana, occurrences are intimately associated with ~Northwestern Great Plains Mixedgrass Prairie (CES303.674)$$, usually occupying higher positions in local landscapes where sandy members of some geologic formations (that are predominantly marine shales) constitute the highest (and most weathering-resistant) points in the landscape. In Texas, this system occurs on rolling to level, eolian or alluvial, deep sand deposits classed as Deep Sand or Sandhill Ecological Sites.

Key Processes and Interactions: The distribution, species richness and productivity of plant species within the sand prairie ecological system are controlled primarily by environmental conditions, and in particular, the temporal and spatial distribution of soil moisture and topography. Another important aspect of this system is its susceptibility to wind erosion. Blowouts and sand draws are some of the unique wind-driven disturbances in the sand prairies, particularly the Nebraska Sandhills, which can profoundly impact vegetation composition and succession within this system.

Fire and grazing constitute the other major disturbances that can influence this system. The most extensive fires are likely to have occurred in years with wet springs followed by hot, dry summers when grazing pressure was low. Wet springs would have resulted in more productive and more continuous plant cover (i.e., fuel) that would have supported and expanded fires ignited under dry conditions occurring later in the season. In addition, litter accumulation over several fire-free years would also have supported widespread fire, in any conditions. The litter component, a determining factor in fire size and frequency, is correlated with seral stage. Several fire-free years produce enough litter to carry another fire (LANDFIRE 2007a).

Drought has additional impact in these very sandy soils and the high water table of the sandhills also affects the vegetation and encourages invasive trees (K. Kindscher pers. comm.). Extended periods of severe drought are likely to have affected both species composition and the stability of the sandhill soil, particularly when compounded by temperature, wind and heavy grazing. These conditions may have led to the development of blowouts making it difficult for vegetation to re-establish quickly. The occurrence of blowout penstemon (*Penstemon haydenii*) suggests long periods when blowouts were common across the landscape although causes resulting in this feature have not been determined (LANDFIRE 2007a).

Overgrazing, fire and trampling that leads to the removal of vegetation within those areas susceptible to blowouts can either trigger a blowout or perpetuate one already occurring. Overgrazing can also lead to significant erosion. The major large grazer, bison (*Bos bison*), occurring in large numbers in this system has largely been replaced by cattle. Both species impact the range by grazing and trampling; however, bison also significantly impacted local areas by wallowing. Unlike elsewhere in the Great Plains mixed and shortgrass prairie dog towns were a minor component of the Sandhills landscape and limited to where soils were finer-textured and in flat uplands and in valleys and the eastern Sandhills where the water table was not high (LANDFIRE 2007a).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has two classes in total (LANDFIRE 2007a, BpS 3111480). These are summarized as:

A) Early Development 1 Open (25% of type in this stage): Herbaceous cover is 0-20%. Class A represents immediate to three-year post-disturbance conditions. Vegetation consists of resprouting and seedling grasses and forbs. Total bare soil is greater than before the disturbance particularly on less productive sites. The vigor of new growth and the specific species affected depend on the season of the disturbance and on pre- and post-disturbance environmental conditions (e.g., available soil moisture). Litter is low initially but increases until, by year three, there is enough to support fire under average burning conditions. Fire was therefore modeled as occurring somewhat less frequently than in class B. In uplands, where soil type is dominated by coarse-grained sands with low water-holding capacity, post-disturbance primary production initially decreases, thus fire may only carry under ideal conditions. Under these conditions, grazing is likely to be light. In lowlands, with finer-textured soils, primary production is determined largely by moisture availability. *Artemisia cana* can resprout immediately after fire, so it could be present in this stage as well. It could, however, be killed following intensive fires. But since there is not much litter in these sites, possibility of intense fire is reduced. Repeated grazing of these areas will prevent succession to class B. Grazing occurs with a probability of 0.05. Prairie dog grazing was modeled as optional 1, with a very unlikely probability of 0.0007. Both will set succession back to the beginning.

B) Mid Development 1 Closed (80% of type in this stage): Herbaceous cover is 21-80%. Class B is sandhill grassland, the dominant historical condition. This class has a moderately dense herbaceous layer (20-80% cover) up to 1 m tall. Fire (every 10 years) would return this class to A, while lack of fire (after 40 years) would move it toward class C. Shrubs may make up to 25% of the cover but is more commonly 0-10%. Native grazing maintains this class. Severe, multiple-year drought (every 100 years) moves this to class C by reducing grass cover and fuel loads and giving a competitive advantage to the usually spare shrub cover.

C) Late Development 1 All Structures (shrub-dominated - 10% of type in this stage): Shrub cover is 21-100%. Class C is the shrub-dominated sandhill grassland and differs from the sandhill shrubland (BpS 1094) which is modeled separately based on edaphic differences. Fire returns this to class A (MFRI = 0.10). Dominate shrubs include sand sagebrush, shinnery oak and sand cherry.

Threats/Stressors: Conversion to agriculture can impact this system, and its range has decreased from human activities. Impacts from energy extraction in oil and gas fields in have recently fragmented larges areas with road networks to well pads and pipelines. Overgrazing by livestock grazing and fires can remove vegetation cover and promote blowouts.

The dominant species are adapted to frequent fires, sprouting from rhizomes post-fire. Fire suppression and moderate grazing have caused unevenness in structure and favored invasion of introduced grasses *Poa pratensis* and *Bromus inermis* across the sandhills (Sims 1988, Hauser 2005). A variety of seral stages are desirable to provide habitat for all phases of the lesser or greater prairie-chicken life cycle. The vegetation ideally exhibits a diversity of native short to tall grasses and native forbs interspersed with sparse to somewhat dense low-growing shrubby cover which includes sufficient cover for nesting and brood-rearing, as well as open areas suitable for leks.

CES303.671 Western Great Plains Sandhill Steppe

CES303.671 CLASSIFICATION

Concept Summary: This shrubland system is found mostly in south-central areas of the Western Great Plains Division ranging from southeastern Wyoming and southwestern Nebraska up into the Nebraska Sandhill region, south through eastern Colorado, and New Mexico to central Texas, although some examples may reach as far north as the Badlands of South Dakota. The climate is semi-arid to arid for much of the region in which this system occurs. This system is found on somewhat excessively to excessively well-drained, deep sandy soils that are often associated with dune systems and ancient floodplains. In some areas, this system may actually occur as a result of overgrazing in ~Western Great Plains Tallgrass Prairie (CES303.673)$$ or ~Western Great Plains Sand Prairie (CES303.670)$$. Typically, this system is characterized by a sparse to moderately dense woody layer dominated or codominated by *Artemisia filifolia*, but other characteristic species may be present, including *Amorpha canescens, Prosopis glandulosa* (southern stands), *Prunus angustifolia, Prunus pumila var. besseyi* (northern stands), *Quercus havardii* (Texas), *Rhus trilobata*, and *Yucca glauca*. Associated herbaceous species can vary with geography, amount and season of precipitation, disturbance, and soil texture. The herbaceous layer typically has a moderate to dense canopy but may include stands with sparse understory. Several mid- to tallgrass species characteristic of sand substrates are usually present to dominant, such as *Andropogon hallii, Calamovilfa gigantea, Calamovilfa longifolia, Schizachyrium scoparium, Sporobolus cryptandrus, Sporobolus giganteus*, or *Hesperostipa comata*.

Distribution: This system is found primarily within the south-central areas of the Western Great Plains Division ranging from the Nebraska Sandhills south into central Texas. However, examples of this system can be found as far north as the Badlands in South Dakota.
Nations: US
Concept Source: S. Menard and K. Kindscher
Description Author: S. Menard, K. Kindscher, K.A. Schulz and L. Elliott

CES303.671 CONCEPTUAL MODEL

Environment: This system is found primarily in semi-arid to arid areas of the Western Great Plains Division. It occurs on somewhat excessively to excessively well-drained and deep sandy soils. This system is often found associated with dune systems and/or ancient floodplains but may occur in soils derived from sandstone residuum. In parts of Texas, this system is apparently restricted to thick sandy deposits in the Seymour Formation (a Pleistocene formation formed from ancient channel deposits of the Clear Fork of the Brazos River), and is found on rolling to level uplands. In these areas, it is restricted to Deep Sand, Sand Hills or Sandy Ecological Sites (Elliott 2011).
Key Processes and Interactions: Fire and grazing constitute the most important processes impacting this system. Burning shrublands reduces cover of *Artemisia filifolia* for several years resulting in grassland patches that form a mosaic pattern with shrublands. Composition of grasslands depends on precipitation and management. Drought stress can also influence this system in some areas. In the southern range of this system, *Quercus havardii* may also be present to dominant and represents one succession pathway that develops over time following a disturbance. *Quercus havardii* is able to resprout following a fire and thus may persist for long periods of time once established, forming extensive clones. Edaphic and climatic factors are the most important dynamic processes for this type, with drought and extreme winds impacting this system significantly in some areas. Because *Quercus havardii* is able to resprout rapidly following fire, fire tends to cause structural changes in the vegetation, and compositional shifts are less significant in most cases. Overgrazing can lead to decreasing dominance of some of the grass species such as *Andropogon hallii, Calamovilfa gigantea*, and *Schizachyrium scoparium*. In the western extent of this system in the shortgrass prairie, more xeric mid- and shortgrass species such as *Hesperostipa comata, Sporobolus cryptandrus* and *Bouteloua gracilis* often dominate the herbaceous layer.

M053. Western Great Plains Shortgrass Prairie

CES303.668 Western Great Plains Mesquite Woodland and Shrubland

CES303.668 CLASSIFICATION

Concept Summary: This system is found primarily in the southern portion of the Western Great Plains Division, primarily in Texas, Oklahoma and eastern New Mexico. It is dominated by *Prosopis glandulosa* with shortgrass species in the understory. *Ziziphus* *obtusifolia* and *Atriplex canescens* can codominate in some examples, as can *Opuntia* species in heavily grazed areas. Shortgrass species *Bouteloua gracilis* or *Bouteloua dactyloides* are typically present. Other grasses may include *Aristida purpurea, Bouteloua curtipendula, Bouteloua eriopoda, Bouteloua hirsuta, Muhlenbergia torreyi, Pleuraphis jamesii, Sporobolus airoides*, and *Sporobolus cryptandrus*. Historically this system probably occurred as a natural component on more fertile soils and along drainages, but it has expanded its range into prairie uplands in recent decades. In Texas, in what are considered the natural alluvial setting of this system, other overstory species may include *Celtis laevigata var. reticulata, Sapindus saponaria var. drummondii, Populus deltoides*, and *Salix nigra*. In these settings, *Prosopis glandulosa* is dominant in the shrub layer, but other shrub species encountered include small representatives of the overstory, and *Ziziphus obtusifolia, Prunus angustifolia*, and *Baccharis* spp. Herbaceous species present in the understory may include *Panicum virgatum, Bothriochloa laguroides ssp. torreyana, Nassella leucotricha*, and *Schizachyrium scoparium*. Non-native species such as *Cynodon dactylon, Bromus catharticus, Sorghum halepense*, and *Bromus arvensis* are also commonly present and may be dominant.

CES303.672 Western Great Plains Shortgrass Prairie

CES303.672 CLASSIFICATION

Concept Summary: This ecological system is found primarily in the western half of the Western Great Plains Division in the rainshadow of the Rocky Mountains and ranges from the Nebraska Panhandle south into Texas and New Mexico, although grazing-impacted areas appearing as this type may reach as far north as southern Canada where it is a component of ~Northwestern Great Plains Mixedgrass Prairie (CES303.674)$$. This system occurs primarily on flat to rolling uplands with loamy, ustic soils ranging from sandy to clayey. In much of its range, this system forms the matrix system with *Bouteloua gracilis* dominating. Associated graminoids may include *Aristida purpurea, Bouteloua curtipendula, Bouteloua hirsuta, Bouteloua dactyloides, Carex filifolia, Carex inops ssp.*

heliophila, Hesperostipa comata, Hesperostipa neomexicana, Koeleria macrantha, Pascopyrum smithii, Pleuraphis jamesii, Sporobolus airoides, and *Sporobolus cryptandrus*. Although mid-height grass species may be present, especially on more mesic land positions and soils, they are secondary in importance to the sod-forming short grasses. Sandy soils have higher cover of *Hesperostipa comata*, and *Sporobolus cryptandrus*. Scattered shrub and dwarf-shrub species such as *Artemisia filifolia, Artemisia frigida, Artemisia tridentata, Atriplex canescens, Eriogonum effusum, Gutierrezia sarothrae, Lycium pallidum*, and *Yucca glauca* may also be present. Also, because this system spans a wide range, there can be some differences in the relative dominance of some species from north to south and from east to west. Large-scale processes such as climate, fire and grazing influence this system. High variation in the amount and timing of annual precipitation impacts the relative cover of cool- and warm-season herbaceous species.

In contrast to other prairie systems, fire is less important, especially in the western range of this system, because the often dry and xeric climate conditions can decrease the fuel load and thus the relative fire frequency within the system. However, historically, fires that did occur were often very extensive. Currently, fire suppression and more extensive livestock grazing in the region have likely decreased the fire frequency even more, and it is unlikely that these processes could occur at a natural scale. A large part of the range for this system (especially in the east and near rivers) has been converted to agriculture. Areas of the central and western range have been impacted by the unsuccessful attempts to develop dryland cultivation during the Dust Bowl of the 1930s. The short grasses that dominate this system are extremely drought- and grazing-tolerant. These species evolved with drought and large herbivores and, because of their stature, are relatively resistant to overgrazing. This system in combination with the associated wetland systems represents one of the richest areas for mammals and birds. The endemic bird species of the shortgrass system may constitute one of the fastest declining bird populations in North America.

CES303.672 CONCEPTUAL MODEL

Environment: This system forms the matrix grassland in the southwest half of the Great Plains and largely occurs in the rainshadow of the Rocky Mountains. This system occurs on various geologic formations, primarily on flat to rolling uplands. Soils typically are loamy and ustic (bordering on aridic) but can range from sandy to clayey (Scifres 1980, Shiflet 1994).

Climate: Climate is temperate, semi-arid, and continental with mean annual precipitation generally about 300 mm ranging to 500 mm to the east. Annual precipitation has a bimodal distribution occurring mostly before the growing season in winter and early spring and then during summer as monsoon thunderstorms (Sims et al. 1978). In most years, rates of evaporation are greater than precipitation for this system. Most of the annual precipitation occurs during the growing season as thunderstorms. Precipitation events are mostly <10 cm with occasional larger events (Sala and Lauenroth 1982). High variation in amount and timing of annual precipitation impacts the relative cover of cool- and warm-season herbaceous species. This is the driest of the Great Plains grasslands ecosystems. Average daily temperature in July varies from 27°C in the southeast to 21°C in the northwest and along the foothills of the Rocky Mountains. Average daily temperature in January varies from 3°C in the south to -6°C in the northwest.

Physiography/landform: Stands occur on primarily flat to rolling uplands and to a lesser extent mesatops and plateaus.

Soil/substrate/hydrology: Soils are typically well-drained, shallow to moderately deep, loamy and ustic and range from sandy to clayey (Scifres 1980, Shiflet 1994). In the southeasternmost expression of the system in Texas, it occurs on sites with soils providing relatively dry conditions such as Rough Breaks, Shallow Clay, Very Shallow, Very Shallow Clay, Moderately Alkaline Deep Hardland, and Hardland Ecological Sites (Elliott 2013).

Key Processes and Interactions: Large-scale processes such as climate, fire and grazing constitute the primary processes impacting this system. The short grasses that dominate this system are extremely drought- and grazing-tolerant (Lauenroth and Milchunas 1992, Lauenroth et al. 1994a). These species evolved with large herbivores and drought (Milchunas and Lauenroth 2008) and adapted to historical heavy grazing with their low stature making them relatively resistant to overgrazing (Lauenroth et al. 1994a). The return intervals for grazing varied with areas distant from water sources likely grazed less heavily as those near water. However, the shortgrass prairie is probably the system with the highest intensity of grazing than other systems historically (Lauenroth et al. 1994a, Milchunas 2006). This is a drought-tolerant system. Many shortgrass species are drought-tolerant and have root systems that extend up near the soil surface where they can utilize low precipitation events (Salas and Lauenroth 1982). If blue grama is eliminated from an area by extended drought (3-4 years) or disturbance such as plowing, regeneration is slow because of very slow tillering rates (Samuel 1985), low and variable seed production (Coffin and Lauenroth 1992), minimal seed storage in soil (Coffin and Lauenroth 1989) and limited seedling germination and establishment due to particular temperature and extended soil moisture requirements for successful seedling establishment (Hyder et al. 1971, Briske and Wilson 1978, 1980).

In contrast to other prairie systems, fire is less frequent, especially in the western range of this system, because the often dry and xeric climate conditions can decrease the fuel load and reduce lightning events, and thus the relative fire frequency within the system. However, historically, fires that did occur were often very extensive. Wright and Bailey (1982c) suggest that in semiarid areas, big prairie fires usually occurred during drought years that followed one to three years of above average precipitation, because of the abundant and continuous fuel. Consequently, these wildfires could travel far when the winds and air temperatures were high and relative humidity was low. There is debate as to the mean fire-return interval (MFRI) for this shortgrass system. Because of the lack of long-lived trees, and trees that do exist are in relatively productive sites, there is absolutely no way to reconstruct a reliable historic fire-return interval. All estimates of historic fire-return intervals must be based on those for surrounding vegetation types that do have means for reconstruction, and then extrapolating based on differences in primary production and herbivore removal of fuel loads. Therefore, there is no means to directly obtain the estimate, and the range is varied. It depends on many factors: portions will be drier, and portions will vary in frequency over time and there will be decadal variation. Anderson (2003) reports a broad fire-return interval (FRI) of <35 years for shortgrass prairie. There is a wide variability of MFRI across this system, based on precipitation, fuel and ignition sources (LANDFIRE 2007a).

LANDFIRE developed a VDDT model for this system which has three classes (LANDFIRE 2007a, BpS 2711490).

A) Mid Development 1 Open (20% of type in this stage): Instead of calling the classes early, mid and late, which do not actually apply in shortgrass prairie and the different stages that we are describing, we are calling all stages "mid-development." The stages of the grassland are created and/or maintained by disturbances or lack thereof. Class A is the low biomass (0-1" based on the Robel pole density / visual obstruction method), heavy disturbance-dependent community. It combines 2 types of communities. One consists of the high cover blue grama-buffalo grass sod that looks like a golf course (high cover in patches). The other is the low cover bare soil, *Aristida*, and forb stage, which could have taller grasses than the sod, but they are spaced apart due to bare soil between. See biomass in Milchunas and Lauenroth (1989) and Milchunas et al. (1994) and basal cover for sod class by point frame in Milchunas et al. (1989). Please note that this system should be distinguished by on-the-ground biomass and not cover, since the cover in class A actually varies from a low, mosaic-bare-ground cover to a high sod-cover, which includes litter too. Due to mapping constraints, we are defining dropdown boxes on cover; however, this stage could go up to 70% cover, including litter, with very low biomass. Basal cover for high cover sod is approximately 45% or higher if including litter. Basal cover for low cover prairie dog areas is approximately 20-25% cover. On the ground, this class should be distinguished by biomass. There are relatively few cool-season grasses in this stage. There is always blue grama in this stage, as in the others. Cactus is present (and could even be a dominant in the class A sod depending on soil type). *Aristida* is present, which increases with prairie dog colonies. Annual grasses - sixweeks fescue, red three-awn, ragweed, annual forbs. [Currently, you would see non-native annuals in this class such as cheatgrass and kochia - only in the high biomass type. Annuals and exotics are actually less abundant in the sod type than any other class (Milchunas et al. 1989, Milchunas and Lauenroth 1989, Milchunas et al. 1988); the landscape might also have non-natives of bindweed on prairie dog towns today, but not historically.] On loamier or sandier sites, there is sand dropseed. For the southern, New Mexico version, other indicator species are lemonweed, showy goldeneye, and verbena.

B) Mid Development 2 Closed (60% of type in this stage): Instead of calling the classes early, mid and late, which do not actually apply in shortgrass prairie and the different stages that we are describing, we are calling all stages "mid-development." The stages of the grassland are created and/or maintained by disturbances or lack thereof. Class B is the mid biomass (2-4" based on the Robel pole density / visual obstruction method), mid cover stage. See biomass in Milchunas and Lauenroth (1989) and Milchunas et al. (1994). This stage again consists of blue grama. Cactus is often present and could even be the second dominant depending on soil type. There is less needle-and-thread and western wheatgrass than in class C. This also includes the "historic climax plant community" with blue grama, buffalograss, and western wheatgrass, galleta grass, green needle grass (not in New Mexico), fringed sage, and New Mexico feather grass in the south. Historically, there would have been more midgrasses (Harvey Sprock et al. pers. comm.). In New Mexico, there would be scatterings of black grama, vine-mesquite on heavier soils. Fire does occur in this stage. If there is 1-2 years of no grazing or 4-10 years of no fire, then 4-10 years post-fire, this class would transition to the high biomass class C stage. This was modeled as "alternate succession" occurring as a probability of 0.05, for modeling purposes. Prairie dogs could occur in this stage. If they do, the long-term prairie dog grazing causes a transition to class A.

C) Mid Development 3 Closed (20% of type in this stage): Instead of calling the classes early, mid and late, which do not actually apply in shortgrass prairie and the different stages that we are describing, we are calling all stages "mid-development." The stages of the grassland are created and/or maintained by disturbances or lack thereof. Class C is the high biomass (4+" based on the Robel pole density / visual obstruction method), high cover stage. See biomass in Milchunas and Lauenroth (1989) and Milchunas et al. (1994) and basal cover in Milchunas et al. (1989). The same grasses are present as the previous. However, there are also more C3 perennial cool-season grasses. (However, some have questioned the increase in cool-season grasses with succession as being speculative. There are definite edaphic differences. Gravelly sites in New Mexico often support *Hesperostipa neomexicana* even under intense grazing regimes.) Blue grama is still present and dominant. Needle-and-thread, galleta grass and western wheatgrass are more prominent. Note also that more annuals and exotics occur in the ungrazed than in the heavily grazed sod class (Milchunas et al. 1989, Milchunas et al. 1992). This stage is arrived at through lack of fire and grazing, although while already in this stage, fire would be more likely to occur due to the increased biomass. Fire does occur in this stage. If there is fire and then grazing, this will over time transition to class B, and with long-term heavy grazing to class A. Fire alone may not cause a transition but can especially on coarser textured soils and also when fire occurs with heavy grazing. Regular grazing can just move the class to class B. Prairie dogs are unlikely to occur in this class, but when they do, they will occur as a patch within the matrix and will cause a transition.

During LANDFIRE modeling workshops, some experts suggest that the MFRI was historically approximately 25-35 years with small fires at times so fire-return interval at one spot was longer than expected, i.e., a fire can burn somewhere on the landscape often, but it may not necessarily return to the same spot for 25-50 years or more (LANDFIRE 2007a). However, other experts thought MFRI was shorter, between 5-20 years, dependent on the precipitation gradient east to west with shorter FRI (~5 years) occurring in the more mesic eastern extent of the shortgrass prairie (LANDFIRE 2007a). A proposed precipitation gradient between drier versus wetter of approximately 350-375 mm annual precipitation to delineate a change in fuels and fire behavior across the west to east gradient in precipitation / above-ground primary productivity. The western portion would have a MFRI of 15-20 years and in the eastern portion, it would be shorter (5-10 years) (LANDFIRE 2007a). A MFRI of 5 years is similar to mixed and tallgrass prairies (Bragg and Hulbert 1976, Bragg 1986, Umbanhowar 1996, LANDFIRE 2007a).

Black-tailed prairie dogs are an ecologically important component of the grazing regime in shortgrass prairie and would have occurred extensively (Lauenroth and Milchunas 1992, Milchunas and Lauenroth 2008). There were some very large towns, but there were also areas without any towns. Quantitative historical estimates of black-tailed prairie dogs abundance are difficult to obtain, but the U.S. Fish and Wildlife Service estimated that about 160 million ha (395 million acres) of potential habitat historically existed in the U.S., and about 20% was occupied at any one time (Gober 2000). Shortgrass has most of the suitable soil types for prairie dogs; in general, they need loamy or clay soil. In historic times, there was frequent and broad-scale grazing by bison and pronghorn antelope. Through the growing season, bison might have been there for relatively short periods in some years and longer in other years. There were also resident herds of bison in areas of Colorado (LANDFIRE 2007a). Historically, such areas would also have been populated by bison in sufficient numbers to support populations of wolves. Bamforth (1987) suggested that bison herds under relatively undisturbed conditions (prior to 1846) most often ranged in size from several hundred to several thousand. Shaw and Lee (1997) reviewed diaries of European travels in the southern Great Plains from 1806 to 1857. Organized by historical period and biome type, the authors suggest populations of three major large herbivores (bison, elk and pronghorn) changed in the first half of the nineteenth century; bison were most numerous on the shortgrass prairie prior to 1821, pronghorn were most abundant on the shortgrass prairie between 1806 and 1820, again in the 1850s (LANDFIRE 2007a). The dry half of the Great Plains has high interannual rainfall variability, so historically, the population declined faster in dry years (LANDFIRE 2007a). This resulted in a time lag or temporal variability, in which density could be reduced greatly. Bison historically moved nomadically in response to vegetation changes associated with rainfall, fire and prairie dog colonies (LANDFIRE 2007a). The time lag for return movements provided deferment during the regrowth period, which according to both historic and archeological records, may have ranged from 1 to 8 years (Malainey and Sherriff 1996). If there was a series of droughts followed by a wetter year, there would have been little grazing pressure, which would then result in a higher severity or frequency of fire. Drought and grazing were probably most important disturbances historically and greatly influenced fire frequency and extent. Insects such as grasshoppers, range caterpillars, and Mormon crickets were also a natural disturbance agent on the landscape (LANDFIRE 2007a).

Biological soils crusts (BSC) are important for soil fertility, soil moisture, and soil stability in semi-arid ecosystems such as the drier portions of the shortgrass prairie (Belnap and Lange 2003). Cyanobacteria (especially *Nostoc*) fix large amounts of soil nitrogen and carbon (Evans and Belnap 1999, Belnap and Lange 2003). Generally, BSC are more important on sites with more exposed soil surface and less herbaceous and litter cover; however, cover varies locally with site characteristics, especially disturbance (Belnap et al. 2001, Belnap and Lange 2003).

Threats/Stressors: Historically, fires were often very expansive, especially after a series of years with above-average precipitation when litter/fine fuels built up. Currently, fire suppression, fragmentation of landscapes, and more extensive grazing in the region have likely decreased the fire frequency even more, and it is unlikely that these processes could occur at a natural scale. Heavy continuous livestock grazing, military training, invasive non-native species, altered fire regime (fire suppression), conversion to agriculture, fragmentation from roads and development such as exurban and urban development, and more recently gas and oil exploration and extraction stress the shortgrass prairie ecosystem. Of these, altered grazing and fire regimes stressors are prevalent throughout the range. Cultivation for row crop agriculture has been widespread and extensive in the higher precipitation parts of the range, where more conducive soil moisture conditions exist, or where irrigation is possible. Habitat fragmentation from roads is common throughout the range, probably less in the drier parts of the range where large ranches are more common, but none the less, still at levels limiting natural fire regimes through the range. Stressors related to urban and suburban development and military training affect a relatively small proportion of the range of this system, but where they occur, impacts are often severe.

Conversion to agriculture and pastureland with subsequent irrigation has degraded and extirpated this system in approximately 40% of its range (Samson and Knopf 1994). Conversion of this type has commonly come from dryland wheat cultivation in the less xeric portion in eastern Colorado and western Kansas and from all types of irrigated agriculture typically near rivers such as the Platte and Arkansas basins. Historically, areas of the central and western range have been impacted by the unsuccessful attempts to develop dryland cultivation during the Dust Bowl of the 1930s (CNHP 2010). Urban and exurban development along the Front Range and water developments/reservoirs are also significant. Locally, mechanical disturbance (roads, mechanized military training, ORVs, sacrifice areas surrounding livestock tanks, etc.) may eliminate cover of blue grama and other grasses that are slow to recover. Conversion to invasive non-native species is generally not a widespread or significant problem on dry upland sites. Invasion and conversion to woodlands by native trees *Juniperus* spp. and *Prosopis glandulosa* (in southern extent) is an issue where alteration of natural fire regime has permitted woodland expansion into former grasslands.

Common stressors and threats include fragmentation, altered fire regime, overgrazing by livestock, and invasive species (in the less xeric regions). Fire suppression and certain grazing patterns such as continuous heavy grazing in the region have likely decreased the fire frequency even more, and it is unlikely that these processes could occur at a natural scale. The short grasses that dominate this system are extremely drought- and grazing-tolerant although continuous heavy grazing and extended drought (3-4 years) will reduce cover of dominant species.

Ecosystem Collapse Thresholds: Ecological collapse at finer scales tends to result from loss of shortgrass species due to mechanical disturbance (locally) (livestock trampling, roads) and excessive grazing by horses which, unlike cattle, can crop grass closer and will recreationally graze until all perennial grass is gone. Additionally, extended drought, such as what occurred in the 1930s, causes mortality of perennial shortgrasses, especially if stressed by excessive grazing and could make areas susceptible to soil erosion and loss of topsoil. Loss of native vegetation will result in loss of much of the biotic diversity such as grassland birds and pronghorn (CNHP 2010), but similar or even more severe droughts occurred in the evolutionary history of this system and native species have recovered. It is unclear what is beyond the evolutionary "capacity" of the system or how modern anthropogenic stressors (e.g., invasive species, climate change, conversion of habitat) may affect recovery from extreme events in the future. It is likely that shortgrass dependent wildlife species historically would have responded in a similar way. Species preferring short and/or sparse vegetation may have been impacted to a lesser degree, while those requiring taller vegetation structure, more litter, and less bare ground would have declined or moved (when possible) to utilize other areas not as impacted by drought.

High-severity environmental degradation appears where occurrences tend to be relatively small (<50,000 acres) in size and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion (CNHP 2010). Fragmentation from anthropogenic alterations such as a high density of roads (e.g., oil and gas exploration and development or exurban development) has heavily impacted sites creating barriers to fire and a source of invasive non-native species. (CNHP 2010). Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval beyond 50 years (LANDFIRE 2007a). This may have resulted in a significant increase in cover (5-10%) and regeneration of trees and shrubs. Alteration of abiotic processes is extensive and restoration potential is low.

Moderate-severity environmental degradation appears where occurrences are moderate (50,000-250,000 acres) in size and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion (CNHP 2010). Fragmentation from anthropogenic alterations such as a moderate density of roads (e.g., oil and gas exploration and development or exurban development) has moderately impacted sites creating barriers to fire and a source of invasive non-native species (CNHP 2010). Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval beyond 25 years (LANDFIRE 2007a). This may have resulted in a significant increase in cover (>10%) and regeneration of trees and shrubs. Alteration of abiotic processes is moderate and restoration potential is moderate.

High-severity disruption appears where vegetation on the occurrence has little or no structural diversity and is likely to have low species diversity (CNHP 2010). Cover required for nesting and/or breeding of grassland birds is not sufficient (CNHP 2010). Plant vigor may be poor and dead or decadent plants are common. Reproductive capability of native perennial plants severely reduced (CNHP 2010). There is may significant cover of shrubs and trees (>10%) because of fire suppression and invasion from adjacent woodlands. Invasive non-native species may be common to dominant (CNHP 2010). Connectivity is severely hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low (CNHP 2010). Grassland birds populations in sharp decline (CNHP 2010).

Moderate-severity disruption appears where species richness is reduced in comparison with higher ranked occurrences. Native bunchgrasses are present but may be nearly equal in canopy cover to non-native species. Native species that increase with livestock grazing may be codominant or dominant. Trees and shrubs may have seedlings, juveniles, or saplings present (CNHP 2010). Plant density and production may be reduced, and litter may be excessive or not present at all. Reproductive capability of native perennial plants is greatly reduced (CNHP 2010). Species composition has shifted to more early-seral species (grazing-increasers) such as *Aristida* spp., *Elymus elymoides, Sporobolus cryptandrus, Gutierrezia sarothrae, Heterotheca villosa*, or, near monocultures of the grazing-tolerant species, *Bouteloua gracilis*. Connectivity is moderately hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and reduce the natural movement of some animal and plant populations (CNHP 2010). Grassland bird populations follow rangewide decline (CNHP 2010).

2.B.2.Nc. Eastern North American Grassland & Shrubland

M506. Appalachian Rocky Felsic & Mafic Scrub & Grassland

CES202.347 Eastern Serpentine Woodland

CES202.347 CLASSIFICATION

Concept Summary: This system consists of distinct vegetation associated with ultramafic rock substrates in the Piedmont and Blue Ridge of the eastern United States. The bedrock is serpentinite, dunite, or other ultramafic rocks. The soil has unusual and extreme chemical composition that includes strongly skewed calcium-to-magnesium ratios and often high levels of heavy metals such as chromium. Most examples are open woodlands with *Pinus rigida, Pinus virginiana*, and/or *Quercus alba, Quercus marilandica*, and *Quercus stellata* in the often stunted canopy. Extreme edaphic conditions lead to locally xerophytic growing conditions that contribute to relatively open canopies and a ground cover dominated by prairie grasses and a variety of forbs. Disjunct species from drier regions and some endemic plant taxa are often present. The unusual and extreme soil chemistry determines the underlying floristics and distinctive flora of the type, but fire frequency, extent, and severity determine the physiognomy of particular examples over time.

Description Author: M. Schafale, R. Evans, S.C. Gawler, M. Pyne

CES202.347 CONCEPTUAL MODEL

Environment: This system occurs in a variety of topographic settings, perhaps excluding only alluvial sites. The bedrock is serpentinite, dunite, or other ultramafic rocks. The soil has unusual and extreme chemical composition that includes strongly skewed calcium-to-magnesium ratios and often high levels of heavy metals such as chromium. Owing to a high level of toxic metals and a deficiency in nutrients, serpentine outcrops are ecologically unique and provide habitat for many plant species that grow nowhere else. The soil may be shallow and rocky, or deep, and is usually very clayey. Seepage may be present locally.

Key Processes and Interactions: Although the unique soil chemistry is the crucial determining factor for this system, fire is generally a crucial process influencing species composition and vegetation structure. The unusual and extreme soil chemistry determines the underlying floristics and distinctive flora of the type, but fire frequency, extent, and severity determine the physiognomy of particular examples over time. Without fire, vegetation can sometimes become dense enough to suppress or eliminate the distinctive herbaceous layer, as well as turning a distinctive savanna or woodland structure into dense forest. Southern pine beetle (*Dendroctonus frontalis*) damage is an important factor in examples dominated by *Pinus* species.

Threats/Stressors: The most critical anthropogenic threat to native grasslands, savannas and barrens is their conversion to human-created land uses, including residential development, quarries, industrial development, infrastructure development, and others (TNC 1996c). Rocky glade areas, if present, may be the last areas to be converted to development and housing due to the unsuitability of the soil to septic tanks. Other common threats and stressors include both the removal of disturbance (e.g., fire, grazing) and the effects of inappropriate or too intensive or constant disturbance. These areas often attract off-road-vehicle use.

Fire plays a critical role in the maintenance of most native grasslands. Without it, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). In landscapes where open grassland or savanna vegetation is part of the matrix, and where woody plants have taken over areas once occupied by open grassland and savanna vegetation, the light-dependent species may only persist on the open edges (roadsides, powerlines) of forested patches (Taft 1997). In southeastern grasslands, complete transition to forest dominated vegetation can occur in one or two decades (Wiens and Dyer 1975). More information is needed about the particular appropriate ranges of fire-return times and intensities in the various systems, along with factors other than fire (e.g., soil/substrate, aspect, herbivory, hydroperiod and flooding) that help maintain grasslands and related communities. Occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing. Too intensive or frequent application of these disturbances will have deleterious effects on stand structure and species diversity. In general, mosaics of scrub and grassland, produced by light to moderate grazing (or occasional fire) will support the greatest diversity (Duffey et al. 1974). Cutting or mowing is not as favorable to plant diversity as is grazing because it is nonselective and does not result in the same kind of soil disturbance and compaction as do the hooves of grazing animals (DeSelm and Murdock 1993). Fire is a critical disturbance factor for southeastern native grasslands, but the intensity, duration, and timing of the fires are all important in their effect on the vegetation (DeSelm and Murdock 1993). In addition to occasional fire, periodic drought may also be important in regulating woody plant encroachment in native grasslands. It is believed that native grasslands have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. A small isolated patch has a low probability of receiving a lightning strike frequently enough to maintain a grassland condition. In many cases, grassland systems were once extensive on the landscape, but have now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). In other cases, the grassland or glade system naturally occurs in small isolated patches occurring within an otherwise forested matrix.

Many native grassland sites, particularly the more productive ones, have been converted to plantations of exotic grasses and legumes (DeSelm and Murdock 1993). Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, as well as *Lespedeza cuneata, Miscanthus sinensis, Microstegium vimineum, Alliaria petiolata, Ailanthus altissima*, and *Albizia julibrissin*) will fundamentally alter the character of native grasslands, barrens, savannas, and glades. Some of these exotics are allelopathic, thereby presenting a greater threat to native species (N. Murdock pers. comm.). Opportunistic native increaser plant species (e.g., *Juniperus virginiana*) can also shade out light-requiring herbaceous plants (TNC 1996c).

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site to other land uses (e.g., residential development, industrial development, infrastructure development, mining or quarrying of underlying bedrock) or conversion to plantations of exotic grasses and legumes. Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, *Ailanthus altissima, Lespedeza cuneata*, and others) will fundamentally alter the character of native grasslands, barrens, savannas, and glades. Ecological collapse may also result from the removal or lessening of appropriate disturbance (fire, grazing). Without fire, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate or invade, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a shift to an alternate stable state and a net loss of species diversity (Taft et al. 1995). In many southeastern grasslands and savannas, complete transition to forest dominated vegetation can occur in one or two decades (Wiens and Dyer 1975).

CES201.571 Northern Appalachian-Acadian Rocky Heath Outcrop

CES201.571 CLASSIFICATION

Concept Summary: This outcrop ecological system ranges across New England and adjacent Canada, and southward at higher elevations to northern Pennsylvania, on ridges or summits of resistant acidic bedrock. Throughout most of its range, it occurs at low to mid elevations (600-1000 m, lower on the coast of eastern Maine and the Maritimes). The vegetation is patchy, often a mosaic of woodlands and open glades. *Quercus rubra* and various conifers, including *Pinus strobus* and *Picea rubens*, or (especially near the coast) *Picea mariana*, are characteristic trees. Low heath shrubs, including *Kalmia angustifolia, Vaccinium angustifolium, Gaylussacia baccata*, and *Aronia melanocarpa (= Photinia melanocarpa)*, are typically present. Exposure and occasional fire are the major factors in keeping the vegetation relatively open.

CES202.348 Southern and Central Appalachian Mafic Glade and Barrens

CES202.348 CLASSIFICATION

Concept Summary: This Southern and Central Appalachian system consists of vegetation associated with shallow soils over predominantly mafic bedrock, usually with significant areas of rock outcrop. Bedrock includes a variety of igneous and metamorphic rock types such as greenstone and amphibolite. These areas support a patchy mosaic of open woodland and grassy herbaceous vegetation sometimes with a predominant woody short-shrub community present.
Related Concepts:

- Low- to Mid-Elevation Mafic Domes, Glades, and Barrens (Edwards et al. 2013) **><**
- Ultramafic Barrens and Woodlands (Edwards et al. 2013) **><**

Distribution: This system occurs in scattered clusters in the Southern Blue Ridge and adjacent portions of the upper Piedmont and Central Appalachians.
Nations: US
Concept Source: M. Schafale, R. Evans, M. Pyne, S.C. Gawler
Description Author: M. Schafale, R. Evans, M. Pyne, S.C. Gawler

CES202.348 CONCEPTUAL MODEL

Environment: This system occurs on upper to mid slopes, usually on gentle to moderate slopes but occasionally steeper. The ground is mostly shallow soil over bedrock, usually with significant areas of rock outcrop. The rock usually has few fractures but may have a pitted or irregular surface. This rock structure supports more extensive and deeper soil development than in ~Southern Appalachian Granitic Dome (CES202.297)$$, but has few of the crevices and deeper rooting sites available in ~Southern Appalachian Rocky Summit (CES202.327)$$. Micro-scale soil depth and presence of seepage are important factors in determining the vegetation patterns. Shallow soil, unable to support a closed tree canopy, separates this system from forest systems. Bedrock includes a variety of igneous and metamorphic rock types. Some examples are on mafic substrates such as amphibolite, some are on felsic rock such as granitic gneiss but have flora that suggests a basic influence, and a few occur on felsic rocks and are clearly acidic. Rock or soil chemistry appears to be the most important factor affecting different associations on sites that have the physical structure to belong to this system. Elevation may also be an important factor causing variation.
Key Processes and Interactions: The dynamics of this system are complex and poorly understood. These sites, with their shallow soil, would likely be affected by fire, drought, and windstorms. Severe droughts kill tree saplings growing in cracks and potholes, helping to retain the open character of the glades (Quarterman et al. 1993). Fire may be an important influence on the vegetation structure, and may function to keep the vegetation more open in the long run. The patchy distribution of vegetation in examples of

this system may limit fire intensity. These glades do not appear to be undergoing the kind of cyclic succession that has been described for granitic domes, but some balance of soil accumulation and destruction may be occurring on a longer term or coarser scale. There may be a zonation or patchiness to glade/barren vegetation, with different zones that may be identified by their characteristic plant species (Quarterman et al. 1993). These zones are apparently relatively stable, with woody plant encroachment evident only in relation to the invasion of shrubs and trees into potholes or crevices where soil accumulates more rapidly. It is possible that the slightly irregular curved surface of some examples represents a late stage in the weathering of old exfoliation surfaces that once supported granitic domes, but most known examples are not spatially associated with existing granitic domes.

Threats/Stressors: The most critical anthropogenic threat to native glade and rock outcrop vegetation is their conversion to human-created land uses, including residential development, quarries, industrial development, infrastructure development, and others (TNC 1996c). Rocky glades and outcrops may be the last areas to be converted to development and housing due to the unsuitability of the soil to septic tanks. Other common threats and stressors include both the removal of disturbance and the effects of inappropriate or too intensive or constant disturbance. These areas often attract off-road-vehicle use.

Fire plays a critical role in the maintenance of most native grasslands, which may surround or interfinger with rocky glades. In the absence of fire and appropriate disturbance in the landscape matrix, the areas with the most shallow soils (e.g., the glades) may be the only open areas persisting in a series of woody shrub thickets. Without fire or other disturbance, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). More information is needed about the particular appropriate ranges of fire-return times and intensities in the various systems. The actual rocky or gravelly glades may not support sufficient fuel to consistently carry fire, but in the adjacent or interpenetrating perennial grasslands, occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing (Duffey et al. 1974). In addition to occasional fire, periodic drought may also be important in regulating woody plant encroachment into native grasslands. It is believed that these native glade-grassland systems have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of glades and their accompanying native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. In many cases, these glade-grassland systems were once extensive on the landscape, but have now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). In other cases, the grassland and/or glade system naturally occurs in small isolated patches occurring within an otherwise forested matrix.

Many glade sites, have been used as pastures, or as dumping grounds for trash (Quarterman et al. 1993). The spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, as well as *Lespedeza cuneata, Ailanthus altissima*, and *Albizia julibrissin*) will fundamentally alter the character of glades and their accompanying native grasslands. Some of these exotics are allelopathic, thereby presenting a greater threat to native species (N. Murdock pers. comm.). Opportunistic native increaser plant species (e.g., *Juniperus virginiana*) can also shade out light-requiring herbaceous plants (TNC 1996c).

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site to other land uses (e.g., residential development, industrial development, infrastructure development, mining or quarrying of underlying bedrock) or conversion to plantations of exotic grasses and legumes. Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, *Ailanthus altissima, Lespedeza cuneata*, and others) will fundamentally alter the character of glades and their accompanying native grasslands. Ecological collapse may also result from the removal or lessening of appropriate disturbance (grazing, fire). Without fire, *Juniperus* species, *Quercus* species and other hardwoods will regenerate or invade into deeper soil areas, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995).

CES202.297 Southern Appalachian Granitic Dome

CES202.297 CLASSIFICATION

Concept Summary: This ecological system consists of smooth, curved, exfoliated outcrops of massive granite and related rocks in the Southern Blue Ridge and adjacent upper/inner Piedmont. Large areas of smooth rock without crevices distinguish this system. The outcrop surface is largely bare rock but has thin soil mats around the edges and patchily throughout. Mats vary in depth with age and level of development. Granitic domes have a distinctive pattern of cyclical primary succession. The resulting vegetation is a complex of small patches of different species and structure on soil mats of different depths, ranging from mosses and lichens to herbs to shrubs and trees. Deeper soils often have pine-dominated vegetation with dense shrubs.

- Low- to Mid-Elevation Mafic Domes, Glades, and Barrens (Edwards et al. 2013) **><**
- Northern Red Oak: 55 (Eyre 1980) **<**

Distribution: This system is restricted to the Southern Blue Ridge and adjacent upper/inner Piedmont in the Carolinas and Georgia.
Nations: US
Concept Source: M. Schafale and R. Evans
Description Author: M. Schafale, R. Evans, M. Pyne

CES202.297 CONCEPTUAL MODEL

Environment: This system occurs on exfoliated granitic outcrops. In the upper/inner Piedmont, it usually occurs as isolated hills (inselbergs or monadnocks) that stand above the surrounding landscape. In the Blue Ridge, it usually occurs as part of larger mountain ranges but often still as somewhat distinctive knobs. Granite, granitic gneiss, and related rocks without many internal joints tend to fracture in thin sheets parallel to the surface, forming curved outcrops with smooth surfaces largely lacking crevices. Granitic dome outcrops develop on upper to midslopes, and most face south. Most individual outcrops grade from nearly level to very steep. The outcrop surface is largely bare rock but has thin soil mats around the edge and in patches throughout. Mats vary in depth with age and level of development. The smooth rock without crevices is the primary factor in the distinctive ecological character of this system. Distinct microenvironments are created by small irregularities in the rock surface and by areas of seepage at the edge. Elevation is an important factor affecting different associations within the system.
Key Processes and Interactions: Granitic domes have a distinctive pattern of cyclical primary succession. Soil mats appear and deepen over time in a process that links vegetational and soil development, but are eventually destroyed by wind throw, drought, other natural disturbances, or simply falling off the rock. The result is a pattern with mats of different levels of development at any given time. Mat dynamics are different in different parts of the rock, with older mats and more permanent patterns near the edges, and sparser and younger mats in the interior. The dynamics are further modified by microtopography and the presence of seepage. The overall vegetation patterns likely respond to climatic cycles and natural disturbance events. The thin soils make these communities sensitive to drought, especially the long-lived woody species.

CES202.294 Southern Appalachian Grass and Shrub Bald

CES202.294 CLASSIFICATION

Concept Summary: This ecological system consists of dense herbaceous and shrubland communities in the highest elevational zone of the Southern Appalachians, generally above 1524 m (5000 feet) but occasionally to 1220 m (4000 feet), and at slightly lower elevations at its northern limit in Virginia and West Virginia, and in the Cumberland Mountains along the Virginia-Kentucky border. Vegetation consists either of dense shrub-dominated areas (heath balds) or dense herbaceous cover dominated by grasses or sedges (grassy balds). Heath balds are most often dominated by *Rhododendron catawbiense*, but substantial examples are also dominated by *Rhododendron carolinianum, Kalmia latifolia*, or a mixture of shrubs. One large example, dominated by *Alnus viridis ssp. crispa*, has been regarded as related to the heath balds, but is better treated separately due to much greater herbaceous diversity and coverage which is clearly different from typical heath balds. Grassy balds are characteristically dominated by *Danthonia compressa, Deschampsia flexuosa*, or *Carex* spp. Large areas have also become dominated by *Rubus allegheniensis* and/or *Rubus canadensis*, and by mixtures of native grasses with exotic pasture grasses. Most examples of grassy balds have some invading shrubs and trees, often dense enough to threaten the herbaceous vegetation. Heath balds may contain sparse stunted trees barely larger than the shrub canopy. The combination of high-elevation, non-wetland sites and dense herbaceous or shrub vegetation without appreciable rock outcrop conceptually distinguishes this system from all others in the Southern Appalachians. However, the widespread areas of degraded spruce-fir with grass and shrub cover and the invasion of grassy balds by trees blur the distinction somewhat.

Related Concepts:

Distribution: This system ranges from the Balsam Mountains and Great Smoky Mountains of North Carolina and Tennessee northward to Virginia and West Virginia. The system is also of limited extent in the Cumberland Mountains along the Virginia-Kentucky border. The current status in Georgia is open to question and the ecological system was apparently never extensive in any case. The distribution and classification of grassy balds and high-elevation pastures has been documented (Gersmehl 1970). Heath balds could be mapped separately from grassy balds as has been done for the Great Smoky Mountains (White et al. 2001). Alder bald can also be mapped separately, but it requires more field verification to map correctly.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, S.C. Gawler, M. Pyne and C. Nordman

CES202.294 CONCEPTUAL MODEL

Environment: This system generally occurs at elevations above 1524 m (5000 feet) but may range as low as 1220 m (4000 feet) in the Southern Blue Ridge, with most examples from 1600-1780 m (5200-5800 feet) elevation (Mark 1958). It is also of limited extent above 1035 m (3400 feet) in the Cumberland Mountains along the Virginia-Kentucky border. It occurs on broad ridgetops and narrow spur ridges. Elevation and orographic effects (winds cooling as they rise to create increased condensation) make the climate cool and wet, with heavy moisture input from fog and cloud interception as well as high rainfall and snowfall. Convex slopes and exposure to wind offset the moisture input to some extent. The high peaks of the Southern Appalachians are not above the treeline; balds occur well below the elevation which would be a treeline today. Concentration of air pollutants has been implicated as an important anthropogenic stress in this elevational range in recent years. Soils range from shallow and rocky to fairly deep residual soils. Any kind of bedrock may be present, but most sites have erosion-resistant felsic igneous or metamorphic rocks, with slate and quartzite particularly frequent. Alder bald tends to occur on areas with thinner and rockier soils than nearby grassy bald (Brown 1941, J. Donaldson pers. comm. 2013), and is distinct from heath bald (Harshberger 1903b, Schafale 2012). The sites that support balds are not obviously different from similar sites that support spruce-fir forests, so the origin of the balds continues to be fodder for debate. Grazing and/or exposure to the elements may help maintain balds. Grass balds occur on less than one percent of the sites suitable for them (White and Sutter 1999b), and heath balds occur on 4-9% of the sites suitable for them (White et al. 2001). Forests occur on most of these sites, such as northern hardwood, high-elevation oak, or spruce-fir forests.

Key Processes and Interactions: The dynamics that maintain and that created the communities in this system have been a major topic of debate, so far without resolution. Most grassy bald occurrences show a strong tendency to succeed to shrub or forest vegetation under present conditions, suggesting that some important maintenance process has been lost. Northern hardwood, high-elevation oak, or spruce-fir forests may occur adjacent to balds. Grazing by native herbivores (elk and bison) and periodic fire have both been suggested as natural mechanisms to keep out woody vegetation. Others have suggested that all grassy balds are of anthropogenic origin and were never ecologically stable. The most definitive grassy balds have been documented as present at the time of the first European settlement, making documentation of their origin impossible. The presence of shade-intolerant endemic or disjunct herbaceous plant species in some suggests even greater age. These include *Lilium grayi, Geum radiatum, Packera schweinitziana*, and *Houstonia purpurea var. montana*. Some areas of the spruce-fir system degraded by a combination of logging, slash fires, and grazing resemble grassy balds, but most do not. The common practice of cattle grazing in grassy balds by early settlers has further obscured their presettlement character and evidence of presettlement disturbance processes.

Heath balds (not including alder balds) are more prone to disturbance by fire (Conkle 2004). However, heavy organic accumulations in the soil suggest great age for some. Most heath balds show limited tendency to succeed to forest, suggesting that the dense heath shrub layer is very competitive with tree seedlings. Spruce-fir forest stands which burned in historical times have not usually developed vegetation identical to heath balds.

Threats/Stressors: The lack of grazing, in combination with acid deposition, very high levels of nitrogen deposition, warmer winter temperatures, and higher levels of atmospheric carbon dioxide are factors which influence the loss of native graminoid species diversity, increases in weedy species and the transition of many grassy balds to tree- and shrub-dominated vegetation (Nodvin et al. 1995, Weiss 1999, Stevens et al. 2004, Boggs et al. 2005, Sturm et al. 2005, Post 2013). Over long periods of time in the past, native large grazing mammals (such as deer, elk, bison, and perhaps other now extinct large mammals) and domesticated livestock (cattle, sheep, and goats) influenced the vegetation by maintaining lower levels of vegetation biomass and ecosystem nutrient levels. Nutrient cycling in balds is faster when grazing animals are present.

Mechanical management (such as mowing or bush-hogging) presents different selection factors for plants compared to animal grazing or fire. There are differences regarding biomass accumulation (thatch buildup), sunlight, nutrient cycling, and plant

selectivity. Mechanical management may, over time, create a markedly different community composition compared to historic species compositions.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from the increase of weedy species of plants, and the increase of trees and shrubs in areas that were formerly grassy balds. As a grassy bald becomes dominated by trees, the native and characteristic grasses and sedges tend to decline. Many grassy balds have been lost to encroaching forest vegetation. This is especially true of smaller balds, which have a larger proportion of forest edge. The lack of grazing (or perhaps mowing, extreme weather or fire) and high amounts of nitrogen deposition are factors related to collapse. Heath balds are more resistant to tree invasion than grassy balds are. Ecosystem collapse is characterized by forest vegetation on a site which formerly was either a grass or shrub bald. The forest vegetation does not support the diversity of native grasses and sedges which characterized grass balds.

CES202.327 Southern Appalachian Rocky Summit

CES202.327 CLASSIFICATION

Concept Summary: This system represents treeless rock outcrops of the southern Appalachian Mountains, primarily in western North Carolina and eastern Tennessee. Outcrops may be vertical to horizontal, rugged or fractured rock outcrops of peaks, ridgetops, upper slopes, and other topographically exposed locations. Higher elevation examples occur from 1200 to 2030 m in elevation; other examples may be found at elevations of 305 m (1000 feet) or lower on foothills. These outcrops occur on felsic to mafic rocks and are distinguished from surrounding systems by the prevalence of bare or lichen-encrusted rocks. The vegetation component of this system is generally characterized by a mixture of low-growing lifeforms, especially lichens, mosses, and short-statured forbs. Less commonly, graminoids and low shrubs are encountered. Species common to all outcrop vegetation types include *Carex misera, Saxifraga michauxii*, and *Vaccinium corymbosum*.

Related Concepts:

- High-Elevation Rock Outcrops (Edwards et al. 2013) **><**
- Low Elevation Rocky Summit (Schafale and Weakley 1990) **<**

Distribution: This system is found at a variety of elevations in the southern Appalachian Mountains, primarily in western North Carolina and eastern Tennessee.

Nations: US

Concept Source: M. Schafale

Description Author: M. Schafale and M. Pyne

CES202.327 CONCEPTUAL MODEL

Environment: This system occurs on rugged rock outcrops on peaks, ridgetops, upper slopes, and other topographically exposed landforms (Schafale and Weakley 1990). Elevations may range from nearly the highest in the region (1200-2030 m), down to 305 m (1000 feet) or lower on foothills. The rock outcrops are irregular, with substantial horizontal surfaces, as well as often vertical surfaces, and generally with fractures. This structure allows soil accumulation in local pockets, sometimes to fair depth, even though most of the substrate is bare rock. Bedrock may be a variety of types. Erosion-resistant rocks such as felsic gneisses and schists or quartzite are most common, but mafic rocks such as amphibolite are also important substrates. Granite and granitic gneiss sometimes form rocky summits, but more often form the smoother outcrops that support ~Southern Appalachian Granitic Dome (CES202.297)$$ or ~Southern and Central Appalachian Mafic Glade and Barrens (CES202.348)$$. Moisture conditions are generally quite dry due to lack of soil but may be heterogeneous. Local deep crevices may accumulate water funneled from bare rock. Seepage is occasionally present but is usually minor. Climate varies substantially with elevation and has a strong effect on variation within the system. Higher elevation sites have high rainfall and receive substantial additional moisture from fog and rime ice.

Key Processes and Interactions: The dynamics of this system have received little study. Most rocky summit sites are probably stable over long periods of time, but variations in the always stressful environment may disturb and change vegetation. The role of crevices and soil in depressions as the primary rooting site makes for a relatively stable pattern of plant distribution and potentially long-lived individuals. This is in contrast to the shallow soil mats predominating in granitic domes. Between disturbances, accumulation of soil and succession of vegetation to greater woody abundance may occur. Fire may naturally be uncommon or fairly common. The topographically high location of this system would make it likely that fires would spread into it, though the sparse fuels would allow only patchy burning. Fires have been indicated to be important in preventing dense woody growth from encroaching on open outcrops in at least some instances. Rock falls or other mass movements are rare, but may be important in creating rock outcrops and keeping them open in the long term. Periodic drought is probably a significant disturbance. Animals and freeze-thaw action may be important disturbances at a local scale. Because of the fragility of soil and vegetation, human disturbance by trampling edges and by climbing may be particularly destructive.

CES202.328 Southern Piedmont Glade and Barrens

CES202.328 CLASSIFICATION

Concept Summary: This glade and barrens system of the southern Piedmont consists of gently to moderately sloping areas with mostly shallow soil over bedrock. Examples usually have significant areas of exposed rock evident. The bedrock potentially includes a variety of igneous and metamorphic rock types, including diabase, mudstone, and shale. Examples support open vegetation of patchy, mixed physiognomy with a significant woody component. Trees may be stunted and/or more widely spaced than in the more typical forests of the region. The shallow soils which impede tree growth help distinguish this system from forest systems of the Piedmont. This system is structurally intermediate between other rock outcrop systems and the more common and typical forest systems. The canopy species are those tolerant of dry, shallow soils, most commonly *Juniperus virginiana* and various oaks and pines, but also including *Fraxinus americana, Ulmus alata*, and *Cercis canadensis* on basic examples. Shrubs may be dense, with species determined by soil chemistry. The herb layer is usually fairly dense and may be dominated by grasses or by a mix of grasses and forbs, both in treeless areas and beneath open canopy. The forbs include species characteristic of other rock outcrops and grassland species, with a smaller number of forest species present. Plant species richness may be fairly high in communities of this system.

Related Concepts:

CES202.328 CONCEPTUAL MODEL

Environment: This system occurs on upper to midslopes, usually on moderate slopes but occasionally flat. The ground is mostly shallow soil over bedrock, usually with significant areas of rock outcrop. The rock usually has few fractures but may have a pitted or irregular surface. This rock structure supports more extensive and deeper soil development than in ~Southern Piedmont Granite Flatrock and Outcrop (CES202.329)$$ or ~Southern Piedmont Cliff (CES202.386)$$, but has few of the crevices and deeper rooting sites available in ~Southern Appalachian Rocky Summit (CES202.327)$$. Micro-scale soil depth and presence of seepage are important factors in determining the vegetation patterns. Shallow soil, unable to support a closed tree canopy, separates this system from forest systems. Bedrock potentially includes a variety of igneous and metamorphic rock types, including diabase, mudstone, and shale. Rock or soil chemistry appears to be the most important factor affecting different associations on sites that have the physical structure to belong to this system.

Key Processes and Interactions: The dynamics of this system are not well known. The occurrence of the system appears to be primarily determined by site physical properties, with physical and chemical properties determining vegetational variation. Fire may be an important influence on vegetation, and may in the long run be important for keeping the vegetation structure open, though the patchy distribution of vegetation might limit fire intensity. It is possible that fire would have allowed glade structure and vegetation to extend onto slightly deeper soils and therefore allowed for more extensive glades. Periodic drought and wind storms may also be an important factor limiting canopy density and stature. The shallow soil would make these sites particularly prone to all three. These glades do not appear to be undergoing the kind of cyclic succession that has been described for granitic flatrocks, but some balance of soil accumulation and destruction may be occurring on a longer term or coarser scale.

Threats/Stressors: The most critical anthropogenic threat to native glade and rock outcrop vegetation is their conversion to human-created land uses, including residential development, quarries, industrial development, infrastructure development, and others (TNC 1996c). Rocky glades and outcrops may be the last areas to be converted to development and housing due to the unsuitability of the soil to septic tanks. Other common threats and stressors include both the removal of disturbance and the effects of inappropriate or too intensive or constant disturbance. These areas often attract off-road-vehicle use.

Fire plays a critical role in the maintenance of most native grasslands, which may surround or interfinger with rocky glades. In the absence of fire and appropriate disturbance in the landscape matrix, the areas with the most shallow soils (e.g., the glades) may be the only open areas persisting in a series of woody shrub thickets. Without fire or other disturbance, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). More information is needed about the particular appropriate ranges of fire-return times and intensities in the various systems. The actual rocky or gravelly glades may not support sufficient fuel to consistently carry fire, but in the adjacent or interpenetrating perennial grasslands, occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing (Duffey et al. 1974). In addition to occasional fire, periodic drought may also be important in regulating woody plant encroachment into native grasslands. It is believed that these native glade-grassland systems have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of glades and their accompanying native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. In many cases, these glade-grassland systems were once extensive on the landscape, but have now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). In other cases, the grassland and/or glade system naturally occurs in small isolated patches occurring within an otherwise forested matrix.

Many glade sites, have been used as pastures, or as dumping grounds for trash (Quarterman et al. 1993). The spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, as well as *Lespedeza cuneata, Ailanthus altissima*, and *Albizia julibrissin*) will fundamentally alter the character of glades and their accompanying native grasslands. Some of these exotics are allelopathic, thereby presenting a greater threat to native species (N. Murdock pers. comm.). Opportunistic native increaser plant species (e.g., *Juniperus virginiana*) can also shade out light-requiring herbaceous plants (TNC 1996c).

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site to other land uses (e.g., residential development, industrial development, infrastructure development, mining or quarrying of underlying bedrock) or conversion to plantations of exotic grasses and legumes. Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, *Ailanthus altissima, Lespedeza cuneata*, and others) will fundamentally alter the character of glades and their accompanying native grasslands. Ecological collapse may also result from the removal or lessening of appropriate disturbance (grazing, fire). Without fire, *Juniperus* species, *Quercus* species and other hardwoods will regenerate or invade into deeper soil areas, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995).

M509. Central Interior Acidic Scrub & Grassland

CES202.692 Central Interior Highlands Dry Acidic Glade and Barrens

CES202.692 CLASSIFICATION

Concept Summary: This ecological system is primarily found in the Interior Highlands of the Ozark, Ouachita, and Interior Low Plateau regions with small occurrences in northern Missouri. It occurs on flatrock outcrops and along moderate to steep slopes or valley walls of rivers along most aspects. Parent material includes chert, igneous and/or sedimentary (sandstone, shale, siltstone) bedrock with well- to excessively well-drained, shallow soils interspersed with rock and boulders. These soils are typically dry during the summer and autumn, becoming saturated during the spring and winter. Grasses such as *Schizachyrium scoparium* and

Sorghastrum nutans dominate this system with stunted oak species (*Quercus stellata, Quercus marilandica*) and shrub species such as *Vaccinium* spp. occurring on variable depth soils. *Juniperus virginiana* can be present and often increases in the absence of fire. In Kentucky, this system includes both sandstone glades found in the Shawnee Hills, as well as shale and siltstone glades and barrens found in the Knobs region, both in the Kentucky Interior Low Plateau. It also includes dry *Quercus stellata*-dominated barrens on Cretaceous-aged gravel substrates on the northern fringes of the Upper East Gulf Coastal Plain Ecoregion in southern Illinois and western Kentucky. This system is influenced by drought and infrequent to occasional fires. Prescribed fires help manage this system by maintaining an open glade structure.

- Virginia Pine: 79 (Eyre 1980) **<**

Distribution: This system is found in the Interior Highlands of the Ozark, Ouachita, and Interior Low Plateau regions, with rare and limited occurrences in the Upper East Gulf Coastal Plain of Kentucky and Illinois. That includes the Shawnee Hills (EPA Ecoregions 71a, 72h of Woods et al. (2002)) and Knobs region (EPA Ecoregions 70d, 71c of Woods et al. (2002)).

CES202.692 CONCEPTUAL MODEL

Environment: This system occurs on flat rock outcrops and along moderate to steep slopes or valley walls of rivers along most aspects. Parent material includes chert, shale, igneous and/or sedimentary (sandstone, shale, siltstone) bedrock with well- to excessively well-drained, shallow soils interspersed with rock and boulders. These soils are typically dry during the summer and autumn, becoming saturated during the spring and winter.

Key Processes and Interactions: Ericaceous shrubs found here are different from calcareous glades. The thin, dry soil characteristic of this system dries out during the growing season and much of the vegetation dries, as well. This allows fires to spread easily and these fires restrict the abundance of woody species. In high-quality examples where the natural fire regime operates, small trees and shrubs are limited to the edges of stands or small "islands" of deeper soil that retain more moisture while grasses are the dominant vegetation. Sparsely vegetated areas between the dominant grassy zones contain most of the rare species found in this system (Ware 2002). In the absence of fire, from active suppression or a lack of fuel due to excessive grazing, woody species can increase greatly.

Threats/Stressors: Disruption of the natural fire regime leads to conversion of this system to shrublands, typically dominated by *Juniperus virginiana*, though ericaceous shrubs can be frequent, too, or woodlands dominated by *Quercus stellata, Quercus marilandica*, or *Quercus prinus*. This disruption can occur as a result of active fire suppression in the glades or surrounding landscape or a lack of fuel due to removal of the herbaceous vegetation, usually due to prolonged overgrazing. In addition to removing fuel for fires, prolonged overgrazing reduces diversity and production of most native herbaceous species but does not reduce shrub invasion (Martin and Houf 1993) and reduces competition for weedy species that can tolerate the glade conditions. Excessive grazing can lead to increased erosion and loss of soil as the roots of the formerly dominant herbaceous vegetation no longer hold the soil.

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when fire is precluded or when sites are overgrazed for extended periods of time. These lead to an increase in the amount of woody cover, principally native shrubs but sometimes trees, and a consequent change in the vegetation structure, flammability, and habitat characteristics. Herbaceous species typical of acidic glades decrease under these conditions and atypical exotic or native species increase. High-quality acidic glades are typically diverse and may contain uncommon or rare species (Homoya 1994, Ware 2002) while low-quality sites have lost much of the diversity. High severity: >30% woody cover, fire frequency >10 years (Nelson 2012). Moderate severity: 10-30% woody cover: fire frequency >5 years (Nelson 2012).

CES202.337 Cumberland Sandstone Glade and Barrens

CES202.337 CLASSIFICATION

Concept Summary: This system encompasses a complex of sparsely vegetated rock outcrops, perennial grasslands, and woodlands on shallow soils on the Cumberland Plateau of Kentucky, Tennessee, Alabama, and Georgia. Herbaceous plants, including *Diamorpha smallii* and *Minuartia glabra*, are typical of the outcrops in Tennessee. In Alabama, *Bigelowia nuttallii* and *Schizachyrium scoparium* are important. *Pinus virginiana* and *Acer rubrum* are typical of the current condition of many of the woodlands surrounding these outcrops on the Cumberland Plateau. This dominance pattern may be due to lack of disturbance. *Pinus rigida, Pinus echinata*, and/or *Quercus montana* may also occur. Scattered shrubs, such as *Gaylussacia* spp., *Vaccinium arboreum*, and *Chionanthus virginicus*, occur on the margins in patches of deeper soil. Various mosses and fruticose lichens such as *Cladonia* spp. may be prominent in some examples. To the west, in the Interior Highlands (Ozark, Ouachita, and Interior Low Plateau regions), this system is replaced by ~Central Interior Highlands Dry Acidic Glade and Barrens (CES202.692)$$ (both are found in Kentucky, with the latter in the Shawnee Hills of the Interior Low Plateau).

Related Concepts:
- Virginia Pine: 79 (Eyre 1980) **<**

Distribution: This system is found in the Cumberland Plateau of Kentucky, Tennessee, Virginia, Alabama, and Georgia.

Nations: US

Concept Source: M. Pyne, R. Evans, C. Nordman

Description Author: M. Pyne, R. Evans, C. Nordman

CES202.337 CONCEPTUAL MODEL

Environment: This suite of glade, barren, and rock outcrop communities are found on flat to gently sloping expanses of sandstone and conglomerate (Edwards et al. 2013) on the surface of the Cumberland Plateau and related formations from Virginia south and west to Alabama. As the cement that holds the sand and conglomerate particles together dissolves and is transported away, sandy particles may collect in crevices and depressions to form sandy soil (Quarterman et al. 1993, Edwards et al. 2013). The sites of this system may be saturated for short times after rainfall, but also experience high temperatures in the summer, creating harsh conditions. Some examples of this system may occur adjacent to sandstone cliff faces.

Key Processes and Interactions: Severe droughts kill tree saplings growing in cracks and potholes, helping to retain the open character of the glades (Quarterman et al. 1993). There is an apparent zonation or patchiness to glade/barren vegetation, with different zones that may be identified by their characteristic plant species (Quarterman et al. 1993). These zones are apparently relatively stable, with woody plant encroachment evident only in relation to the invasion of shrubs and trees into potholes or crevices where soil accumulates more rapidly.

Threats/Stressors: The most critical anthropogenic threat to native glade and rock outcrop vegetation is their conversion to human-created land uses, including residential development, quarries, industrial development, infrastructure development, and others (TNC 1996c). Rocky glades and outcrops may be the last areas to be converted to development and housing due to the unsuitability of the soil to septic tanks. Other common threats and stressors include both the removal of disturbance and the effects of inappropriate or too intensive or constant disturbance. These areas often attract off-road-vehicle use. Trampling from human disturbance and over-use is a threat to the vegetation (Perkins 1981).

Fire plays a critical role in the maintenance of most native grasslands, which may surround or interfinger with rocky glades. In the absence of fire and appropriate disturbance in the landscape matrix, the areas with the most shallow soils (e.g., the glades) may be the only open areas persisting in a series of woody shrub thickets. Without fire or other disturbance, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). More information is needed about the particular appropriate ranges of fire-return times and intensities in the various systems. The actual rocky or gravelly glades may not support sufficient fuel to consistently carry fire, but in the adjacent or interpenetrating perennial grasslands, occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing (Duffey et al. 1974). In addition to occasional fire, periodic drought may also be important in regulating woody plant encroachment into native grasslands. It is believed that these native glade-grassland systems have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of glades and their accompanying native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. In many cases, these glade-grassland systems were once extensive on the landscape, but have now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). In other cases, the grassland and/or glade system naturally occurs in small isolated patches occurring within an otherwise forested matrix.

Many glade sites, have been used as pastures, or as dumping grounds for trash (Quarterman et al. 1993). The spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, as well as *Lespedeza cuneata, Ailanthus altissima*, and *Albizia julibrissin*) will fundamentally alter the character of glades and their accompanying native grasslands. Some of these exotics are allelopathic, thereby presenting a greater threat to native species (N. Murdock pers. comm.). Opportunistic native increaser plant species (e.g., *Juniperus virginiana*) can also shade out light-requiring herbaceous plants (TNC 1996c).

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site to other land uses (e.g., residential development, industrial development, infrastructure development, mining or quarrying of underlying bedrock) or conversion to plantations of exotic grasses and legumes. Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, *Ailanthus altissima, Lespedeza cuneata*, and others) will fundamentally alter the character of glades and their accompanying native grasslands. Ecological collapse may also result from the removal or lessening of appropriate disturbance (grazing, fire). Without fire, *Juniperus* species, *Quercus* species and other hardwoods will regenerate or invade into deeper soil areas, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995).

CES202.329 Southern Piedmont Granite Flatrock and Outcrop

CES202.329 CLASSIFICATION

Concept Summary: This ecological system consists of smooth, exfoliated outcrops of massive granite and related rocks in the eastern and central Piedmont of the southeastern United States, and rarely in the adjacent Atlantic Coastal Plain, there confined to the fall-line where erosion has exposed underlying rocks. Examples occur from Virginia south to Alabama but are found most abundant in the upper Piedmont of Georgia. Some noteworthy examples in central Georgia include Stone Mountain, Panola Mountain, and Arabia Mountain in DeKalb, Henry, and Rockdale counties. Depending upon the location, examples may rise above the surrounding landscape by as much as 200 m, or may lie flush with the surrounding land surface. The vegetation is a complex of small-patch communities of different species and structure occupying different microhabitats which are present on the outcrops, ranging from mosses and lichens, to herbs, to shrubs and trees. In some areas, these microhabitats include solution pits or depressions that retain water and form a distinctive wetland community. This outcrop system supports a relatively large number of endemic plants.

Related Concepts:

- Granitic Flatrock (Schafale and Weakley 1990) **=**
- Rock Outcrops (Wharton 1978) **>**
- Virginia Pine: 79 (Eyre 1980) **<**

Distribution: This system is found scattered in the eastern and central Piedmont, from Alabama to Virginia. Rare examples occur in the upper Piedmont. A few, occurring surrounded by Tertiary sediments in the Fall Zone, may be considered to be in the Coastal Plain.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, M. Pyne

CES202.329 CONCEPTUAL MODEL

Environment: This system occurs on exfoliated granitic outcrops; these are Precambrian metamorphic rocks generally found in the Piedmont Plateau (McVaugh 1943). Outcrops are level or gently sloped, occurring as low domes up to 200 m above the surrounding landscape or as flatrocks varying considerably in size (Shure 1999). Smooth rock without crevices is the primary factor in the distinctive ecological character of this system. Granite, granitic gneiss, and related granitoid rocks (Edwards et al. 2013) without many internal joints tend to fracture into thin sheets parallel to the surface, forming outcrops with smooth surfaces largely lacking crevices. The outcrop surface is largely bare rock but has thin soil mats around the edges and in patches throughout. Mats vary in depth with age and level of development. Distinct microenvironments are created by small irregularities in the rock surface and by areas of seepage at the edge. Some examples (e.g., in central Georgia) may have prominent seepage-related features, where areas of perennial herbaceous vegetation are very wet in the winter and spring. In these cases, the only vegetated areas on the granite outcrop are seepage-related. One possible substrate is the Lilesville granite.

Key Processes and Interactions: Large numbers of soil island depression may be scattered across the surface of granite outcrops and occasional pools of shallow water may stand in certain depressions which trap rainfall (McVaugh 1943, Shure 1999). Where soil accumulates in depressions formed by exfoliating surface rock, a distinctive and fairly predictable pattern of successional changes occurs [see references in Shure (1999)]. Soil mats appear and deepen over time in a process that links vegetational and soil development, but are eventually destroyed by windthrow, drought, other natural disturbances. The result is a mosaic with mats of different levels of development at any given time. Mat dynamics are different in different parts of the rock, with older mats and more permanent patterns near the edges and sparser and younger mats in the interior. The dynamics are further modified by microtopography and the presence of seepage. The larger vegetation patterns such the relative amount of different stages likely respond to climatic cycles and natural disturbance events. The thin soils make these communities sensitive to drought, especially the long-lived woody species. Fire is probably rare in the interior, given the sparse fuel, but may be important in determining the size of the open area and may affect the dynamics of the bordering woodlands.

Severe droughts kill tree saplings growing in cracks and potholes, helping to retain the open character of the glades (Quarterman et al. 1993). There is an apparent zonation or patchiness to glade/barren vegetation, with different zones that may be identified by their characteristic plant species (Quarterman et al. 1993). These zones are apparently relatively stable, with woody plant encroachment evident only in relation to the invasion of shrubs and trees into potholes or crevices where soil accumulates more rapidly.

Threats/Stressors: The most critical anthropogenic threat to native glade and rock outcrop vegetation is their conversion to human-created land uses, including residential development, quarries, industrial development, infrastructure development, and others (TNC 1996c). Rocky glades and outcrops may be the last areas to be converted to development and housing due to the unsuitability of the soil to septic tanks. Other common threats and stressors include both the removal of disturbance and the effects of inappropriate or too intensive or constant disturbance. These areas often attract off-road-vehicle use.

Fire plays a critical role in the maintenance of most native grasslands, which may surround or interfinger with rocky glades. In the absence of fire and appropriate disturbance in the landscape matrix, the areas with the most shallow soils (e.g., the glades) may be the only open areas persisting in a series of woody shrub thickets. Without fire or other disturbance, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). More information is needed about the particular appropriate ranges of fire-return times and intensities in the various systems. The actual rocky or gravelly glades may not support sufficient fuel to consistently carry fire, but in the adjacent or interpenetrating perennial grasslands, occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing (Duffey et al. 1974). In addition to occasional fire, periodic drought may also be important in regulating woody plant encroachment into native grasslands. It is believed that these native glade-grassland systems have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of glades and their accompanying native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. In many cases, these glade-grassland systems were once extensive on the landscape, but have now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). In other cases, the grassland and/or glade system naturally occurs in small isolated patches occurring within an otherwise forested matrix.

Many glade sites, have been used as pastures, or as dumping grounds for trash (Quarterman et al. 1993). The spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, as well as *Lespedeza cuneata, Ailanthus altissima*, and *Albizia julibrissin*) will fundamentally alter the character of glades and their accompanying native grasslands. Some of these exotics are allelopathic, thereby presenting a greater threat to native species (N. Murdock pers. comm.). Opportunistic native increaser plant species (e.g., *Juniperus virginiana*) can also shade out light-requiring herbaceous plants (TNC 1996c).

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site to other land uses (e.g., residential development, industrial development, infrastructure development, mining or quarrying of underlying bedrock) or conversion to plantations of exotic grasses and legumes. Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, *Ailanthus altissima, Lespedeza cuneata*, and others) will fundamentally alter the character of glades and their accompanying native grasslands. Ecological collapse may also result from the removal or lessening of appropriate disturbance (grazing, fire). Without fire, *Juniperus* species, *Quercus* species and other hardwoods will regenerate or invade into deeper soil areas, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995).

M508. Central Interior Calcareous Scrub & Grassland

CES202.602 Central Appalachian Alkaline Glade and Woodland

CES202.602 CLASSIFICATION

Concept Summary: This system occurs at low to moderate elevations from the Central Appalachians (with a few northward incursions into southernmost New York and New England possible) south to the Ridge and Valley and Piedmont. It consists of woodlands and open glades on thin soils over limestone, dolostone or similar calcareous rock. *Juniperus virginiana* is a common tree, often increasing in the absence of fire, and *Quercus muehlenbergii* is indicative of the limestone substrate. *Rhus aromatica, Cercis canadensis*, and *Ostrya virginiana* may occur. Prairie grasses are the dominant herbs (*Andropogon gerardii, Schizachyrium scoparium, Bouteloua* spp.). Forb richness is often high; characteristic forbs include *Asclepias verticillata, Brickellia eupatorioides, Erigeron pulchellus, Monarda fistulosa, Packera obovata, Salvia lyrata*, and *Symphyotrichum oblongifolium*. Fire is sometimes an important natural disturbance factor, but open physiognomies may also be maintained by drought.

- Sugar Maple: 27 (Eyre 1980) **<**
- White Oak - Black Oak - Northern Red Oak: 52 (Eyre 1980) **<**

Distribution: This system is known from Pennsylvania and northwestern New Jersey south through the Ridge and Valley to western Virginia, possibly extending to southeasternmost New York and the marble valleys of northwestern Connecticut.

Nations: US

Concept Source: S.C. Gawler, G. Fleming, and R. Evans

Description Author: S.C. Gawler, G. Fleming, R. Evans, M. Pyne and L.A. Sneddon

CES202.602 CONCEPTUAL MODEL

Environment: This system occupies mid-elevation rocky ridges, gentle to steep south- and southwest-facing slopes, and outcrops with thin soils and calcareous bedrock. Large amounts of exposed mineral soils and/or gravel are characteristic. Soils are high in pH and rich in calcium and magnesium. Although these areas are subject to prolonged droughts, local areas of ephemeral vernal seepage occur in microtopographic concavities, and they may have distinctive vegetation (e.g., colonies of Dodecatheon meadia). A series of glades in western Virginia is somewhat distinctive because of the dolostone, which contains a high magnesium content. These glades are located on low dolomite knobs and foothills of Elbrook dolomite that occupy middle to upper slopes and crests of south- or southwest-facing spur ridges at relatively low elevations. In the Allegheny Mountains and along the Allegheny Front of Pennsylvania, the surface geology is primarily sandstone and shale, but the Mauch Chunk formation includes several narrow bands of limestone that outcrop frequently on steep slopes (Berg et al. 1980).

Key Processes and Interactions: Drought stress appears to drive patch dynamics. Fire is likely to have a somewhat lesser impact due to thin soils and sparse vegetation, although fire scars on woody vegetation of barrens in Virginia suggest that fire may also play a role in maintaining the open character of this system (Ludwig 1999), and fire is also thought to contribute to arresting succession by woody species in Pennsylvania (Laughlin 2004, McPherson 2013). Where this system occurs on steep slopes, debris avalanches may cause periodic disturbance, but this process needs further study (Bartgis 1993); anthropogenic disturbance is thought to have played a role in establishment of some occurrences in Pennsylvania; quarrying has been noted to create habitat for the establishment of species characteristic of limestone prairies, but overall this activity poses a threat through outright destruction or habitat degradation (Laughlin 2004, McPherson 2013).

Threats/Stressors: Glades and barrens in West Virginia have a history of grazing by sheep, allowing for establishment of invasive species such as *Salvia reflexa* (Bartgis 1993). Development and quarrying are threats to this system in West Virginia (Bartgis 1993, Dreese 2010). The soils formed from limestone in the Ridge and Valley and Piedmont are also prime farmland, and large portions have been converted for farming and residential development. Quarrying has also impacted habitat significantly (McPherson 2013). Less than 1% of Pennsylvania's protected lands include calcareous geology. This is problematic as 23% of all rare vascular plant taxa in the state are calciphiles and 10% of Pennsylvania's flora (197 taxa) are considered to be habitat specialists, mainly found in calcareous habitats. Of these, 57% are rare in the state including 31 globally rare calciphile taxa (ranked G2-G4G5) (McPherson 2013). Global climate change could pose significant problems to limestone specialists.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur when occurrences are encroached by development; invasive species cover >10%, <50% native flora; absence or low cover of expected characteristic species.

CES202.691 Central Interior Highlands Calcareous Glade and Barrens

CES202.691 CLASSIFICATION

Concept Summary: This system is found primarily in the Interior Highlands of the Ozark, Ouachita, and Interior Low Plateau regions with scattered occurrences in northern Missouri. It occurs along moderate to steep slopes and steep valleys on primarily southerly to westerly facing slopes. Limestone and/or dolomite bedrock typify this system with shallow, moderately to well-drained soils interspersed with rocks. These soils often dry out during the summer and autumn, and then become saturated during the winter and spring. *Schizachyrium scoparium* dominates this system and is commonly associated with *Andropogon gerardii, Bouteloua curtipendula*, and calcium-loving plant species. Stunted woodlands primarily dominated by *Quercus muehlenbergii* interspersed with *Juniperus virginiana* occur on variable-depth-to-bedrock soils. Fire is the primary natural dynamic, and prescribed fires help manage this system by restricting woody growth and maintaining the more open glade structure.

- Eastern Redcedar: 46 (Eyre 1980) **<**
- Post Oak - Blackjack Oak: 40 (Eyre 1980) **<**

Distribution: This system is found primarily in the Interior Highlands of the Ozark, Ouachita, and the Interior Low Plateau regions ranging east to southern Ohio and including the Knobs region and Cliff section of Kentucky, the Cumberland Plateau escarpment of Tennessee, the Western Valley of the Tennessee River, and the Moulton Valley of northern Alabama.

Nations: US

Concept Source: S. Menard, T. Nigh, M. Pyne

Description Author: S. Menard, T. Nigh, M. Pyne, J. Drake

CES202.691 CONCEPTUAL MODEL

Environment: This system is found primarily along moderate to steep slopes and steep valleys on primarily southerly to westerly facing slopes. Limestone and/or dolomite bedrock typify this system with shallow, moderately to well-drained soils interspersed with rocks. Soils are affected by the bedrock chemistry and tend to have high levels of calcium and potassium and a relatively high pH. Due to seasonal rainfall patterns and the extremely thin soils, these soils dry out during the summer and autumn and become saturated during the winter and spring. In northern Alabama (Moulton Valley), the stratum on which the system is found is a type of "marl." Seeps may occur where impervious rock strata meet relatively permeable limestone.

Key Processes and Interactions: The thin, dry soil characteristic of this system dries out during the growing season and much of the vegetation dries, as well. This allows fires to spread easily and these fires restrict the abundance of woody species. In high-quality examples where the natural fire regime operates, small trees and shrubs are limited to the edges of stands or small "islands" of deeper soil that retain more moisture while grasses are the dominant vegetation. Sparsely vegetated areas between the dominant grassy zones contain most of the rare species found in this system (Ware 2002). In the absence of fire, from active suppression or a lack of fuel due to excessive grazing, woody species can increase greatly.

Threats/Stressors: Disruption of the natural fire regime leads to conversion of this system to shrublands, typically dominated by *Juniperus virginiana*, though *Rhus aromatica* and *Rhus copallinum* can be frequent, too, or sometimes *Quercus*-dominated woodlands (Baskin and Baskin 2000). This disruption can occur as a result of active fire suppression in the glades or surrounding landscape or a lack of fuel due to removal of the herbaceous vegetation, usually due to prolonged overgrazing. In addition to removing fuel for fires, prolonged overgrazing reduces diversity and production of most native herbaceous species but does not reduce shrub invasion (Martin and Houf 1993) and reduces competition for weedy species that can tolerate the glade conditions. Excessive grazing can also lead to increased erosion as the soil is not held by the dominant herbaceous species. In the absence of fire and appropriate disturbance in the landscape matrix, the areas with the most shallow soils (e.g., the glades) may be the only open areas persisting in a series of woody shrub thickets. Without fire or other disturbance, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when fire is precluded or when sites are overgrazed for extended periods of time. These lead to an increase in the amount of woody cover, principally native shrubs but sometimes trees, and a consequent change in the vegetation structure, flammability, and animal habitat characteristics. Herbaceous species typical of calcareous glades decrease under these conditions and atypical exotic or native species increase. High-quality calcareous glades are typically very diverse and may contain uncommon or rare species (Homoya 1994, Ware 2002), while low-quality sites have lost much of the diversity. High severity: >30% woody cover, fire frequency >10 years (Nelson 2012). Moderate severity: 10-30% woody cover: fire frequency >5 years (Nelson 2012).

CES202.354 Eastern Highland Rim Prairie and Barrens

CES202.354 CLASSIFICATION

Concept Summary: This system represents "The Barrens" of the Southeast Highland Rim of Tennessee, as well as related areas of Kentucky. This is a distinctive part of Tennessee and the Eastern Highland Rim and includes a series of plant communities with open canopies, ranging from herbaceous-dominated barrens (some of which are maintained today by mowing instead of fire and grazing) through savanna and woodland types. Open ponds and other wetlands are scattered throughout the landscape. The variety of relatively open habitats which are present here include prairie-like areas, as well as savanna woodlands and upland depression ponds. Stands may vary in physiognomy from savanna-grasslands to oak-dominated woodlands and forests. Many stands are in a forested condition today due to lack of fire. Typical mesic grassland vegetation of the barrens of the southeastern Highland Rim of Tennessee is dominated by *Andropogon gerardii* along with *Schizachyrium scoparium* and *Sorghastrum nutans*. There is also related vegetation in Kentucky (e.g., Hazel Dell Meadow and related sites) which is also included here.

Related Concepts:
- Eastern Redcedar: 46 (Eyre 1980) **<**
- Post Oak - Blackjack Oak: 40 (Eyre 1980) **<**
- Sweetgum - Willow Oak: 92 (Eyre 1980) **<**
- Willow Oak - Water Oak - Diamondleaf (Laurel) Oak: 88 (Eyre 1980) **<**

Distribution: This system is restricted to "The Barrens" of the southeastern Highland Rim of Tennessee (today primarily extant in Coffee, Franklin, and Warren counties, Tennessee). This is a small part of Subsection 223Eb (USFS) and EPA Level IV Ecoregion 71g. Also included are related smaller areas in the Eastern Highland Rim of Kentucky.

Description Author: M. Pyne, R. Evans, and C. Nordman

CES202.354 CONCEPTUAL MODEL

Environment: These various barren communities occur on Fragiudult soils formed in Pleistocene loess over karstic Mississippian Limestone. Their topography is flat to gently sloping. Some proposed factors which have functioned to maintain their openness include the hardpan soils and fire (as well as natural and managed grazing, and modern anthropogenic factors such as mowing for hay, etc.). These barrens include a variety of systems whose primary presettlement environmental factors were specialized soils and extremes of hydrology, as influenced by fire and grazing. The prevalent soils within the polygon labeled "Dickson-Mountview-Guthrie" (D32 of Elder and Springer (1978), Springer and Elder (1980)) are generally flatter, wetter, and more likely to have fragipans than adjoining units. Average conditions in the area of The Barrens can be summarized as follows (Wolfe 1996): January is typically the coldest month, with average high and low temperatures of 8.8º C (47.8º F) and 1.9º C (35.4º F), respectively. July is the warmest month, with average high and low temperatures of 31.3º C (88.3º F) and 18.9º C (66.0º F), respectively. Monthly mean temperatures range from 3.5º C (38.3º F) in January to 25.11º C (77.2º F) in July. The mean annual precipitation is 1438 mm (56.6 inches) (Wolfe 1996, Pyne 2000). Precipitation is heaviest from November through May, averaging between 113 and 171 mm (4.4 to 6.7 in) per month. Rainfall is lightest during the months of June through October, with averages ranging from 83 mm (3.3 inches) per month to a minor peak of 122 mm (4.8 inches) in July.

Key Processes and Interactions: Past fire and grazing constitute the major dynamic processes for this system. Fires were frequent (potentially on a five-year return interval (Guyette et al. 2006), documented over approximately the last 370 years), primarily of human origin, occurring in late summer to early autumn. Forestry activities (including planting of off-site *Pinus taeda*, which is not truly native to the region) and fire suppression have led to the current forested condition with solar intensity as low as 10%. The current persistence of prairies, shrublands, and grassy-woodland/savannas is largely dependent on contemporary management regimes. The woodlands, savannas and prairies are often grown up in woody vegetation (e.g., *Acer rubrum, Liquidambar styraciflua*, as well as *Quercus* spp. and *Carya* spp.) due to fire suppression. Woodlands dominated by *Quercus alba, Quercus stellata*, and to a lesser extent *Quercus marilandica* often "fill in" with less fire-tolerant species (e.g., *Acer rubrum, Liquidambar styraciflua, Nyssa sylvatica, Quercus coccinea, Quercus falcata*, etc.) resulting in a closed-canopy forest.

Threats/Stressors: The most critical anthropogenic threat to native grasslands, savannas and barrens is their conversion to human-created land uses, including residential development, quarries, industrial development, infrastructure development, and others (TNC 1996c). Rocky glade areas, if present, may be the last areas to be converted to development and housing due to the unsuitability of the soil to septic tanks. Other common threats and stressors include both the removal of disturbance (e.g., fire, grazing) and the effects of inappropriate or too intensive or constant disturbance. These areas often attract off-road-vehicle use.

Fire plays a critical role in the maintenance of most native grasslands. Without it, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). In landscapes where open grassland or savanna vegetation is part of the matrix, and where woody plants have taken over areas once occupied by open grassland and savanna vegetation, the light-dependent species may only persist on the open edges (roadsides, powerlines) of forested patches (Taft 1997). In southeastern grasslands, complete transition to forest dominated vegetation can occur in one or two decades (Wiens and Dyer 1975). More information is needed about the particular appropriate ranges of fire-return times and intensities in the various systems, along with factors other than fire (e.g., soil/substrate, aspect, herbivory, hydroperiod and flooding) that help maintain grasslands and related communities. Occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing. Too intensive or frequent application of these disturbances will have deleterious effects on stand structure and species diversity. In general, mosaics of scrub and grassland, produced by light to moderate grazing (or occasional fire) will support the greatest diversity (Duffey et al. 1974). Cutting or mowing is not as favorable to plant diversity as is grazing because it is nonselective and does not result in the same kind of soil disturbance and compaction as do the hooves of grazing animals (DeSelm and Murdock 1993). Fire is a critical disturbance factor for southeastern native grasslands, but the intensity, duration, and timing of the fires are all important in their effect on the vegetation (DeSelm and Murdock 1993). In addition to occasional fire, periodic drought may also be important in regulating woody plant encroachment in native grasslands. It is believed that native grasslands have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. A small isolated patch has a low probability of receiving a lightning strike frequently enough to maintain a grassland condition. In many cases, grassland systems were once extensive on the landscape, but have now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). In other cases, the grassland or glade system naturally occurs in small isolated patches occurring within an otherwise forested matrix.

Many native grassland sites, particularly the more productive ones, have been converted to plantations of exotic grasses and legumes (DeSelm and Murdock 1993). Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, as well as *Ailanthus altissima, Albizia julibrissin, Alliaria petiolata, Lespedeza cuneata, Microstegium vimineum*, and *Miscanthus sinensis*) will fundamentally alter the character of native grasslands, barrens, savannas, and glades. Some of these exotics are allelopathic, thereby presenting a greater threat to native species (N. Murdock pers. comm.). Opportunistic native increaser plant species (e.g., *Juniperus virginiana*) can also shade out light-requiring herbaceous plants (TNC 1996c).

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site to other land uses (e.g., residential development, industrial development, infrastructure development, mining or quarrying of underlying bedrock) or conversion to plantations of exotic grasses and legumes. Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, *Ailanthus altissima, Lespedeza cuneata*, and others) will fundamentally alter the character of native grasslands, barrens, savannas, and glades. Ecological collapse may also result from the removal or lessening of appropriate disturbance (fire, grazing). Without fire, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate or invade, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a shift to an alternate stable state and a net loss of species diversity (Taft et al. 1995). In many southeastern grasslands and savannas, complete transition to forest dominated vegetation can occur in one or two decades (Wiens and Dyer 1975).

CES202.334 Nashville Basin Limestone Glade and Woodland

CES202.334 CLASSIFICATION

Concept Summary: This system encompasses a range of plant communities associated with thin soils on flat areas of Ordovician limestone in the Nashville Basin of Tennessee (mostly inner basin, also outer basin), with a few disjunct occurrences in Kentucky. The vegetation of this system includes sparsely vegetated rock outcrops, annual *Sporobolus* spp.-dominated grasslands, *Schizachyrium scoparium*-dominated perennial grasslands, seasonally wet herbaceous washes and seeps, shrublands, as well as woodlands dominated by *Juniperus virginiana* and oaks. In addition, *Echinacea tennesseensis* and *Astragalus bibullatus* are completely endemic to this system. There are numerous other disjunct and near-endemic plants.

Related Concepts:

- Eastern Redcedar: 46 (Eyre 1980) **<**
- Post Oak - Blackjack Oak: 40 (Eyre 1980) **<**

Distribution: This system is restricted to flat areas of Ordovician limestone in the Inner Nashville Basin of Tennessee (Ecoregion 71i of Griffith et al. (1998); Subsection 222Ed of Keys et al. (1995)), as well as limited and disjunct examples on flat Mississippian limestones in Kentucky.

Nations: US

Concept Source: M. Pyne, R. Evans, C. Nordman

Description Author: M. Pyne, R. Evans, C. Nordman

CES202.334 CONCEPTUAL MODEL

Environment: This system is associated with thin soils on flat areas of Ordovician limestone in the Inner Nashville Basin of Tennessee (Ecoregion 71i of Griffith et al. 1998 and EPA 2004; Subsection 222Ed of Keys et al. 1995), with a few disjunct occurrences in Kentucky.

Key Processes and Interactions: There is an apparent zonation or patchiness to glade/barren vegetation, with different zones that may be identified by their characteristic plant species (Quarterman et al. 1993). These zones are apparently relatively stable, with woody plant encroachment evident only in relation to the invasion of shrubs and trees into potholes or crevices where soil accumulates more rapidly.

Periodic droughts, fire, historic grazing, and ice storms all play a role in the dynamics of the system by restricting woody growth and maintaining the more open glade structure. Historic grazing by wild and domestic ungulate species represented a significant disturbance regime in the past. Regionally significant drought cycles lead to death or decline of *Juniperus virginiana*, as well as affecting the severity of other disturbance regimes. Severe droughts kill tree saplings growing in cracks and potholes, helping to retain the open character of the glades (Quarterman et al. 1993). Fire carries best in zones or areas dominated by perennial grasses, which provide the most abundant and consistent fuel. This zone is also the most vulnerable to succession, with *Juniperus virginiana* and various native (and exotic) shrubs occupying these areas in periods without disturbance (Landfire 2007a).

The ecological processes that maintain these open grasslands and glades within a forested matrix are not completely understood. Clearly periodic drought cycles of varying lengths play a role, along with fire and free-ranging grazing livestock, at least until the 1940s, when open range laws were changed (DeSelm 1994). Livestock confinement, habitat fragmentation, and the ingrowth of exotic shrubs have caused many examples of these communities to become more densely covered by woody plants, including the native but weedy *Juniperus virginiana var. virginiana*.

Open range laws and the use of fire to clear native grass pastures worked to keep large parts of the rural Nashville Basin in an open, grass-dominated condition, either as open, prairie-like areas, or as oak woodlands with a native grass and forb understory. This combination of conditions persisted until about 1945 (DeSelm 1994). In a Missouri study of presettlement fire using composite fire scar chronologies, Guyette and McGinnes (1982 as cited in Frost 1998) reconstructed a presettlement fire frequency of 3.2 years in Missouri cedar glade vegetation.

Threats/Stressors: The most critical anthropogenic threat to native glade and rock outcrop vegetation is their conversion to human-created land uses, including residential development, quarries, industrial development, infrastructure development, and others (TNC 1996c). Rocky glades and outcrops may be the last areas to be converted to development and housing due to the unsuitability of the soil to septic tanks. Other common threats and stressors include both the removal of disturbance and the effects of inappropriate or too intensive or constant disturbance. These areas often attract off-road-vehicle use.

Fire plays a critical role in the maintenance of most native grasslands, which may surround or interfinger with rocky glades. In the absence of fire and appropriate disturbance in the landscape matrix, the areas with the most shallow soils (e.g., the glades) may be the only open areas persisting in a series of woody shrub thickets. Without fire or other disturbance, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). More information is needed about the particular appropriate ranges of fire-return times and intensities in the various systems. The actual rocky or gravelly glades may not support sufficient fuel to consistently carry fire, but in the adjacent or interpenetrating perennial grasslands, occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing (Duffey et al. 1974). In addition to occasional fire, periodic drought may also be important in regulating woody plant encroachment into native grasslands. It is believed that these native glade-grassland systems have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of glades and their accompanying native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. In many cases, these glade-grassland systems were once extensive on the landscape, but have now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). In other cases, the grassland and/or glade system naturally occurs in small isolated patches occurring within an otherwise forested matrix.

Many glade sites, have been used as pastures, or as dumping grounds for trash (Quarterman et al. 1993). The spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, as well as *Ailanthus altissima, Albizia julibrissin*, and *Lespedeza cuneata*) will fundamentally alter the character of glades and their accompanying native grasslands. Some of these exotics are allelopathic, thereby presenting a greater threat to native species (N. Murdock pers. comm.). Opportunistic native increaser plant species (e.g., *Juniperus virginiana*) can also shade out light-requiring herbaceous plants (TNC 1996c).

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site to other land uses (e.g., residential development, industrial development, infrastructure development, mining or quarrying of underlying bedrock) or conversion to plantations of exotic grasses and legumes. The Nashville Basin of Tennessee has experienced rapid population growth in the latter 20th and early 21st century. Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, *Ailanthus altissima, Lespedeza cuneata*, and others) will fundamentally alter the character of glades and their accompanying native grasslands. Ecological collapse may also result from the removal or lessening of appropriate disturbance (grazing, fire). Without fire, *Juniperus* species, *Quercus* species and other hardwoods will regenerate or invade into deeper soil areas, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995).

CES202.024 Southern Ridge and Valley Calcareous Glade and Woodland

CES202.024 CLASSIFICATION

Concept Summary: This ecological system consists of open glades and surrounding woodlands on shallow, high pH soils of the Ridge and Valley region from southwestern Virginia southward. Examples of related calcareous vegetation from the Cumberland Plateau area of Alabama (231Cd of Ecomap 2007; 68e of EPA) are included here as well. These glades occur in broad valley bottoms, rolling basins, and adjacent slopes where soils are shallow over flat-lying limestone strata. The flat to rolling terrain and locally xeric soils may have been especially conducive to periodic fires that helped maintain the prairielike openings and savannalike woodlands. Today, much of the system is currently somewhat more closed and brushy, suggesting fire suppression. *Quercus muehlenbergii* and *Quercus stellata* are typical where the canopy is present. Dominant or abundant *Juniperus virginiana var. virginiana* is probably a result of the lack of fire.

Related Concepts:

- Eastern Redcedar: 46 (Eyre 1980) **<**
- Sugar Maple: 27 (Eyre 1980) **<**

Distribution: This system occurs from southwestern Virginia (roughly Roanoke) south through the southern Ridge and Valley into Georgia (as well as in the Cumberlands of Alabama).

Nations: US

Description Author: M. Pyne, G. Fleming, R. Evans, S.C. Gawler

CES202.024 CONCEPTUAL MODEL

Environment: Examples occur on shallow, high pH soils, in broad valley bottoms, rolling basins, and adjacent slopes over limestone strata.

Key Processes and Interactions: The flat to rolling terrain and locally xeric soils may have been especially conducive to periodic fires that helped maintain the grass-dominated openings and open woodlands. In addition to occasional fire, periodic drought may also be important in regulating woody plant encroachment into native grasslands. It is believed that these native glade-grassland systems have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Threats/Stressors: The most critical anthropogenic threat to native glade and rock outcrop vegetation is their conversion to human-created land uses, including residential development, quarries, industrial development, infrastructure development, and others (TNC 1996c). Rocky glades and outcrops may be the last areas to be converted to development and housing due to the unsuitability of the soil to septic tanks. Other common threats and stressors include both the removal of disturbance and the effects of inappropriate or too intensive or constant disturbance. These areas often attract off-road-vehicle use.

Fire plays a critical role in the maintenance of most native grasslands, which may surround or interfinger with rocky glades. In the absence of fire and appropriate disturbance in the landscape matrix, the areas with the most shallow soils (e.g., the glades) may be the only open areas persisting in a series of woody shrub thickets. Without fire or other disturbance, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). More information is needed about the particular appropriate ranges of fire-return times and intensities in the various systems. The actual rocky or gravelly glades may not support sufficient fuel to consistently carry fire, but in the adjacent or interpenetrating perennial grasslands, occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing (Duffey et al. 1974).

Fragmentation of glades and their accompanying native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. In many cases, these glade-grassland systems were once extensive on the landscape, but have now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). In other cases, the grassland and/or glade system naturally occurs in small isolated patches occurring within an otherwise forested matrix.

Many glade sites, have been used as pastures, or as dumping grounds for trash (Quarterman et al. 1993). The spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, as well as *Lespedeza cuneata, Ailanthus altissima*, and *Albizia julibrissin*) will fundamentally alter the character of glades and their accompanying native grasslands. Some of these exotics are allelopathic, thereby presenting a greater threat to native species (N. Murdock pers. comm.). Opportunistic native increaser plant species (e.g., *Juniperus virginiana*) can also shade out light-requiring herbaceous plants (TNC 1996c).

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site to other land uses (e.g., residential development, industrial development, infrastructure development, mining or quarrying of underlying bedrock) or conversion to plantations of exotic grasses and legumes. Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, *Ailanthus altissima, Lespedeza cuneata*, and others) will fundamentally alter the character of glades and their accompanying native grasslands. Ecological collapse may also result from the removal or lessening of appropriate disturbance (grazing, fire). Without fire, *Juniperus* species, *Quercus* species and other hardwoods will regenerate or invade into deeper soil areas, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995).

M505. Laurentian-Acadian Acidic Rocky Scrub & Grassland

CES201.019 Laurentian Acidic Rocky Outcrop

CES201.019 CLASSIFICATION

Concept Summary: This Laurentian and near-boreal outcrop system is found across central southern Canada and the upper Midwest of the United States. It is found on ridges or summits of resistant acidic bedrock at low to mid elevations. The vegetation is patchy, often a mosaic of woodlands and open glades. The system is typically dominated by various conifers, including *Pinus banksiana* and *Picea mariana*, with occasional *Picea glauca* or *Populus tremuloides*. Hardwoods include *Quercus rubra, Quercus ellipsoidalis*, and *Populus tremuloides*. Structure can vary from treed to low heath shrubs to open lichen woodland. Exposure and occasional fire are the major factors in keeping the vegetation relatively open.

M507. Laurentian-Acadian Calcareous Scrub & Grassland

CES201.721 Great Lakes Alvar

CES201.721 CLASSIFICATION

Concept Summary: Alvars are natural systems of humid and subhumid climates, centered around areas of glaciated horizontal limestone/dolomite (dolostone) bedrock pavement with a discontinuous thin soil mantle. These communities are characterized by distinctive flora and fauna with less than 60% tree cover that is maintained by associated geologic, hydrologic, and other landscape processes. In particular, all forms of alvar tend to flood each spring, then experience moderate to severe drought in summer months. They include open pavement, grassland, and shrubland/woodland types. Alvar communities occur in an ecological matrix with similar bedrock and hydrologically influenced communities. Almost all of North America's alvars occur within the Great Lakes basin, primarily in an arc along the Niagaran Escarpment from northern Lake Michigan across northern Lake Huron and eastern Ontario and northwestern New York state.

Related Concepts:

- Eastern Redcedar: 46 (Eyre 1980) **<**
- Northern White-Cedar: 37 (Eyre 1980) **<**

Distribution: Alvars occur within the Great Lakes basin.

Nations: CA, US

Concept Source: C. Reschke

Description Author: C. Reschke, S.C. Gawler and J. Drake

CES201.721 CONCEPTUAL MODEL

Environment: Alvars are found near Great Lakes shores where flat limestone or dolostone bedrock pavement is exposed. Soils are shallow and discontinuous and tend to accumulate in cracks and shallow depressions in the bedrock. Where present, they are <25 cm deep. In the spring, soils are saturated or even flooded where shallow depressions occur. The thin soils dry quickly and are usually very dry by late summer.

Key Processes and Interactions: The thin soils and large changes in soil moisture during the growing season shape the vegetation of alvars. These conditions favor herbaceous species over woody species. The composition of alvars varies largely with the soil moisture from seasonal herbaceous wetlands to dry grassy areas to sparsely vegetation bedrock. Small shrublands or stunted woodlands can be found where soil accumulates (Reschke et al. 1998). Fires do not carry well on alvars in most years but they did occur with low frequency (Landfire 2007a). Woody species grow slowly on alvars, so even low frequency fires limited their abundance.

Threats/Stressors: Major threats are related to road construction, quarry development, off-road vehicle use, invasive species, and trampling of vegetation (Kost et al. 2007). Road construction results in modification of the hydrology by disrupting overland surface flows, typically flooding one side of the road and drying out the other. Road corridors and associated maintenance and off-road vehicle use facilitate the rapid introduction and expansion of invasive plants. While fire was infrequent, it was important in limiting the spread of woody species, so fire suppression activities negatively affects this system. This system recovers slowly from disturbance, so even moderate stressors can accumulate over time.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the hydrology of a site is affected, either causing flooding or diverting water from sites; when physical damage to a site occurs from quarry development, road building, off-road vehicle use, or other activities; and when invasive species become dominant. Severe environmental degradation occurs when the hydrologic regime is greatly altered leading to long-term flooding or greatly reducing overland flow and causing significant drying of a site; when development and recreational use disturb the majority of a site. Moderate environmental degradation occurs when the hydrologic regime is altered leading to flooding or reducing overland flow and causing drying of a site; when development and recreational use disturb >25% of a site. Severe disruption of biotic processes occurs when invasive species dominate the vegetation. Moderate disruption of biotic processes occurs when invasive species are common components of the vegetation.

2.B.2.Nd. Western North American Interior Sclerophyllous Chaparral Shrubland

M094. Cool Interior Chaparral

CES206.925 California Montane Woodland and Chaparral

CES206.925 CLASSIFICATION

Concept Summary: This ecological system includes chaparral or open shrubby woodlands found among montane forests above 1500 m (4550 feet) elevation from the southern Cascades of Oregon to the Peninsular Ranges of California into Baja California, Mexico, where much annual precipitation occurs as snow. These are often locations with steep, exposed slopes with rocky and/or shallow soils, often glaciated. Stands are not found in the foothills but rather occur commonly above 1524 m (5000 feet) in elevation. These are mosaics of woodlands with chaparral understories, shrub-dominated chaparral, or short-lived chaparral with conifer species invading, if good seed source is available. Shrubs will often have higher densities than the trees, which are more limited due to the rocky/thin soils. These can also be short-duration chaparrals in previously forested areas that have experienced crown fires. Trees tend to have a scattered open canopy or can be clustered, over a usually continuous dense shrub layer. Trees can include *Pinus jeffreyi, Abies lowiana (= Abies concolor var. lowiana), Abies magnifica, Pinus monticola, Pinus lambertiana, Pinus coulteri, Pinus attenuata, Hesperocyparis forbesii (= Cupressus forbesii), Hesperocyparis stephensonii (= Cupressus arizonica ssp. stephensonii)*, and *Hesperocyparis nevadensis (= Cupressus nevadensis)*. Typical sclerophyllous chaparral shrubs include *Arctostaphylos nevadensis, Arctostaphylos patula, Arctostaphylos glandulosa, Ceanothus cordulatus, Ceanothus diversifolius, Ceanothus pinetorum, Ceanothus velutinus*, and *Chrysolepis sempervirens (= Castanopsis sempervirens)*. Some stands can be dominated by winter deciduous shrubs, such as *Prunus emarginata, Prunus subcordata* and *Ceanothus sanguineus* (in Oregon), *Prunus virginiana, Ceanothus integerrimus, Holodiscus discolor (= Holodiscus microphyllus)*, and *Quercus garryana var. fruticosa (= var. breweri)*. Most chaparral species are fire-adapted, resprouting vigorously after burning or producing fire-resistant seeds. Occurrences of this system likely shift across montane forested landscapes with catastrophic fire events.

Related Concepts:

- Montane Shrubland (209) (Shiflet 1994) **>**
- Sierra Nevada Mixed Conifer: 243 (Eyre 1980) **><**

Distribution: This system occurs above 1500 m (4550 feet) elevation from the southern Cascades of Oregon to the Klamath Mountains and Peninsular Ranges of California into Baja California, Mexico.

Nations: MX, US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.925 CONCEPTUAL MODEL

Environment: [from M094] These are chaparral or open shrublands found at montane elevations throughout much of the western U.S., from the Sierra Nevada and Cascades and into the western Great Basin, Colorado Plateau, and Rocky Mountains. They occur in summer-dry habitats from 800 to 3000 m elevation. Can occur as low as 50 m in California, but mostly is found above 1500 m. Much of the precipitation comes as winter snow, and summer drought-stress is characteristic. These shrublands are mostly found on steep, usually south-facing or exposed slopes, where soils are rocky, shallow and well-drained, often glaciated. These are typically zonal disclimax or, occasionally, edaphic climax brushfields which occur in association with dry needle-leaved evergreen forests or woodlands. These shrublands are typically established after stand-replacing fires or clearcut logging in montane conifer forests or pinyon-juniper woodlands, and may be seral to forest after several decades. Excessively rocky or droughty, fire-prone sites in the forest may support relatively persistent stands of this macrogroup. These are in mosaics of woodlands and chaparral and may have conifer species invading if good seed source is available.

Key Processes and Interactions: [from M094] Two phases are recognized: first, early-seral and post-fire or post-logging shrub fields with few conifers; and second, edaphically controlled sites, with soils that are too dry or shallow-soiled for trees, hence sites where shrubs stay dominant (such as *Quercus vacciniifolia, Chrysolepis sempervirens*). Most chaparral species are fire-adapted, resprouting vigorously after burning or producing fire-resistant seeds. Occurrences of this macrogroup likely shift across montane forested landscapes with catastrophic fire events. Clearcut logging can also trigger regeneration of some of the chaparral species.

Threats/Stressors:

Ecosystem Collapse Thresholds: Ecological collapse tends to occur from direct land conversion.

CES304.001 Great Basin Semi-Desert Chaparral

CES304.001 CLASSIFICATION

Concept Summary: This system includes chaparral on sideslopes transitioning from low-elevation desert landscapes up into pinyon-juniper woodlands of the western and central Great Basin. There are limited occurrences extending as far west as the inner Coast Ranges in central California. These are typically fairly open-canopy shrublands with open spaces either bare or supporting patchy grasses and forbs. Characteristic species may include *Arctostaphylos patula, Arctostaphylos pungens, Ceanothus greggii, Ceanothus velutinus, Cercocarpus montanus var. glaber, Cercocarpus intricatus, Eriogonum fasciculatum, Garrya flavescens, Quercus turbinella, Purshia stansburiana*, and *Rhus trilobata*. *Cercocarpus ledifolius* is generally absent. Typical fire regime in these systems varies with the amount of organic accumulation.

CES304.001 CONCEPTUAL MODEL

Environment: This chaparral system is found in the western and central Great Basin, and east slopes of the Sierra Nevada and Cascades on slopes between lower-elevation desert landscapes and higher-elevation pinyon- or juniper-dominated woodlands. It is also found in limited, small-patch occurrences in the montane zone of many mountain ranges in the western U.S. and a few small pockets in the inner Coast Ranges of central California. These shrublands occur in summer-dry habitats from 800 to 3000 m elevation, typically on piedmont slopes, foothills, plateaus and mountains. Much of the precipitation comes as winter snow, and summer drought-stress is characteristic. These shrublands are mostly found on steep, usually south-facing slopes, where soils are rocky and well-drained. These are typically zonal disclimax or, occasionally, edaphic climax brushfields which occur in association with dry needle-leaved evergreen forests or woodlands. These shrublands are typically established after stand-replacing fires or clearcut logging in *Pinus ponderosa, Abies concolor*, or *Pseudotsuga menziesii* forests or pinyon-juniper woodlands, and are seral to forest after several decades. Excessively rocky or droughty, fire-prone sites in the forest may support relatively persistent stands of this system. In the Rocky Mountains, stands are found in small patches within a matrix of montane conifer forest and woodland. Adjacent systems in alpine include ~California Montane Jeffrey Pine-(Ponderosa Pine) Woodland (CES206.918)$$, ~Southern Rocky Mountain Dry-Mesic Montane Mixed Conifer Forest and Woodland (CES306.823)$$, ~Great Basin Pinyon-Juniper Woodland (CES304.773)$$, and ~Rocky Mountain Cliff, Canyon and Massive Bedrock (CES306.815)$$ above and ~Mojave Mid-Elevation Mixed Desert Scrub (CES302.742)$$ or ~Great Basin Xeric Mixed Sagebrush Shrubland (CES304.774)$$ below. The environmental description is based on several other references, including Kauffman (1986), Tirmenstein (1989), Pavek (1993), Holland and Keil (1995), Reid et al. (1999), Zouhar (2000), Anderson (2001a, 2004a), League (2005), Barbour et al. (2007), Hauser (2007), and Sawyer et al. (2009).

Key Processes and Interactions: Disturbance dynamics in this system are variable because of variation in the compositions; however, most dominant shrubs are evergreen species that are adapted to medium-frequency, medium- to large-sized and medium- to high-intensity fire in late summer or fall (Hauser 2007, Sawyer et al. 2009). Some species, such as *Arctostaphylos patula, Ceanothus velutinus, Ceanothus leucodermis*, and *Fremontodendron californicum*, are generally top-killed in burns, but then vigorously resprout from rootcrowns or buried lignotubers. Most have seeds stored in soil and duff that need fire scarification to germinate (Pavek 1993, Anderson 2001a, Hauser 2007, Sawyer et al. 2009). Other chaparral shrubs, such as *Arctostaphylos pungens*

and *Ceanothus greggii*, are killed or sprout only weakly after fire and regenerate from fire-scarified seeds in the seedbank (Zouhar 2000, League 2005, Sawyer et al. 2009). The shorter-lived species such as *Ceanothus leucodermis* are dependent on fire for regeneration and will disappear after 40-70 years if not burned (Minnich 1976, Tirmenstein 1989). Higher-severity fires cause greater seedling establishment than lower-severity fires in chaparral (Kauffman 1986). Some deciduous species such as *Rhus trilobata* are also adapted to fire, vigorously resprout after burning and have fire-scarified seeds (Anderson 2004a). Fire-return interval (FRI) for this systems is medium (10-100 years) on most of the dominant species (Sawyer et al. 2009).
Threats/Stressors: Much of this chaparral system has been impacted by livestock use because of high accessibility and relatively gentle terrain, especially in lower-elevation stands (Brown 1982). Higher-elevation stands on rocky sites with sparse grass understory and dominated by relatively unpalatable browse such as *Arctostaphylos patula* and *Ceanothus velutinus* (USFS 1937) have little or no livestock impacts.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

The primary land uses that alter the natural processes of this system are associated with livestock practices, annual exotic species, fire regime alteration, direct soil surface disturbance, and fragmentation. Excessive grazing stresses the system through soil disturbance (also ORV use), diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and annual grasses, particularly Bromus madritensis and other exotic annual bromes.

M091. Warm Interior Chaparral

CES302.905 Mexican Transvolcanic Chaparral

CES302.905 CLASSIFICATION

Concept Summary: Asociación generalmente densa, de arbustos resistentes al fuego, que se desarrolla principalmente en laderas de cerros por arriba del nivel de los matorrales de zonas áridas y semiáridas de Pastizales Naturales y en ocasiones mezclada con los Bosques de Pino y Encino. Esta formada por especies arbustivas de *Quercus* spp. (Encinillo, Charrasquillo), *Adenostoma* spp. (Chamizos), *Arctostaphylos* spp. (Manzanita), *Cercocarpus* spp. (Rosa de castilla), etc.

CES302.905 CONCEPTUAL MODEL

Environment: [from M091] This type occurs across central Arizona (Mogollon Rim) and southern New Mexico, east in mountains across Trans-Pecos Texas, and south into the Madrean Occidentale and Madrean Oriental in northern Mexico. Occurrences are also found in desert mountains in the Sonoran and Mojave deserts. Stands are found on foothills, xeric mountain slopes and canyons in hotter and drier habitats. They often dominate along the mid-elevation (1000-2500 m) transition zone between desert scrub and montane woodlands (encinal, pine-oak, and ponderosa pine). Sites are variable but often steep and rocky. Sometimes this macrogroup occurs in thickets along upper canyon watercourses and northerly upland slopes within the pinyon-juniper woodland zone.

Climate: This macrogroup occurs in warm semi-desert regions in the southwestern U.S. The climate is hot and may have a somewhat bi-modal precipitation regime with spring rains and warm-season monsoonal rains as well. Frosts occur in winter, and even sometime snows, which will melt rapidly. *Soil/substrate/hydrology:* Parent materials are varied. This macrogroup is found on igneous intrusives and extrusives, sedimentary, and metamorphic including andesite, basalt, diabase, gneiss, schist, shale, slate, rhyolite, sandstone, tuff, and, more commonly, limestone and coarse-textured granitic substrates.

Key Processes and Interactions: [from M091] Many of the communities in this macrogroup are dominated by fire-adapted shrubs. *Quercus cornelius-mulleri* sprouts vigorously from root crowns after fire. Since *Quercus cornelius-mulleri* chaparral occurs in areas of lower rainfall and sparser vegetation cover, it typically has less frequent fire and slower recovery rates than typical cismontane chaparral types elsewhere in California. *Quercus turbinella* in Arizona and New Mexico is a fire-type; it sprouts vigorously from the root crown and rhizomes. Typical fire intervals in Arizona exceed 74 years (Reid et al. 1999, Tirmenstein 1999d). Plants in the New York Mountains of California are treelike, suggesting that fires have been absent for perhaps greater than 100 years. Instead, flooding has initiated stem breakage and sprouting of some canyon bottom stands. *Ceanothus greggii* is an obligate seeder and germinates from seed after fire, and older stands will lose dominance of this shrub to other longer-lived sprouting shrubs.

Site conditions aside, the dynamics of fire within chaparral are still complex. In southern California, it has been suggested that the even-aged and large size of modern chaparral patches are a function of 20th century fire suppression feedbacks whereby intensive suppression has led to large fuel buildups over large areas of landscape leading to large stand-replacement fires of ever increasing size (Minnich 1983, 2001). Others contend that the large patch patterns are within that natural range of variability, and that they are driven more by climate trends, prevailing weather patterns, increased human ignition frequencies with increased population density, changes in land use, and landscape characteristics rather than suppression (Keeley and Fotheringham 2001a, 2001c, Moritz 2003). The pattern of chaparral distribution in southern New Mexico suggests that the latter scenario might be the case here. Because of the rugged country, effective suppression has been minimal. Hence, the large patches of chaparral may be representative of a more or less natural fire regime, but one possibly modified by increased human caused fires and fire suppression on neighboring forested lands. More frequent, intense fires leads to the decline of the grassy woodland savannas on the ridge top summits and a favoring of shrublands (possibly enhanced by increased fine fuels with the cessation of livestock grazing). In this type of fire regime, Keeley and Fotheringham (2001a) and Moritz (2003) contend that prescribed burning may be useless or even harmful and that fire suppression, at least in the short term, may be more appropriate for maintaining an ecosystem near its natural state. Minnich (2001) would likely argue the opposite saying it is fire suppression that generates the large patch pattern and that prescribed fire is needed to restore a small patch mosaic with imbedded natural fuel firebreaks. Detailed fire history studies that focus on chaparral patch age structure in a landscape context would be useful (and perhaps necessary) to help resolve these conflicting viewpoints and generate management options that are tailored to interior chaparral.

At the other end of the elevation spectrum, repeated burning of chaparral, particularly Pinchot juniper, has been suggested as a way to increase grass cover in shrubland communities (Ahlstrand 1982). Most of our understanding of how to manage of Pinchot juniper comes from the high Plains of Texas where it is seen as an invader of fine textured plains grasslands soils, and where management has focused on control and eradication to increase livestock forage. Research from the high plains indicates that the effectiveness of fire in controlling Pinchot juniper is a function of fire intensity, climatic conditions and position of the bud zone above or below the soil (Steuter and Britton 1983). Fire was particularly effective in inducing mortality in young plants with exposed buds on rocky sites, but this dropped off significantly with older plants. In addition, increased grass cover (grama grasses) can inhibit reproduction (Smith et al. 1975). As Ahlstrand (1982) has shown, fires can lead to at least short-term increases in grass cover, but because Pinchot juniper can recover 50% or more of its original cover within six or seven years of a burn, repeated prescribed fires at 10- to 15-year intervals would be needed to sustain a grassland type.

CES302.031 Madrean Oriental Chaparral

CES302.031 CLASSIFICATION

Concept Summary: This ecological system occurs in mountains across southeastern New Mexico (Guadalupe Mountains), Trans-Pecos Texas (Chisos and Davis mountains) and Madrean Oriental in northern Mexico. It often dominates along the mid-elevation transition from the Chihuahuan Desert into mountains (1700-2500 m). It occurs on foothills, mountain slopes and canyons in drier habitats below the encinal and pine woodlands, and is often associated with more xeric and coarse-textured substrates such as limestone, basalt or alluvium, especially in transition areas with more mesic woodlands. The moderate to dense shrub canopy includes many shrub oak species, such as *Quercus emoryi, Quercus grisea, Quercus intricata, Quercus invaginata, Quercus laceyi, Quercus mohriana, Quercus pringlei, Quercus pungens*, and *Quercus vaseyana*, and several widespread chaparral species, such as *Arctostaphylos pungens, Ceanothus greggii, Cercocarpus montanus, Fallugia paradoxa*, and *Garrya wrightii*; other species characteristic of this system include *Arbutus xalapensis, Fraxinus greggii, Fendlera rigida, Garrya ovata, Purshia mexicana, Rhus virens var. choriophylla, Salvia lycioides, Salvia roemeriana*, and *Salvia regla*. In the Trans-Pecos of Texas, disjunct *Quercus gambelii* may occur as a significant component of this shrubland. In addition, Texas occurrences may also include *Agave lechuguilla, Aloysia wrightii, Ceanothus greggii, Cercocarpus montanus, Chrysactinia mexicana, Dasylirion leiophyllum, Fallugia paradoxa, Fraxinus greggii, Garrya wrightii, Juniperus pinchotii, Nolina texana, Opuntia engelmannii var. engelmannii, Pinus cembroides* or *Pinus edulis* (in the Guadalupe Mountain region), *Quercus turbinella, Quercus x pauciloba, Rhus virens*, and *Viguiera stenoloba*. Most chaparral species are fire-adapted, resprouting vigorously after burning or producing fire-resistant seeds. Stands occurring within montane woodlands are seral and a result of recent fires. Grass cover may be significant. Dominant grasses often include *Bouteloua curtipendula, Bouteloua hirsuta*, and *Muhlenbergia emersleyi*. In Texas, the herbaceous cover is patchy and bare rock is frequently visible. Where present, graminoids dominate the herbaceous layer with species such as *Bouteloua curtipendula, Bouteloua hirsuta, Muhlenbergia emersleyi, Muhlenbergia pauciflora, Muhlenbergia setifolia, Achnatherum lobatum, Muhlenbergia dubia*, and *Heteropogon contortus*.

CES302.031 CONCEPTUAL MODEL

Environment: This system occurs at elevations above desert shrublands on dry rocky habitats of foothills, mountains, and canyons. In Texas, it often occurs at elevations coincident with the occurrence of Madrean Encinal and Madrean coniferous woodlands, but typically occupies more xeric sites, often with steeper slopes and less soil development.

Key Processes and Interactions: [from M091] Many of the communities in this macrogroup are dominated by fire-adapted shrubs. *Quercus cornelius-mulleri* sprouts vigorously from root crowns after fire. Since *Quercus cornelius-mulleri* chaparral occurs in areas of lower rainfall and sparser vegetation cover, it typically has less frequent fire and slower recovery rates than typical cismontane chaparral types elsewhere in California. *Quercus turbinella* in Arizona and New Mexico is a fire-type; it sprouts vigorously from the root crown and rhizomes. Typical fire intervals in Arizona exceed 74 years (Reid et al. 1999, Tirmenstein 1999d). Plants in the New York Mountains of California are treelike, suggesting that fires have been absent for perhaps greater than 100 years. Instead, flooding has initiated stem breakage and sprouting of some canyon bottom stands. *Ceanothus greggii* is an obligate seeder and germinates from seed after fire, and older stands will lose dominance of this shrub to other longer-lived sprouting shrubs.

Site conditions aside, the dynamics of fire within chaparral are still complex. In southern California, it has been suggested that the even-aged and large size of modern chaparral patches are a function of 20th century fire suppression feedbacks whereby intensive suppression has led to large fuel buildups over large areas of landscape leading to large stand-replacement fires of ever increasing size (Minnich 1983, 2001). Others contend that the large patch patterns are within that natural range of variability, and that they are driven more by climate trends, prevailing weather patterns, increased human ignition frequencies with increased population density, changes in land use, and landscape characteristics rather than suppression (Keeley and Fotheringham 2001a, 2001c, Moritz 2003). The pattern of chaparral distribution in southern New Mexico suggests that the latter scenario might be the case here. Because of the rugged country, effective suppression has been minimal. Hence, the large patches of chaparral may be representative of a more or less natural fire regime, but one possibly modified by increased human caused fires and fire suppression on neighboring forested lands. More frequent, intense fires leads to the decline of the grassy woodland savannas on the ridge top summits and a favoring of shrublands (possibly enhanced by increased fine fuels with the cessation of livestock grazing). In this type of fire regime, Keeley and Fotheringham (2001a) and Moritz (2003) contend that prescribed burning may be useless or even harmful and that fire suppression, at least in the short term, may be more appropriate for maintaining an ecosystem near its natural state. CES302.741 Mogollon Chaparral

CES302.741 CLASSIFICATION

Concept Summary: This ecological system occurs across central Arizona (Mogollon Rim), western New Mexico, and southern Utah and Nevada. It often dominates along the mid-elevation transition from the Mojave, Sonoran, and northern Chihuahuan deserts into mountains (1000-2200 m). It occurs on foothills, mountain slopes and canyons in hotter and drier habitats below the encinal and *Pinus ponderosa* woodlands. Stands are often associated with more xeric and coarse-textured substrates such as limestone, basalt or alluvium, especially in transition areas with more mesic woodlands. The moderate to dense shrub canopy includes species such as *Quercus turbinella, Quercus toumeyi, Cercocarpus montanus var. paucidentatus, Canotia holacantha, Ceanothus greggii, Garrya wrightii, Purshia stansburiana, Rhus ovata, Rhus trilobata*, and *Arctostaphylos pungens* and *Arctostaphylos pringlei* at higher elevations. Scattered remnant pinyon and juniper trees may be present. Most chaparral species are fire-adapted, resprouting vigorously after burning or producing fire-resistant seeds. Stands occurring within montane woodlands are seral and a result of recent fires.

CES302.741 CONCEPTUAL MODEL

Environment: This chaparral system occurs across central Arizona (Mogollon Rim), western New Mexico, and southern Utah and Nevada. It does not occur as far west as California. It often dominates along the mid-elevation transition from the eastern Mojave, Sonoran, and northern Chihuahuan deserts into mountains (1000-2200 m). It occurs on foothills, mountain slopes and canyons in hotter and drier habitats below the encinal and *Pinus ponderosa* woodlands. Stands are often associated with more xeric and coarse-textured substrates such as limestone, basalt or alluvium, especially in transition areas with more mesic woodlands. Adjacent upland systems include ~Southern Rocky Mountain Ponderosa Pine Woodland (CES306.648)$$, ~Madrean Encinal (CES305.795)$$, ~Madrean Pinyon-Juniper Woodland (CES305.797)$$ or ~Great Basin Pinyon-Juniper Woodland (CES304.773)$$ above and at lower elevations, ~Sonoran Mid-Elevation Desert Scrub (CES302.035)$$ and ~Mojave Mid-Elevation Mixed Desert Scrub (CES302.742)$$. The environmental description is based on several references, including Cable (1975a), Carmichael et al. (1978), Brown (1982), Dick-Peddie (1993), Reid et al. (1999), Tirmenstein (1999d), Comer et al. (2003), and NatureServe Explorer (2011).

Key Processes and Interactions: Most chaparral species are fire-adapted, resprouting vigorously after burning or producing fire-resistant seeds. Stands occurring within montane woodlands are seral and a result of recent fires. Disturbance dynamics in this system are variable because of variation in composition of dominant species; however, most dominant shrubs are evergreen species that are adapted to medium frequency, medium to large-sized and medium- to high-intensity fire, in late summer or fall. Some species such as *Cercocarpus montanus, Garrya wrightii*, and *Quercus turbinella* are generally top-killed in burns, but then vigorously resprout from root crown or buried lignotubers (Uchytil 1990, Tirmenstein 1999d, Gucker 2006e). Most also have seeds stored in soil and duff that need fire scarification to germinate. Other chaparral shrub such as *Arctostaphylos pungens, Ceanothus greggii*, and *Purshia stansburiana* are killed or sprout only weakly after fire and regenerate from fire-scarified seeds in the seedbank (Howard 1995, Zouhar 2000, League 2005). Some deciduous species such as *Rhus trilobata* are also adapted to fire, vigorously resprout after burning and have fire-scarified seeds (Anderson 2004a). Fire-return interval (FRI) for this systems is medium (5-70 years) on most of the dominant species (Howard 1995, Tirmenstein 1999d, Zouhar 2000, Anderson 2004a, League 2005, Gucker 2006e). Recovery times after fire for *Quercus turbinella*-dominated chaparral stands range from 4 to 8 years or more (Tiedemann and Schmutz 1966). Cable (1957) observed that this shrub regained preburn density within 5 years after fire in Arizona.

The foliage of most of these chaparral shrubs is utilized as browse at least to some degree (new growth) by big game species with *Ceanothus greggii, Cercocarpus montanus, Purshia stansburiana, Garrya wrightii*, and *Rhus trilobata* being especially important (Uchytil 1990, Howard 1995, Zouhar 2000, Anderson 2004a, Gucker 2006e). Small mammal and birds use the acorns and fruits of many of the dominant chaparral species (Cable 1975a, Howard 1995, Tirmenstein 1999d, Zouhar 2000, Anderson 2004a, League 2005, Gucker 2006e).

Threats/Stressors: Chaparral stands dominated by *Quercus turbinella* are used by cattle, domestic sheep (USFS 1937), and domestic goats at least moderately (Cable 1957, 1975a). Much of this chaparral system has been impacted by livestock use because of high accessibility and relatively gentle terrain, especially in lower-elevation stands (Brown 1982a).

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES302.757 Sonora-Mojave Semi-Desert Chaparral

CES302.757 CLASSIFICATION

Concept Summary: This ecological system is composed of evergreen shrublands or dwarf-woodlands on sideslopes transitioning from low-elevation desert landscapes up into woodlands of the western Mojave and Sonoran deserts. It extends from northeast Kern County, California, into Baja Norte, Mexico. Associated species include *Quercus john-tuckeri, Quercus cornelius-mulleri, Quercus berberidifolia, Arctostaphylos patula, Arctostaphylos pungens, Arctostaphylos glauca, Rhus ovata, Cercocarpus montanus var. glaber, Ceanothus greggii, Garrya flavescens, Juniperus californica*, and *Nolina parryi*. Sometimes *Juniperus californica* forms an open, shrubby tree layer over the evergreen oaks and other shrubs.

Related Concepts:

- Snowbush (420) (Shiflet 1994) **?**

Distribution: This system occurs in the western Mojave and Sonoran deserts, from northeast Kern County, California, into Baja Norte, Mexico.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES302.757 CONCEPTUAL MODEL

Environment: This ecological system occurs on sideslopes transitioning from low-elevation desert landscapes up into woodlands of the western Mojave and Sonoran deserts. It extends from northeastern Kern County, California, into Baja Norte, Mexico. This system includes chaparral on sideslopes transitioning from low-elevation desert landscapes up into pinyon-juniper and ponderosa pine woodlands of the western Great Basin between 1220 and 2135 m (4000-7000 feet) elevation. Adjacent upland systems include ~Madrean Encinal (CES305.795)$$, ~Madrean Pinyon-Juniper Woodland (CES305.797)$$ or ~Great Basin Pinyon-Juniper Woodland (CES304.773)$$ above and at lower elevations, ~Sonoran Mid-Elevation Desert Scrub (CES302.035)$$ and ~Mojave Mid-Elevation Mixed Desert Scrub (CES302.742)$$. The environmental description is based on several references, including Cable (1975a), Carmichael et al. (1978), Brown (1982a), Cope (1992b), Howard (1993), Reid et al. (1999), Comer et al. (2003), League (2005), Gucker (2006e), Hauser (2007), Sawyer et al. (2009), and NatureServe Explorer (2011).

Key Processes and Interactions: Most chaparral species are fire-adapted, resprouting vigorously after burning or producing fire-resistant seeds. Stands occurring within montane woodlands are seral and a result of recent fires. Disturbance dynamics in this system are variable because of variation in composition of dominant species; however, most dominant shrubs are evergreen species that are adapted to medium frequency, medium to large-sized and medium- to high-intensity fire, in late summer or fall. Some species, such as *Arctostaphylos patula, Cercocarpus montanus, Garrya flavescens, Quercus cornelius-mulleri, Quercus berberidifolia, Quercus john-tuckeri*, and *Rhus ovata*, are generally top-killed in burns, but then vigorously resprout from root crown or buried lignotubers (Gucker 2006e, Hauser 2007, Sawyer et al. 2009). Most also have seeds stored in soil and duff that need fire scarification to germinate. Other chaparral shrub, such as *Arctostaphylos glauca, Arctostaphylos pungens, Ceanothus greggii*, and *Juniperus californica*, are killed or sprout only weakly after fire and regenerate from fire-scarified seeds in the seedbank (Cope 1992b, Howard 1993, Zouhar 2000, League 2005, Sawyer et al. 2009). Some deciduous species such as *Cercocarpus montanus* are also adapted to fire, vigorously resprout after burning and have fire-scarified seeds (Gucker 2006e). Fire-return interval (FRI) for this systems is medium (10-100 years) on most of the dominant species (Howard 1993, Zouhar 2000, League 2005, Gucker 2006e, Sawyer et al. 2009). Fire-return intervals for *Juniperus californica*-dominated stands are between 100 and 200 years (Sawyer et al. 2009).

The foliage of most of these chaparral shrubs is utilized as browse at least to some degree (new growth) by big game species with *Ceanothus greggii, Cercocarpus montanus*, and *Garrya wrightii* being especially important (Howard 1993, Zouhar 2000, Gucker 2006e). Small mammals and birds use the acorns and fruits of many of the dominant chaparral species (Cable 1975a, Howard 1993, Zouhar 2000, League 2005, Gucker 2006e).

Threats/Stressors: Chaparral shrubs are generally considered to be poor forage for cattle (USFS 1937), but good for domestic goats (Cable 1957, 1975a); however, the more open shrub stands may have a moderate to dense grass layer. Much of this chaparral system has been impacted by livestock use because of high accessibility and relatively gentle terrain, especially in lower-elevation stands (Brown 1982a).

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

2.B.2.Ne. Southeastern North American Grassland & Shrubland

M162. Florida Peninsula Scrub & Herb

CES203.380 Florida Dry Prairie

CES203.380 CLASSIFICATION

Concept Summary: This system, which is endemic to subtropical Florida, is characterized by nearly treeless plains with dense cover of grasses and low shrubs, primarily stunted *Serenoa repens* and a wide variety of grasses and forbs. Examples occur on flat, low-lying terrain over moderately to poorly drained soils with sandy surfaces overlying organic hardpans or clayey subsoil. This type was historically expansive in several regions of Florida. Early surveyors noted large expanses of this system on the plains near the Kissimmee River, north from Lake Okeechobee, and in the area west of Lake Okeechobee (Fisheating Creek). The original extent has been heavily reduced by clearing for agriculture and conversion for forage production. Intact examples have been further altered by fire suppression which changes the proportion of grasses and shrubs and may further alter species composition. Frequent fires were an important natural process in this system, with an estimated frequency of 1-4 years.

Related Concepts:

- Cabbage Palmetto: 74 (Eyre 1980) **<**

Distribution: This system occurs in southern Florida mainly north of the Everglades and Big Cypress area. For instance, it is found on the plains near the Myakka River, Kissimmee River, as well as north of Lake Okeechobee and near Fisheating Creek (west of Lake Okeechobee). This type was historically expansive in several regions of Florida (Harper 1927). For more detail, see map of historic extent in the report of the Florida Dry Prairie Conference (Bridges 2006).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, C.W. Nordman and M. Pyne

CES203.380 CONCEPTUAL MODEL

Environment: The climate where this ecological system occurs is subtropical, characterized by hot, wet summers and mild, dry winters. Average annual rainfall is about 127 cm and occurs mostly in June through September. It occurs on flat, moderately to poorly drained sandy soils with sandy surfaces overlying organic hardpans or clayey subsoil (FNAI 1990). These extensive flat prairies are seldom inundated but may flood with several centimeters of water in the wet summer. Frequent spring fires followed by summer flooding may have limited the survival of *Pinus elliottii var. densa* (Platt et al. 2006a). The normal water table is several centimeters (in summer and fall) to several meters (in winter and spring) below the ground surface (Duever and Brinson 1984a, Abrahamson and Hartnett 1990, Hardin 1990). Soils consist of 0.1-0.9 m of undifferentiated quartz sand with a spodic horizon or clayey subsoil 30-107 cm below the surface. These acidic, nutrient-poor sands have few weatherable minerals and low clay nutrients in the surface soil (Abrahamson and Hartnett 1990). Soils supporting these sparse shrublands are classified as Arenic Haplaquods and include such series as Smyrna; types are Myakka (sandy, siliceous, hyperthermic Aeric Alaquod), Wabasso (sandy, siliceous, hyperthermic Alfic Alaquod), Oldsmar (sandy, siliceous, hyperthermic Alfic Arenic Alaquod), Immokalee (sandy, siliceous, hyperthermic Arenic Alaquod), Leon, Adamsville, and Keri sands (Moore and Swindel 1981, Duever and Brinson 1984a).

Key Processes and Interactions: Like the floristically and ecologically related pine flatwoods, the open structure and species composition of dry prairies is maintained by frequent fire. However, the natural fire frequency is thought to be greater than in the surrounding mesic pine flatwoods (Duever et al. 1982, Abrahamson and Hartnett 1990, Hardin 1990). Dry prairie is readily invaded by woody vegetation in the absence of fire, especially in the absence of fires which occur during the dry portions of early spring. In "good condition" this system has abundant herbaceous cover and relatively low cover (<40%) of *Serenoa repens*; degraded conditions are indicated by reduced herbaceous cover and increased cover of *Serenoa repens* (Huffman and Werner 2000). Outright replacement of dry prairies by oak - palmetto stands has been well documented at Myakka River State Park (Huffman and Blanchard 1990). Some sources suggest that examples of this system may be the result of anthropogenic factors that provided an unnaturally high fire frequency or removed vegetation through logging or grazing (Hardin 1990). Bridges (2006) asserts that the system is a natural one and does not result from logging; it may be maintained by grazing, however.

Threats/Stressors: Drainage and conversion of Florida dry prairie to agriculture (including sod farms) and pasture has led to significant decline of this habitat. However, examples of dry prairie can still be found throughout its presettlement range (FNAI 2010a). Lack of fire is a threat to sites that have not been converted. Fires likely occurred every one to two years in this habitat. Frequent fire is essential to restore or manage Florida dry prairie. After long periods of fire exclusion, restoration can be difficult (Huffman and Werner 2000). Anything that reduces the ability to use frequent prescribed burning will limit the ability of land managers to maintain this system. Roller-chopping has the potential to damage other species, and lead to increases in weedy species (FNAI 2010a). But one-time restoration roller-chopping, in coordination with frequent fire has been used to reduce *Serenoa repens* cover and height in areas where it has increased because of changes in fire regime, such as fire exclusion or a long history of low-intensity winter fires (J. Huffman pers. comm., Watts et al. 2006). Invasive exotic plants are a serious threat to this habitat, especially *Imperata cylindrica*.

Ecosystem Collapse Thresholds: Ecosystem collapse may result from drainage, conversion to pasture with exotic pasture grasses, conversion to other land uses, invasion by the exotic grass *Imperata cylindrica*, and fragmentation. The reduction and fragmentation of remaining areas of dry prairie contributes to ecological collapse, since smaller remaining areas of dry prairie are difficult to manage with prescribed fire. This is due to urban interface factors, such as smoke management, increased management costs, and increased risk. Smaller fragmented areas of habitat are also more threatened by invasive exotic plants.

Ecosystem collapse is characterized by lack of native grasses characteristic of the habitat, such as *Aristida beyrichiana, Aristida spiciformis, Dichanthelium dichotomum var. ensifolium (= Dichanthelium ensifolium), Dichanthelium sabulorum var. thinium (= Dichanthelium portoricense), Schizachyrium scoparium*, and *Sorghastrum secundum*, the lack of characteristic low shrubs, such as *Asimina reticulata, Hypericum reductum, Ilex glabra, Lyonia lucida, Morella cerifera (= Morella pumila), Quercus minima*, and *Vaccinium myrsinites* (Orzell and Bridges 2006b, FNAI 2010a). Degraded sites may be dominated by *Serenoa repens* and other native shrubs, with invasive exotic plants, or may be dominated by native trees such as *Quercus virginiana* or *Pinus elliottii var. densa*. The loss of rare species is an indication of habitat decline. Sites in ecosystem collapse generally would not provide good habitat for rare animal species, including Florida grasshopper sparrow (*Ammodramus savannarum floridanus*), Florida burrowing owl (*Athene cunicularia floridana*), crested caracara (*Caracara cheriway*), white-tailed kite (*Elanus leucurus*), and Florida sandhill crane (*Grus canadensis pratensis*). However, of these, only Florida grasshopper sparrow is confined to dry prairie habitat, preferring areas burned less than 24 months previously (FNAI 2010a).

CES203.057 Florida Peninsula Inland Scrub

CES203.057 CLASSIFICATION

Concept Summary: This system appears in many forms, but generally consists of xeromorphic shrub vegetation (mostly evergreen oak species) with or without an emergent overstory of *Pinus clausa*. The shrubs can be very thick in places, but usually there are open patches. Ground cover is always sparse, and bare soil patches are typically evident. It is found on a sequence of sand ridges and ancient dune fields which are oriented essentially north-south in the Florida Peninsula. The appearance, floristics, and boundary of Florida scrub may contrast dramatically with the "high pine" or sandhill vegetation which is often adjacent, although lack of fire can blur these boundaries.

Related Concepts:
- Sand Pine: 69 (Eyre 1980) **><**
- Southern Scrub Oak: 72 (Eyre 1980) **<**

Distribution: This system is endemic to the Florida Peninsula. It is most common in two discrete islands or patches, the Big Scrub of Ocala and the Lake Wales Ridge, which is now highly fragmented and mostly lost to agriculture and development (Weekley et al. 2008).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans and C.W. Nordman

CES203.057 CONCEPTUAL MODEL

Environment: This system is restricted to a sequence of north/south-trending sand ridges, ancient dune fields, and former shorelines in the Florida peninsula. The largest inland scrub is found in two primary areas, essentially isolated from one another. The so called "Big Scrub" of the Ocala National Forest is the largest expanse of this system, with a somewhat smaller, more southerly area associated with the Lake Wales Ridge. According to Myers (1990), inland scrub occurs on Quartzipsamments which are excessively well-drained, nearly pure siliceous sands low in nutrients. Although all scrub soils are Entisols, there is considerable variation in soil color. This color variation appears to be related to the amount of leaching which has taken place, and appears to be related to the amount of time a site has been occupied by scrub vegetation. Excessive leaching, due to inferred long occupation by scrub vegetation, is believed to bleach upper soil horizons and develop pure white soils (such as the St. Lucie series), while moderate leaching, due to shorter occupation by scrub, contributes to less bleaching and consequently more yellow-colored soils (Paola and Orsino series).

Key Processes and Interactions: Florida scrub is a pyrogenic system with floral and faunal components adapted to fire. Unlike most ecological systems of the Gulf and Atlantic coastal plains, this system is maintained by high-intensity, infrequent fires. Litter-fall rates are high, while turnover rates are low, contributing to fuel buildup (Lugo and Zucca 1983, Schmalzer and Hinkle 1996). However, scrub typically lacks fine-textured fuels necessary to ignite fires; most scrub fires ignite in other adjacent ecological systems. If fire spreads into scrub it is often under severe conditions of high wind, low humidity, and low fuel moisture. When fires occur in scrub they can be stand-replacing events. *Pinus clausa*, if present, is killed outright but may regenerate from seed released from serotinous cones. In parts of fires that burn completely, the shrub layer is typically killed back to ground layer but rapidly resprouts and returns to prefire levels of cover (Abrahamson 1984, Schmalzer and Hinkle 1992b). Other species such as *Ceratiola ericoides* may regenerate from seeds stored in soil (Johnson 1982). *Eryngium cuneifolium* and *Dicerandra christmanii* are narrowly endemic herb species which exhibit peaks in survival, recruitment, and density after fire (Menges 1999, Menges et al. 1999, Menges and Quintana-Ascencio 2004). Many scrub fires burn heterogeneously with resulting patches of unburned fuels. This gap dynamics can be significant (Weekley and Menges 2003), especially in the most xeric types like rosemary scrub (Menges 1994). In the sustained absence of fire, smaller shrubs and herbs may be lost as a consequence of increasing dominance of oak stems (Menges et al. 1993).

This system has likely persisted on fossil dunes since the Pleistocene (Laessle 1968), but remaining examples are merely remnants of an ecosystem once expansive in the late Pleistocene (Myers 1990). The stature and appearance of Florida scrub may be due primarily to nutrient-poor soils, to which many of the scrub species have adapted evergreen habits (Monk 1966). Drought stress is most likely during winter and early spring, but frequent fog during these periods may ameliorate such conditions (Menges 1994). Surprisingly, given the excessively well-drained soils, drought stress may not be an important ecological factor except to limit seedling establishment (Myers 1987, 1990).

Threats/Stressors: Lack of fire is a big threat to Florida scrub ecosystems. Threats also include the loss of habitat to agriculture, commercial and residential development, and fragmentation of remaining Florida scrub habitat by roads and development (Weekley et al. 2008). These threats limit prescribed burning due to urban interface, safety and smoke management concerns. Since Florida scrub burns at high intensity, the use of prescribed fire on land which includes urban interface is especially difficult. Invasive exotic plant species are threats, but due to the very dry and low-nutrient coarse sand soils, invasive plant threats are less than in certain other habitats in Florida. Conversion to intensively managed pine plantations, citrus, and pasture has been a threat. By 1990, the scrubs of the Lake Wales Ridge were nearly gone (Myers 1990, Weekley et al. 2008). Scrub has been protected at numerous sites, but management with prescribed fire is difficult, so many are still threatened with lack of fire. The extensive scrub on Ocala National Forest is managed in blocks clearcut for pulpwood, in a manner which attempts to mimic the natural dynamics of a patch mosaic of disturbance (Myers 1990). Mechanical treatments (including logging, mowing and roller-chopping) and herbicides have been used to reduce woody vegetation in scrubs, but these should be used in conjunction with fire if possible. These methods may be useful to prepare sites for prescribed fire, which otherwise would not be possible due to very high fuel buildup (Menges and Gordon 2010).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of habitat, fragmentation of remaining habitat, long-term lack of fire or other canopy opening disturbance, and invasion by exotic plants, which could include *Imperata cylindrica, Melinis repens (= Rhynchelytrum repens), Paspalum notatum, Ricinus communis, Schinus terebinthifolius*, and *Sporobolus indicus* (MacAllister and Harper 1998). Hog-rooting, creation of wildlife food plots or fire plowlines and off-road vehicle use can all contribute to the invasion of scrub by invasive exotic plants (MacAllister and Harper 1998). As scrub areas have been converted to other uses, the remaining habitat patches of scrub have become fragmented, reduced in size and bordered in many cases by urban interface. These remaining scrub habitat patches are more difficult to burn, and are exposed to the invasive exotic plants which can spread into the remaining scrub from nearby converted lands.

Ecosystem collapse of remaining habitat areas is characterized by lack of bare soil patches and scrub with many areas of shrubs greater than 3 m tall (Menges and Gordon 2010). These open patches are good habitat for many of the endemic species of Florida scrub. Very low herbaceous plant densities are also a negative sign of ecosystem health. The presence of many invasive exotic plants is also a characteristic of a collapsed ecosystem. Areas such as this could be restorable, but that may entail a series of management actions such as fuel reduction through mechanical means, and control of invasive plants, followed by prescribed fire.

M309. Southeastern Coastal Plain Patch Prairie

CES203.478 Southern Coastal Plain Blackland Prairie and Woodland

CES203.478 CLASSIFICATION

Concept Summary: This system includes natural grassland vegetation and associated wooded vegetation found primarily in two relatively small natural regions in the southeastern Coastal Plains, primarily in Alabama and Mississippi (with one of these extending barely into southern Tennessee), and a related area of southern Georgia. The larger of these, the so-called Black Belt, is approximately 480 km (300 miles) long and 40-50 km (25-30 miles) wide, and is delineated as the Black Belt Subsection 231Ba and the Blackland Prairie EPA Ecoregion 65a. The smaller and more southerly one of the two is known as the Jackson Prairie region, is found on younger geologic strata and is delineated as the Jackson Hills Subsection (231Bj) and as the Jackson Prairie EPA Ecoregion (65r). The vegetation of this system is comproed of natural grasslands and associated wooded vegetation (woodlands and savannas). The Black Belt region derives its name from the nearly black, rich topsoil that developed over Selma Chalk, and has long been noted as a distinct topographic region in the state of Mississippi. In Alabama, the formations on which this system primarily occurs are Demopolis Chalk and Mooreville Chalk (members of the Selma Group). In Tennessee, only Demopolis Chalk is mapped. Examples occur over relatively deep soils (as opposed to "glades and barrens" on or adjacent to rock outcrops), with circumneutral surface soil pH. Vegetation of this ecological system includes evergreen *Juniperus virginiana*-dominated forests and deciduous *Quercus*-dominated woodlands of varying densities, interspersed with native prairielike grasslands. Much of the natural vegetation of the region has been converted to pasture and agricultural uses, but even old-field vegetation reflects the distinctive composition of the flora and ecological dynamics. In most cases individual prairie openings are small and isolated from one another, but were formerly more extensive prior to European settlement, forming a mosaic of grasslands and woodlands under frequent fire regimes. The flora has much in common with other prairies of the East Gulf Coastal Plains, as well as the classic Midwestern prairies. Within this natural region, there are pockets of acidic soils which produce more typical pine-oak woodland or forest vegetation. The Jackson Prairie component of the system includes natural grassland vegetation and associated wooded vegetation in the Jackson Hills Subsection (231Bj), also called the Jackson Prairie EPA Ecoregion (65r), a relatively small natural region of Mississippi and adjacent Alabama. This system occurs on montmorillonitic Vertisols, which are deep, slowly permeable soils formed in residuum weathered from marl or chalk. Examples occur in a larger matrix of primarily acidic soils and of generally *Pinus taeda*-dominated forest vegetation. In most cases individual prairie openings are small and isolated from one another but were formerly more extensive prior to European settlement, forming a mosaic of grassland and woodland under frequent fire regimes. Much of the natural vegetation of the region has been converted to pasture and agricultural uses, with concomitant destruction of most prairie remnants.

Related Concepts:

- Eastern Redcedar: 46 (Eyre 1980) **<**

- Post Oak - Blackjack Oak: 40 (Eyre 1980) <

Distribution: This system has several distinct components. The Black Belt Prairie component is primarily restricted to the Black Belt (Subsection 231Ba of Keys et al. 1995) or Blackland Prairie area (EPA Ecoregion 65a) and Flatwoods/Blackland Prairie Margins area (EPA Ecoregion 65b) of Griffith et al. (2001). This region is primarily in Alabama and Mississippi, ranging north in a depauperate form to southern Tennessee (McNairy County) (DeSelm 1989b). The Jackson Prairie component of this system is found in a relatively small natural region of Mississippi, known as the Jackson Hills Subsection 231Bj of Keys et al. (1995) and the Jackson Prairie Ecoregion 65r of EPA (EPA 2004). There is also a recently recognized component found in limited parts of Georgia (e.g., on both sides of the Ocmulgee River on the Fort Valley Plateau of Bleckley, Houston, Peach, and Twiggs counties). There are also outlying occurrences southward in the Chunnenuggee Hills and Red Hills (both of these parts of the Southern Hilly Coastal Plain -EPA Ecoregion 65d), and Buhrstone/Lime Hills (EPA Ecoregion 65q) of southern Alabama (in Washington, Wilcox, Monroe, and Clark counties). There are some limited examples in EPA Ecoregion 65i (Fall Line Hills; e.g., Jones Bluff in Alabama).

CES203.478 CONCEPTUAL MODEL

Environment: The Black Belt component of this system generally occurs on Cretaceous age chalk, marl and calcareous clay. This includes calcareous soils of the Sumter, Binnsville, and Demopolis series, described as beds of marly clay over Selma Chalk (including the Demopolis and Mooreville formations). The area has an average annual precipitation of 130-140 cm and a frost-free period of 200-250 days. The soils of the Jackson Prairie openings are presently mapped as the Maytag Series, a fine montmorillonitic, thermic Entic Chromudert. This deep slowly permeable soil has formed in residuum weathered from marl of chalk of the Blackland Prairies (Wieland 1995). Examples occur in a larger matrix of primarily acidic soils and of generally Pinus taeda-dominated forest vegetation (Jones 1971).
Key Processes and Interactions: In the presettlement landscape and throughout the nineteenth century, a combination of fire and grazing (first by native ungulates and then by free-ranging cattle) kept these sites open and grass-dominated (DeSelm and Murdock 1993).

Blackland prairie and woodland occurs on eponymous rich, black, circumneutral topsoils formed over clayey, heavy, usually calcareous subsoils with carbonatic or montmorillonitic mineralogy. The system occurs in association with formations of the Tertiary Jackson (Yazoo Clay), Claiborne (Cook Mountain) and Fleming groups, and the Cretaceous Selma group (Selma, Mooreville or Demopolis chalks). The matrix around the blackland prairies is pine-oak forests growing in acidic, sandier soils with less clay (recent STATSGO soils maps).

Floristic similarity among sites across this geographic range generally appears to be 50% or greater, although a number of different alliances within this type have been recognized according to dominant, codominant, and diagnostic species. Extant prairies occur in single patches as well as mosaics less than one acre to over several hundred acres in response to soil depth, slope and fire. Mosaics may include virtually treeless patches associated with other patches of widely scattered trees, open deciduous woodlands and evergreen thickets (eastern red-cedar "balds"). This vegetation is a mosaic of *Juniperus virginiana* woodland, *Quercus stellata - Quercus marilandica* woodland, and *Schizachyrium scoparium - Sorghastrum nutans* herbaceous alliances. It is a rare and imperiled vegetation type consisting of scattered remnants. Most of the original cover has been destroyed or altered by conversion to agriculture and the exclusion of fire (Landfire 2007a).

For the last 500-1000 years, fires were probably annual in most of the system, many if not most set by Native Americans. Fires were probably used to clear prairies for agricultural planting, to eliminate woody growth, and to aid in hunting. The modern landscape shows a tendency toward erosion, creating shallow-soil areas known as "cedar balds" where soil erosion, presumably from historic agriculture or overgrazing, has reduced topsoil. These areas often show exposures of underlying chalk. Such areas may have resulted (albeit at much lower frequencies) from aboriginal agriculture or overgrazing by native herbivores (Landfire 2007a).
Threats/Stressors: The Black Belt was one of the South's most important agricultural areas before the American Civil War, and has long been noted as a distinct topographic region in the state of Mississippi (Lowe 1921). A long history of cultivation and disturbance has left few large, intact prairies remaining. With range enclosure and fire suppression increasing during the twentieth century, the dynamics of the landscape changed, and the coverage of fire-intolerant woody species increased. The formerly extensive system is now reduced to patches or its flora persists in pastures which are under more continuous grazing pressure than the former processes would have allowed. This has probably led to more uniformity of the vegetation and would favor some taxa over others. More study is needed. Invasive exotic plants include *Ligustrum sinense, Maclura pomifera*, and *Sorghum halepense*; many of these are bird-dispersed and were deliberately or accidentally introduced to the region. The increase in eastern red-cedar (also bird-dispersed) has also been pronounced. Pasture improvement, replacement of native warm-season grasses with exotic forage grasses, is also a threat. Black Belt prairie sites characterized as having good to exceptional integrity are very limited in number. Those that were extant as of 2009 were characterized at that time as being represented by a diverse natural landscape context (i.e., a mosaic of native prairies and forests), diversity of native prairie taxa, and a minimal incursion of exotic and native weedy species (e.g., eastern red-cedar) (Schotz and Barbour 2009). In contrast to native prairies, abandoned pastures may be dominated by Bermuda grass, Johnson grass and eastern red-cedar, but may appear similar in remote sensing to native prairies.

The most critical anthropogenic threat to native grasslands, savannas and barrens is their conversion to human-created land uses, including residential development, quarries, industrial development, infrastructure development, and others (TNC 1996c). Rocky glade areas, if present, may be the last areas to be converted to development and housing due to the unsuitability of the soil to septic tanks. Other common threats and stressors include both the removal of disturbance (e.g., fire, grazing) and the effects of inappropriate or too intensive or constant disturbance. These areas often attract off-road-vehicle use.

Fire plays a critical role in the maintenance of most native grasslands. Without it, *Juniperus* species, *Quercus* species and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). In landscapes where open grassland or savanna vegetation is part of the matrix, and where woody plants have taken over areas once occupied by open grassland and savanna vegetation, the light-dependent species may only persist on the open edges (roadsides, powerlines) of forested patches (Taft 1997). In southeastern grasslands, complete transition to forest dominated vegetation can occur in one or two decades (Wiens and Dyer 1975). More information is needed about the particular appropriate ranges of fire-return times and intensities in the various systems, along with factors other than fire (e.g., soil/substrate, aspect, herbivory, hydroperiod and flooding) that help maintain grasslands and related communities. Occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing. Too intensive or frequent application of these disturbances will have deleterious effects on stand structure and species diversity. In general, mosaics of scrub and grassland, produced by light to moderate grazing (or occasional fire) will support the greatest diversity (Duffey et al. 1974). Cutting or mowing is not as favorable to plant diversity as is grazing because it is nonselective and does not result in the same kind of soil disturbance and compaction as do the hooves of grazing animals (DeSelm and Murdock 1993). Fire is a critical disturbance factor for southeastern native grasslands, but the intensity, duration, and timing of the fires are all important in their effect on the vegetation (DeSelm and Murdock 1993). In addition to occasional fire, periodic drought may also be important in regulating woody plant encroachment in native grasslands. It is believed that native grasslands have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. A small isolated patch has a low probability of receiving a lightning strike frequently enough to maintain a grassland condition. In many cases, grassland systems were once extensive on the landscape, but have now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). In other cases, the grassland or glade system naturally occurs in small isolated patches occurring within an otherwise forested matrix.

Many native grassland sites, particularly the more productive ones, have been converted to plantations of exotic grasses and legumes (DeSelm and Murdock 1993). Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, as well as *Lespedeza cuneata, Miscanthus sinensis, Microstegium vimineum, Alliaria petiolata, Ailanthus altissima*, and *Albizia julibrissin*) will fundamentally alter the character of native grasslands, barrens, savannas, and glades. Some of these exotics are allelopathic, thereby presenting a greater threat to native species (N. Murdock pers. comm.). Opportunistic native increaser plant species (e.g., *Juniperus virginiana*) can also shade out light-requiring herbaceous plants (TNC 1996c).

The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site to other land uses (e.g., residential development, industrial development, infrastructure development, mining or quarrying of underlying bedrock) or conversion to plantations of exotic grasses and legumes. Even if not completely converted, the extirpation of native species and the concomitant spread of invasive exotic plants (particularly *Ligustrum* species and *Lonicera* species shrubs, *Ailanthus altissima, Lespedeza cuneata*, and others) will fundamentally alter the character of native grasslands, barrens, savannas, and glades. Ecological collapse may also result from the removal or lessening of appropriate disturbance (fire, grazing). Without fire, *Juniperus* species, *Quercus* species, *Maclura pomifera* (which is native to North America but not to the Black Belt), and other hardwoods quickly regenerate or invade, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a shift to an alternate stable state and a net loss of species diversity (Taft et al. 1995). Lack of fire contributes to this and past and current human alteration of the landscape contribute to the success of these exotic and ruderal plant species. In many southeastern grasslands and savannas, complete transition to forest dominated vegetation can occur in one or two decades (Wiens and Dyer 1975).

CES203.377 West Gulf Coastal Plain Northern Calcareous Prairie

CES203.377 CLASSIFICATION

Concept Summary: This is one of two described calcareous prairie ecological systems which occur within the pine-dominated portions of the Coastal Plain west of the Mississippi River. This type is the more northerly ranging of the two [compare against ~West Gulf Coastal Plain Southern Calcareous Prairie (CES203.379)$$]. This system includes natural grassland vegetation and associated wooded vegetation in a relatively small natural region of the Upper West Gulf Coastal Plain of Arkansas and adjacent Oklahoma. Although other calcareous prairies are found west of the Mississippi River, this system represents some of the largest known and highest quality remaining examples. Plant communities in this system occur over relatively deep soils (as well as shallow soils over chalk and limestone) with circumneutral surface soil pH, which is unusual given the predominance of acidic, generally forested soils in the region. In most cases individual prairie openings are small and isolated from one another, but were formerly more extensive prior to European settlement, forming a mosaic of grassland and woodlands under frequent fire regimes. The flora has much in common with other prairie systems of the East Gulf Coastal Plains as well as classic Midwestern prairies.

Related Concepts:
- Eastern Redcedar: 46 (Eyre 1980) **<**
- Post Oak - Blackjack Oak: 40 (Eyre 1980) **<**

Distribution: This system is known only from a relatively small natural region of the Upper West Gulf Coastal Plain of Arkansas and adjacent Oklahoma.

Nations: US

Concept Source: T. Foti and R. Evans

Description Author: T. Foti, R. Evans, M. Pyne and J. Teague

CES203.377 CONCEPTUAL MODEL

Environment: This system is characterized by deep to shallow soils with circumneutral surface soil pH that have developed over Cretaceous-aged calcareous substrates. Soils vary from well-drained to poorly drained clays, silty clays, silty clay loams, and fine sandy loams, and are typically excessively dry in summer exhibiting high shrink-swell potential. Within this general landscape, fine-scale abiotic characteristics in conjunction with ecological processes, frequent fire in particular, supported a mosaic of grasslands and short-statured woodlands comprising the ecological system.

Key Processes and Interactions: The composition and structure of this grassland and open woodland ecological system are primarily maintained by edaphic conditions, fire, and climate. Fires less than every four or so years are necessary to maintain the grassland and open woodland states. Under normal weather conditions, eight to ten years without fire will result in a shrub-dominated physiognomy. Continued fire suppression under normal climate conditions will result in a closed-canopy condition. Tight soils provide a barrier to root penetration and limit water availability during dry periods, thereby also inhibiting the establishment and growth of woody plants, but soils alone cannot limit woody growth. Historically, native grazers or browsers also played a role in the maintenance of this system.

Threats/Stressors: To date, habitat conversion to tame pasture has resulted in the biggest loss of this ecosystem. What remains is highly threatened by disruption of fire regimes necessary for maintenance of vegetation composition and structure. Intensive land management in conjunction with friable soils has led to severe erosion in some areas, characterized by gullies which can exceed 10.6 m (35 feet) in depth. If changes in regional climate bring about an increase in precipitation, this could lead to an increase in erosion and woody encroachment. Virtually all remaining natural habitat is experiencing degradation due to the spread of tame pasture grasses (D. Zollner pers. comm. 2013).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss and fragmentation of habitat through direct conversion to agriculture or development, and long-term lack of fire or other disturbances that are necessary to limit woody plant establishment. In addition, current land uses such as heavy grazing and intensive management for pasture/hay have resulted in shifts in vegetation composition to invasive species and off-site natives. Ecosystem collapse of remaining habitat areas is characterized by any of the following: occurrence of the system in small isolated patches, eroded soils, abundance of off-site native woody species such as *Cornus florida, Diospyros virginiana, Frangula caroliniana, Fraxinus americana, Ilex decidua, Juniperus virginiana, Maclura pomifera, Ulmus alata*, and *Viburnum rufidulum*, and invasive non-native species such as *Cynodon dactylon, Lonicera japonica, Medicago lupulina, Melilotus* spp., *Lolium arundinaceum (= Schedonorus arundinaceus)*, and *Trifolium* spp.

CES203.379 West Gulf Coastal Plain Southern Calcareous Prairie

CES203.379 CLASSIFICATION

Concept Summary: This is one of two described calcareous prairie ecological systems which occur within the pine-dominated portions of the West Gulf Coastal Plain west of the Mississippi River. This type is the more southerly-ranging of the two [compare against ~West Gulf Coastal Plain Northern Calcareous Prairie (CES203.377)$$]. Examples include natural grassland vegetation and adjacent wooded vegetation in a relatively small natural region of Arkansas, Louisiana and Texas. Although most examples are typically upland, some include small stream bottoms or riparian areas that bisect the prairies. Plant communities in this system occur over relatively deep soils that are unusual in the local landscape because they are much less acidic than the soils of the surrounding forests. Stands are dominated by perennial grasses and graminoids, including *Carex cherokeensis, Carex microdonta, Muhlenbergia expansa, Schizachyrium scoparium, Schizachyrium tenerum, Sorghastrum nutans*, and *Sporobolus silveanus*. Historically, this system is thought to have occupied large patches (up to a couple thousand acres), but currently, most individual prairie openings are small and isolated from one another.

- Post Oak - Blackjack Oak: 40 (Eyre 1980) **<**
- Swamp Chestnut Oak - Cherrybark Oak: 91 (Eyre 1980) **<**

Distribution: This system is restricted to a relatively small natural region of Arkansas, Louisiana and Texas.
Nations: US
Concept Source: R. Evans and T. Foti
Description Author: R. Evans, T. Foti, M. Pyne, L. Elliott and J. Teague

CES203.379 CONCEPTUAL MODEL

Environment: This system is best documented from the Fleming geologic formation, but is also known from the Cook Mountain Formation in Louisiana. Examples from the Jackson Group (in Louisiana) are also included here, as well as the Morse Clay Calcareous Prairie of northwestern Louisiana and adjacent Arkansas. It occupies deep vertic soils with circumneutral surface pH, a condition uncommon in a region of predominantly acidic, forested soils. It typically occurs on upper slopes and broad uplands in gently undulating landscapes. Soils are circumneutral to moderately alkaline, including vertic soils such as Ferris, Houston Black, or Wiergate clays (Elliott 2011). Occurrences may reflect a relationship to the Blackland Prairie further to the west (including the Fayette Prairie), and some consider these small-patch prairies to be outliers of the Blackland Tallgrass Prairie. In Arkansas, it also occurs on the Gore silt loam and McKamie silt loam, as well as the Morse clay (Foti 1987). Within this general landscape, fine scale abiotic characteristics in conjunction with ecological processes, frequent fire in particular, supported a mosaic of grasslands and short stature woodlands comprising the ecological system. Prior to European settlement this system is believed to have occupied patches up to a couple thousand acres.

Key Processes and Interactions: The composition and structure of this grassland and open woodland ecological system are primarily maintained by edaphic conditions, fire, and climate. Examples historically formed a mosaic of grassland and open woodlands under frequent fire regimes. With fire suppression, trees invade from surrounding pine forests. As a result, some evidence suggests that soil properties are modified, especially the surface pH and nutrient dynamics. Fires every four or so years are necessary to maintain the grassland and open woodland states. Under normal weather conditions, 15 to 20 years without fire will result in a shrub-dominated physiognomy. Continued fire suppression under normal climate conditions will result in a closed-canopy condition. Tight soils provide a barrier to root penetration and limit water availability during dry periods, thereby also inhibiting the establishment and growth of woody plants.

Threats/Stressors: To date, habitat conversion to other land uses may have resulted in the biggest loss of this ecosystem. In Louisiana, only 5-10% of the historic extent is thought to remain today (Smith 1993). What remains is highly threatened by disruption of fire regimes necessary for maintenance of vegetation composition and structure. Vegetation composition and structure are threatened by native and non-native invasive species. Louisiana's Keiffer Prairie (an example of this system) saw a 50% decrease in size of prairie patches from 1935 to 1995. The Tanock Prairie was mapped in early survey records as occupying more than 1000 acres, but today it is a series of 5- to 10-acre remnants (Landfire 2007a). If changes in regional climate bring about an increase in precipitation, this could lead to an increase in woody encroachment.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss and fragmentation of habitat through direct conversion and long-term lack of fire or other disturbances that limit woody plants. In addition, current land uses such as heavy grazing and intensive management for pasture/hay have resulted in shifts in vegetation composition to invasive species and off-site natives. Ecosystem collapse of remaining habitat areas is characterized by any of the following: occurrence of the system in small isolated patches (1-5 acres), eroded soils, abundance of off-site native woody species such as *Cornus florida, Viburnum rufidulum, Diospyros virginiana, Frangula caroliniana, Fraxinus americana, Ilex decidua, Ilex vomitoria, Juniperus virginiana, Maclura pomifera, Morella cerifera, Quercus nigra*, and *Ulmus alata*, and invasive non-native species such as *Cynodon dactylon, Medicago lupulina, Melilotus* spp., *Lolium arundinaceum (= Schedonorus arundinaceus)*, and *Trifolium* spp. Since the time of European settlement, it is estimated that ~West Gulf Coastal Plain Southern Calcareous Prairie (CES203.379)$$ has suffered a loss of 90 to 95%.

M308. Southern Barrens & Glade

CES203.364 West Gulf Coastal Plain Catahoula Barrens

CES203.364 CLASSIFICATION

Concept Summary: This system is confined to the Catahoula geologic formation of eastern Texas and western Louisiana. It includes a vegetational mosaic ranging from herbaceous-dominated areas on shallow soil and exposed sandstone to deeper soils with open woodland vegetation. Woodlands include a post oak-dominated overstory grading into longleaf pine-dominated areas. Seasonal droughtiness, shallow soils, aluminum toxicity, and periodic fires are important factors that influence the composition and structure of this system. Vegetation associated with thin soils over the tuffaceous sandstone of the Catahoula Formation is primarily herbaceous. But where the soil is deeper, or fire is excluded for long periods, it can display significant woody cover, with usually stunted representatives of species such as *Pinus palustris, Pinus taeda, Pinus echinata, Quercus stellata, Quercus marilandica*, and *Carya texana* dominating the canopy. Shrubs may form a patchy, discontinuous layer. Open sites may have significant herbaceous cover, usually dominated by graminoid species.

Related Concepts:

- Catahoula Barrens (Bridges and Orzell 1989a) =
- Eastern Redcedar: 46 (Eyre 1980) <
- Pineywoods: Catahoula Herbaceous Barrens (4307) [CES203.365.7] (Elliott 2011) <
- Pineywoods: Catahoula Woodland or Shrubland Barrens (4308) [CES203.365.5] (Elliott 2011) <
- Post Oak - Blackjack Oak: 40 (Eyre 1980) <

Distribution: This system is endemic to areas where sandstones of the Catahoula Formation occur near and at the surface in western Louisiana and eastern Texas. Sandstone glades are estimated to have historically covered less than 2000 acres in Louisiana and today 50-75% of that historic distribution is thought to remain (Smith 1993).
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, M. Pyne, L. Elliott and J. Teague

CES203.364 CONCEPTUAL MODEL

Environment: The habitat of this system includes shallow soil and exposed sandstone, which tend to an herbaceous-dominated vegetation expression, as well as zones of deeper soils with open woodland vegetation. Examples of this system are restricted to surface outcrops of the Oligocene Catahoula geologic formation, an often tuffaceous sandstone. Sites are generally level to gently undulating (but sometimes steep), with surface or near-surface exposure of the underlying sandstone bedrock. Soils are shallow loams, such as Browndell-Rock outcrop. Soils may contain montmorillonitic clays. These thin soils can be extremely xeric during dry periods, but can also be saturated during wetter months (Elliott 2011).
Key Processes and Interactions: Seasonal droughtiness, shallow soils, aluminum toxicity, and periodic fires are important factors that influence the maintenance of this system as one with primarily herbaceous composition and structure. This ecological system is maintained by a combination of edaphic factors and natural disturbances including severe drought and fire. The outcrops themselves are relatively extreme environments for plant growth due to mild alkalinity, exfoliation of rock surfaces, and surface moisture and temperature fluctuations. Severe droughts kill tree saplings growing in cracks and potholes, helping to retain the open character of the glades (Quarterman et al. 1993). There is an apparent zonation or patchiness to glade/barren vegetation, with different zones that may be identified by their characteristic plant species (Quarterman et al. 1993). These zones are apparently relatively stable, with woody plant encroachment evident only in relation to the invasion of shrubs and trees into potholes or crevices where soil accumulates more rapidly.
Threats/Stressors: The primary threats to this system are conversion and degradation of abiotic and biotic components through fire suppression, tree farming, recreational vehicle use, and livestock. These incompatible land uses result in an increase in woody cover, invasive species (e.g., *Sorghum halepense*), and erosion and loss of soil. Threats include fragmentation and disruption of ecological processes, and the resulting alteration of species composition and structure. The intensity of human activity in the landscape has a proportionate impact on the ecological processes of natural ecosystems. Fire plays a critical role in the maintenance of this woodland-glade system, which may surround or interfinger with rocky glades. In the absence of fire and appropriate disturbance in the landscape matrix, the areas with the shallowest soils (e.g., the glades) may be the only open areas persisting in a series of woody shrub thickets. Without fire or other disturbance, *Juniperus virginiana, Pinus taeda, Quercus* species, and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). The actual rocky or gravelly glades may not support sufficient fuel to consistently carry fire, but in the adjacent or interpenetrating perennial grasslands, occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing (Duffey et al. 1974). In addition to occasional fire, periodic drought is important in regulating woody plant encroachment. Native glade-grassland systems have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of glades and their accompanying native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. This woodland-glade system was once more extensive on the landscape, but has now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.
Ecosystem Collapse Thresholds: Ecological collapse tends to result from either conversion of the site and actual removal or loss of sandstone and/or soils, or the disruption of ecological processes such as natural disturbance regimes (fire) resulting in altered species composition and structure. Without fire or other disturbance, *Juniperus virginiana, Pinus taeda, Quercus* species, and other hardwoods will regenerate or invade into deeper soil areas, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). Characteristics of collapsed examples include degraded habitats dominated by off-site woody native species or invasive exotics with reduced native herbaceous cover and surrounded by an altered landscape.

CES203.371 West Gulf Coastal Plain Nepheline Syenite Glade

CES203.371 CLASSIFICATION

Concept Summary: This glade system is present only in Saline and Pulaski counties, Arkansas, on distinctive, massive outcrops of igneous substrate ("nepheline syenite"). Some typical dominant grasses include *Aristida purpurascens, Piptochaetium avenaceum, Schizachyrium scoparium*, and *Sporobolus clandestinus*. Other herbs may include *Camassia scilloides, Clinopodium arkansanum, Delphinium carolinianum, Sabatia campestris*, and *Phemeranthus calycinus*. Lichens are common on the rocky substrate of some examples. Some examples will have open stands of *Quercus stellata*, but trees may be absent. Zonal vegetation communities are present around the outcrops. Interior herbaceous-dominated zones can be mesic to wet as springs and small ephemeral streams flow across the rock outcrops and water pools in flat areas. Deeper, more heavily wooded vegetation develops along the flat or slightly sloping outcrop edges.

Related Concepts:

Distribution: This system is present only in the Upper West Gulf Coastal Plain of Saline and Pulaski counties, Arkansas. It may have existed historically in Garland and Hot Spring counties (and thereby at least partly in the Ouachita region). Less than 10 occurrences of this ecological system are known to persist.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and J. Teague

CES203.371 CONCEPTUAL MODEL

Environment: This ecological system is found where the igneous rock nepheline syenite occurs at or near the surface in the Upper West Gulf Coastal Plain of Arkansas. This glade system is characterized by patches of bare rock interspersed with areas of shallow soil imbedded within a matrix of deeper soil supporting forested ecosystems. Slope varies from gentle to flat. Gently sloping areas are often extremely xeric whereas flatter areas can accumulate moisture, creating seasonally wet microhabitats. Exposed bedrock may have abundant lichen and moss cover and limited vascular plants. At the edges of the rock outcrops, areas with shallow soils support grasslands with scattered stunted trees. As soils become deeper, grasslands grade into open woodlands (Witsell 2007).

Key Processes and Interactions: This ecological system is maintained by a combination of edaphic factors and natural disturbances, including severe drought and fire (Witsell 2007). The outcrops themselves are relatively extreme environments for plant growth due to mild alkalinity, exfoliation of rock surfaces, and surface moisture and temperature fluctuations. Severe droughts kill tree saplings growing in cracks and potholes, helping to retain the open character of the glades (Quarterman et al. 1993). There is an apparent zonation or patchiness to glade/barren vegetation, with different zones that may be identified by their characteristic plant species (Quarterman et al. 1993). These zones are apparently relatively stable, with woody plant encroachment evident only in relation to the invasion of shrubs and trees into potholes or crevices where soil accumulates more rapidly.

Threats/Stressors: The greatest threat to this ecological system is past and ongoing mining of the underlying bedrock. More than 85% of the system has been destroyed and only 20% of extant occurrences are under conservation ownership. Other threats include fragmentation and disruption of ecological processes, and the resulting alteration of species composition and structure. The intensity of human activity in the landscape has a proportionate impact on the ecological processes of natural ecosystems. Invasive species such as *Juniperus virginiana, Ligustrum sinense, Sorghum halepense, Lespedeza cuneata, Albizia julibrissin*, and *Cynodon dactylon* dominate some areas. Fire plays a critical role in the maintenance of this woodland-glade system, which may surround or interfinger with rocky glades. In the absence of fire and appropriate disturbance in the landscape matrix, the areas with the shallowest soils (e.g., the glades) may be the only open areas persisting in a series of woody shrub thickets. Without fire or other disturbance, *Juniperus* spp., *Quercus* spp., and other hardwoods quickly regenerate, shading out the herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). At sites with intermediate levels of woody encroachment, a signal of restoration potential is an inverse relationship between woody stem density and ground layer species richness (Taft 2009). The actual rocky or gravelly glades may not support sufficient fuel to consistently carry fire, but in the adjacent or interpenetrating perennial grasslands, occasional surface fire will retard woody plant encroachment and help maintain herbaceous diversity, as will, to an extent, grazing or mowing (Duffey et al. 1974). In addition to occasional fire, periodic drought is important in regulating woody plant encroachment. Native glade-grassland systems have evolved under a combined system of grazing, drought, and periodic fire (Duffey et al. 1974, Estes et al. 1979, Noss 2013).

Fragmentation of glades and their accompanying native grasslands, barrens, and savannas occurs with the development of housing and industrial sites, as well as the construction of roads, which not only function as firebreaks, limiting the areas that can be burned with one ignition event, but which make it more difficult to mitigate the effects of smoke on human populations and their activities. This woodland-glade system was once more extensive on the landscape, but has now been reduced to scattered and isolated remnant patches, presenting conservation and management challenges. These disturbances have had damaging effects on fragile soil profiles and plant and animal species. These combined impacts also foster a trend toward biotic homogenization, which results in the gradual replacement of ecologically distinct natural communities by those dominated by weedy generalists (McKinney and Lockwood 1999). The most significant potential climate change effects over the next 50 years include shifts to dramatically drier or moister climate regimes. A cooler and wetter regime would most likely accelerate the trend toward woody plant encroachment, removing drought as a factor in its inhibition. A moderately drier regime during the growing season could favor the characteristic native grasses and forbs, which are adapted to these conditions better than the generalists. An extremely drier regime for an extended period of time could ultimately have negative effects.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from conversion of the site to other land uses (e.g., mining or quarrying of underlying bedrock, industrial development, infrastructure development) and disruption of natural disturbance regimes (fire, grazing) resulting in altered species composition and structure. Without fire, *Juniperus* spp., *Quercus* spp., and other hardwoods will regenerate or invade into deeper soil areas, shading out the characteristic native herbaceous plants, and leading to a shift in species diversity from the ground layer to the upper woody strata, resulting in a net loss of species diversity (Taft et al. 1995). Characteristics of collapsed examples include degraded habitats dominated by off-site woody native species or invasive exotics with reduced native herbaceous cover and surrounded by an altered landscape.

M060. Eastern North American Coastal Beach & Rocky Shore

CES203.266 Florida Panhandle Beach Vegetation

CES203.266 CLASSIFICATION

Concept Summary: The panhandle beach system ranges from northwestern Florida (Ochlockonee River) to southeastern Mississippi. It includes the outermost zone of coastal vegetation extending seaward from foredunes. Within the northern Gulf of Mexico, the natural boundaries of this system are fairly distinct; the western boundary is mineralogical and the eastern is defined by a region of sunken, flooded coast line where beaches are absent. In addition, these beaches are distinguished by high cover of *Uniola paniculata* and *Schizachyrium maritimum*, along with local endemic species of *Chrysoma* and *Paronychia*.

Related Concepts:

Distribution: Ranges from northwestern Florida (Ochlockonee River) to southeastern Mississippi.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans

CES203.266 CONCEPTUAL MODEL

Environment: The beach includes the sand intertidal shore and the low-gradient sand above the daily high tide line, which is between the foredune and the Gulf of Mexico. This area of upper beach is affected by wind and salt spray, seasonal high tides, and storm surge. These beaches are rich in pyroxene, epidote, and garnet (Barbour et al. 1987). Within the northern Gulf of Mexico, the sandy substrate of this system is uniquely rich in medium, nutritionally poor sands. Especially low concentrations of potassium may be of great importance to plant growth and species distributions (Barbour et al. 1987).

Key Processes and Interactions: The natural coastal dynamics include the movement of sand from wind, tides, and storm surge. This includes transport of sand along the coast (primarily from east to west), and movement of sand by wind or water between the dunes, beach and subtidal areas, and the movement of sand from the foredunes to the interior. If not restricted by infrastructure or engineered hard structures, beaches and dunes can migrate as coastlines change over time in response to the action of wind and water. The Gulf of Mexico coast is affected by one tide per day. Wrack and seaweed deposited along the shore is an important source of nutrients for the coastal ecosystem, and helps promote revegetation in newly disturbed areas (Defeo et al. 2009).

Threats/Stressors: Threats include recreation, beach cleaning (removal of wrack), beach renourishment (if not planned and carried out in a way compatible with the beach ecosystem), water pollution, sea-level rise, coastal development, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009). Many coastlines are starved of sand due to dams on rivers which restrict the transport of sand to coastal areas. This is the case for the Apalachicola-Chattahoochee River and the Mobile-Tensaw River systems. Coastal engineering hard structures reflect wave energy, constrain coastal sand migration and often lead to greater loss of beach sand (Defeo et al. 2009). Structures such as jetties around inlets restrict the natural movement of sand from east to west, starving beaches to the west of sand. The developed residential and tourism infrastructure of coastal areas has restricted natural dune and beach migration. Increasing sea-level rise associated with global climate change, will lead to more loss of beach, especially in developed areas where infrastructure such as seawalls, buildings and coastal roads restrict the potential for inland migration of the beach and dunes. Beach renourishment has been carried out on many beaches along the Gulf of Mexico coast. The use of sand for renourishment which does not match the grain size and composition of the beach to be restored can be a threat, especially where sand is applied deeply.

Invasive exotic plants which are threats include *Vitex rotundifolia, Casuarina equisetifolia*, and *Panicum repens* which can alter beach and dune sand vegetation dynamics. Invasive animals include imported red fire ants (*Solenopsis invicta*) and feral hogs (*Sus scrofa*) which prey on the eggs of sea turtles (Defeo et al. 2009). Feral house cats, dogs, and coyotes are a threat to nesting birds and other small animals which occur in coastal habitats. The beaches of the Gulf of Mexico coast provide important nesting habitat for sea turtles and shorebirds; certain restrictions on the timing and location of recreational uses may help accommodate nesting wildlife and promote nesting success.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of sand to erosion, especially in conjunction with engineered hard structures, and developed infrastructure on the shore side of the beach which restricts the inland migration of sand and dunes. There are many other threats which can contribute to ecosystem collapse. Ecosystem collapse is characterized by a large reduction of the width of the beach and the degradation and loss of beach ecosystem as habitat for various species, including shorebirds, sea turtles, and many invertebrates.

CES203.544 Gulf Coast Chenier Plain Beach

CES203.544 CLASSIFICATION

Concept Summary: This ecological system includes sparsely vegetated ocean beaches along the Gulf of Mexico from the mainland shores of the Chenier Plain of Louisiana and Texas north of Boliver peninsula. These beaches are generally eroding and narrow, and constitute the outermost zone of coastal vegetation in this area. Although these habitats are situated just above the mean high tide limit, they are constantly impacted by waves and flooded by storm surges. Dynamic disturbance regimes largely limit the vegetation to pioneering, salt-tolerant, succulent annuals or perennial vines (e.g. *Ipomoea* spp.). These beaches are generally unstable and highly impacted by attempts to limit the natural erosional processes. Sediment is carried by westerly-moving longshore currents from Louisiana to Texas, and these beaches have all been impacted by the reduction of sediment related to the altered deltaic processes of the Mississippi River.

Related Concepts:

- Chenier: Beach (6000) [CES203.544] (Elliott 2011) =

Distribution: This system ranges from the mainland shores of the Chenier Plain of Louisiana and Texas.

Nations: US

Concept Source: J. Teague

Description Author: J. Teague, M. Pyne and L. Elliott

CES203.544 CONCEPTUAL MODEL

Environment: This ecological system includes the typically sparsely vegetated, sandy, back beach area of the mainland as it transitions into more stabilized communities. Examples are found on recent deposits of sand resulting from ongoing coastal sediment transport, as well as clays remaining on the Gulf margin after longshore transport of sand off of the sites. Sites are gently sloping towards the Gulf, with some development of foreshore dunes. This system occurs in the Chenier Plain region of Louisiana and Texas. Beaches along this part of the coast currently tend to be eroding and narrow, though historically these beaches were part of a system of alternating prograding barrier ridges and eroding tidal flats (Owen 2008). Soils are clays and sands. It is found on the narrow margin of mostly unvegetated sands receiving frequent inundation, erosion, or sediment deposition from eolian processes.

The topography is low, and the substrate is dynamic, leading to reduced vegetation development. It is impacted by salt spray, tidal inundation, storm surge, and wind.
Key Processes and Interactions: These beaches are generally eroding and narrow, and they are constantly impacted by waves and may be flooded by storm surges. They are generally unstable and highly impacted by attempts to limit the natural erosional processes. Sediment is carried by westerly-moving longshore currents from Louisiana to Texas, and these beaches have all been impacted by the reduction of sediment related to the altered deltaic processes of the Mississippi River. Historically, the Chenier Plain coast was place where headland ridges were either prograding or eroding based the proximity of sediment deposited by the Mississippi River as it meandered across its delta. Today, since new sediments are limited because of the control of the Mississippi River, existing headlands that comprise this ecological system are eroding (Morton et al. 2004).
Threats/Stressors: Based on the dependence of this system on the natural processes of the Mississippi River, and the current alteration of those processes, this system has been severely degraded, no new beaches are forming and existing beaches are eroding. Other threats include sea-level rise (coastal squeeze), coastal development, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009).
Ecosystem Collapse Thresholds: Ecosystem collapse is resulting from loss of sediment to erosion, and no replenishment of sediment because of the altered processes of the Mississippi River. Collapse also includes a rising sea level further squeezing this system against the mainland. Ecosystem collapse is characterized by a large reduction of the width of the beach and the degradation and loss of beach ecosystem as habitat for various species.

CES201.586 Laurentian-Acadian Lakeshore Beach

CES201.586 CLASSIFICATION

Concept Summary: This system encompasses primarily upland vegetation along lakeshores or rivershores in northern New England, southeastern Canada, and the upper Midwest (not including the Great Lakes). Some areas may be briefly inundated during high water periods. The substrate is sandy to gravelly, sometimes consolidated rock; there may be muddy patches. Ice-scour is not a major influence, although it may be locally important. These shores may be narrow zones of shrubs and/or sparse vegetation on rocks or sandy beaches. Descriptions of these beaches from Maine, New Hampshire, Vermont, and Minnesota suggests a variable structure and composition influenced by exposure, substrate, and how wet the substrate remains. The upper zone often features shrubs; these may include *Myrica gale, Gaylussacia baccata, Salix* spp., and *Aronia melanocarpa*. Creeping shrubs such as *Hudsonia* spp., *Juniperus horizontalis*, and *Prunus susquehanae* may be locally important. The herbaceous flora likewise varies; *Schizachyrium scoparium, Dichanthelium clandestinum, Cyperus* spp., *Dulichium arundinaceum*, and *Spartina pectinata* are representative graminoids; forbs may include *Argentina anserina, Lechea intermedia, Scutellaria lateriflora*, and *Mimulus ringens*, among others.
Related Concepts:
Distribution: This system ranges across northern New England and northern New York west across the upper Great Lakes to northern Minnesota, and adjacent Canada; and occasional southwards.

CES203.469 Louisiana Beach

CES203.469 CLASSIFICATION

Concept Summary: Louisiana beaches are predominantly found on remnant barrier islands associated with historic delta lobes of the Mississippi River. Since normal deltaic processes have been altered, the formation of new barrier islands has been halted and Louisiana barrier islands are undergoing deterioration. Within the northern Gulf region, these barrier islands are distinguished by dominance of *Spartina patens* instead of *Uniola paniculata*. Also characteristic are *Cenchrus spinifex* and *Sporobolus virginicus*.

Related Concepts:

Distribution: This system is found on remnant barrier islands associated with historic delta lobes of the Mississippi River. Very few examples remain intact.

Nations: US

Concept Source: J. Teague

Description Author: J. Teague

CES203.469 CONCEPTUAL MODEL

Environment: This ecological system includes the usually sparsely vegetated, sandy, back beach area in a microtidal environment (< 0.5m) as it transitions into more stabilized dune or barrier flat communities.

Key Processes and Interactions: The primary processes controlling this system are the natural deltaic process of the Mississippi River. The process of sand movement due to the forces of wind and water are part of its the natural dynamics. This includes transport of sand along the coast, and movement of sand by wind or water between the dunes, beach and subtidal areas. If the natural supply of sediment is maintained and not restricted by infrastructure or engineered hard structures, beaches and dunes will migrate and cause coastlines to change over time in response to the action of wind and water. Based on the dependence of this system on the natural processes of the Mississippi River, and the current alteration of those processes, this system has been severely degraded; no new beaches are forming and existing beaches are eroding (Morton et al. 2004). The loss of this system will impact the many wildlife that depend on it - terns, shorebirds, wading birds, brown pelican, and sea turtles.

Threats/Stressors: The primary threat to this system is the control and accompanying loss of natural deltaic processes for the Mississippi River on which this system depends. Since normal deltaic processes have been altered, the formation of new barrier islands has been halted and Louisiana barrier islands are undergoing erosion and deterioration. Other threats include sea-level rise, coastal development, erosion, vehicle-use impacts, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009). This system is experiencing some of the highest rates of erosion present in the Gulf of Mexico (Morton et al. 2004).

Ecosystem Collapse Thresholds: Ecosystem collapse is resulting from loss of sediment to erosion, and no replenishment of sediment because of the altered processes of the Mississippi River. Collapse also includes a rising sea level further reducing this system. Ecosystem collapse is characterized by a large reduction of the width of the beach and the degradation and loss of beach ecosystem as habitat for various species.

CES203.301 Northern Atlantic Coastal Plain Sandy Beach

CES203.301 CLASSIFICATION

Concept Summary: This ecological system includes sparsely vegetated ocean beaches constituting the outermost zone of coastal vegetation ranging from northern North Carolina (north of Bodie Island) northward to the terminus of extensive sandy coastlines and the beginning of rocky coasts. Examples generally extend seaward from foredunes but may include flats behind breached foredunes. Although these habitats are situated just above the mean high tide limit, they are constantly impacted by waves and may be flooded by high spring tides and storm surges. Constant salt spray and rainwater maintain generally moist conditions. Substrates consist of unconsolidated sand and shell sediments that are constantly shifted by winds and floods. Dynamic disturbance regimes largely limit vegetation to pioneering, salt-tolerant, succulent annuals. *Cakile edentula ssp. edentula* and *Salsola kali* are usually most numerous and characteristic. Other scattered associates include *Sesuvium maritimum, Polygonum glaucum, Polygonum ramosissimum var. prolificum, Suaeda linearis* and *Suaeda maritima*, and *Atriplex cristata*.

Related Concepts:

Distribution: This system ranges from northern North Carolina northward to the northern end of extensive sandy coastlines and the beginning of rocky coasts in southern Maine.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans

CES203.301 CONCEPTUAL MODEL

Environment: This system includes sparsely vegetated ocean beaches that constitute the outermost zone of coastal vegetation ranging from northern North Carolina northward to the northern end of extensive sandy coastlines and the beginning of rocky coasts in southern Maine. Examples generally extend seaward from foredunes but may include flats behind breached foredunes. The beach includes the sand intertidal shore and the low-gradient sand above the daily high tide line, which is between the foredune and the Atlantic Ocean. This area of upper beach is affected by wind and salt spray, seasonal high tides, and storm surge.

Key Processes and Interactions: Although these habitats are situated just above the mean high tide limit, they are constantly impacted by waves and may be flooded by high spring tides and storm surges (Fleming et al. 2001). The process of sand movement due to the forces of wind and water are part of the natural dynamics of beach ecosystems. This includes transport of sand along the coast, and movement of sand by wind or water between the dunes, beach and subtidal areas. If not restricted by infrastructure or engineered hard structures, beaches and dunes can migrate as coastlines change over time in response to the action of wind and water. The beaches of the Atlantic coast are affected by two tides per day. Extensive construction of high, artificial dunes along the Atlantic coast has reduced the extent of these habitats by increasing oceanside beach erosion and eliminating the disturbance regime that creates and maintains overwash flats.

Threats/Stressors: Threats include recreation, beach cleaning (removal of wrack), beach renourishment (if not planned and carried out in a way compatible with the beach ecosystem), water pollution, sea-level rise, coastal development, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009). Many coastlines are starved of sand due to dams on rivers which restrict the transport of sand to coastal areas. Coastal engineering hard structures reflect wave energy, constrain coastal sand migration and often lead to greater loss of beach sand (Defeo et al. 2009). Structures such as jetties around inlets restrict the natural movement of sand from north to south, starving beaches to the south of sand. The developed residential and tourism infrastructure of coastal areas has restricted natural dune and beach migration. Increasing sea-level rise associated with global climate change, will lead to more loss of beach, especially in developed areas where infrastructure such as seawalls, buildings and coastal roads restrict the potential for inland migration of the beach and dunes. Beach renourishment has been carried out on many beaches along the Atlantic coast. The use of sand for renourishment which does not match the grain size and composition of the beach to be restored can be a threat, especially where sand is applied deeply.

Invasive exotic plants which are threats include *Celastrus orbiculata, Hedera helix, Lonicera japonica*, and *Vitex rotundifolia* which is a problem in South Carolina and can alter beach and dune sand vegetation dynamics. Invasive animals include imported red fire ants (*Solenopsis invicta*) and feral hogs (*Sus scrofa*) which prey on the eggs of sea turtles (Defeo et al. 2009). Feral house cats, dogs, and coyotes are a threat to nesting birds and other small animals which occur in coastal habitats. The beaches of the Atlantic coast provide important nesting habitat for sea turtles and shorebirds; certain restrictions on the timing and location of recreational uses may help accommodate nesting wildlife and promote nesting success.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of sand to erosion, especially in conjunction with engineered hard structures, and developed infrastructure on the shore side of the beach which restricts the inland migration of sand and dunes. There are many other threats which can contribute to ecosystem collapse. Ecosystem collapse is characterized by a large reduction of the width of the beach and the degradation and loss of beach ecosystem as habitat for various species, including shorebirds, sea turtles, and many invertebrates.

CES203.535 Southern Atlantic Coastal Plain Florida Beach

CES203.535 CLASSIFICATION

Concept Summary: This beach ecological system is found along the Atlantic Coast from the St. Johns River in northeastern Florida south to approximately Cape Canaveral. Unlike ~Southern Atlantic Coastal Plain Sea Island Beach (CES203.383)$$ north of the St. Johns River, this system is subject to higher wave energy and a greater component of sand. The vegetation of this area is distinct from that farther south along the coast of Florida, lacking the tropical element found south of Cape Canaveral.

Related Concepts:

Distribution: This system is found along the Atlantic Coast from the St. Johns River in northeastern Florida south to approximately Cape Canaveral.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, C.W. Nordman and M. Pyne

CES203.535 CONCEPTUAL MODEL

Environment: The beach includes the sand intertidal shore and the low-gradient sand above the daily high tide line, which is between the foredune and the Atlantic Ocean. This area of upper beach is affected by wind and salt spray, seasonal high tides, and storm surge.

Key Processes and Interactions: The process of sand movement due to the forces of wind and water are part of the natural dynamics of beach ecosystems. This includes transport of sand along the coast, and movement of sand by wind or water between the dunes, beach and subtidal areas. If not restricted by infrastructure or engineered hard structures, beaches and dunes can migrate as coastlines change over time in response to the action of wind and water. The beaches of the east coast of Florida are affected by two tides per day.

Threats/Stressors: Threats include recreation, beach cleaning (removal of wrack), beach renourishment (if not planned and carried out in a way compatible with the beach ecosystem), water pollution, sea-level rise, coastal development, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009). Many coastlines are starved of sand due to dams on rivers which restrict the transport of sand to coastal areas, but the St. Johns River is not impounded with dams, as the Savannah River is. Coastal engineering hard structures reflect wave energy, constrain coastal sand migration and often lead to greater loss of beach sand (Defeo et al. 2009). Structures such as jetties around inlets restrict the natural movement of sand from north to south, starving beaches to the south of sand. Two long rock jetties at the mouth of the St. Johns River have restricted the natural movement of sand from north to south, depriving areas south of the St. Johns River of sand. The developed residential and tourism infrastructure of coastal areas has restricted natural dune and beach migration. Increasing sea-level rise associated with global climate change will lead to more loss of beach, especially in developed areas where infrastructure such as seawalls, buildings and coastal roads restrict the potential for inland migration of the beach and dunes. Beach renourishment has been carried out on many beaches along the Florida coast. The use of sand for renourishment which does not match the grain size and composition of the beach to be restored can be a threat, especially where sand is applied deeply.

Invasive exotic plants which are threats include *Casuarina equisetifolia* and *Scaevola sericea var. taccada (= Scaevola taccada)* which can alter beach and dune sand vegetation dynamics (FNAI 2010a). Invasive animals include imported red fire ants (*Solenopsis invicta*) and feral hogs (*Sus scrofa*) which prey on the eggs of sea turtles (Defeo et al. 2009). Feral house cats, dogs, and coyotes are a threat to nesting birds and other small animals which occur in coastal habitats. The beaches of the Atlantic coast provide important nesting habitat for sea turtles and shorebirds; certain restrictions on the timing and location of recreational uses may help accommodate nesting wildlife and promote nesting success.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of sand to erosion, especially in conjunction with engineered hard structures, and developed infrastructure on the shore side of the beach which restricts the inland migration of sand and dunes. There are many other threats which can contribute to ecosystem collapse. Ecosystem collapse is characterized by a large reduction of the width of the beach and the degradation and loss of beach ecosystem as habitat for various species, including shorebirds, sea turtles, and many invertebrates.

CES203.383 Southern Atlantic Coastal Plain Sea Island Beach

CES203.383 CLASSIFICATION

Concept Summary: This ecological system represents beaches and overwash flats in the Sea Island region of South Carolina and Georgia. The entire region is distinctive, and wave energy is generally lower here than any other point along the Atlantic Coast. Huge quantities of fine-textured sediments are deposited by the region's alluvial rivers, many of which drain relatively large interior areas of the Piedmont, where clay is an abundant by-product of weathering and erosion. These beaches are distinguished from others of the Atlantic Coast by the prevalence of fine-textured sediments. The low wave energy and high tidal range create relatively short barrier islands (as opposed to the long narrow islands of North Carolina and the Gulf of Mexico). In addition, the extensive Continental Shelf coupled with low wave energy contributes to a paucity of shell components of the beach substrates.

Related Concepts:

Distribution: This system is found in the Sea Island region of South Carolina and Georgia, extending to the St. Johns River in northern Florida.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans and M. Pyne

CES203.383 CONCEPTUAL MODEL

Environment: Sea island beaches are found on the true barrier islands present in the region. Wave energy is generally lower here than any other point along the Atlantic coast (Tanner 1960). Low wave energy and high tidal range create relatively short barrier islands (as opposed to long narrow islands of North Carolina and the Gulf of Mexico).

Key Processes and Interactions: The process of sand movement due to the forces of wind and water are part of the natural dynamics of beach ecosystems. This includes transport of sand along the coast, and movement of sand by wind or water between the dunes, beach and subtidal areas. If not restricted by infrastructure or engineered hard structures, beaches and dunes can migrate as coastlines change over time in response to the action of wind and water. The beaches of the Atlantic coast are affected by two tides per day.

Threats/Stressors: Threats include recreation, beach cleaning (removal of wrack), beach renourishment (if not planned and carried out in a way compatible with the beach ecosystem), water pollution, sea-level rise, coastal development, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009). Many coastlines are starved of sand due to dams on rivers which restrict the transport of sand to coastal areas. Larger rivers affected by dams include the Santee, Cooper, Savannah and Great Pee Dee. Coastal engineering hard structures reflect wave energy, constrain coastal sand migration and often lead to greater loss of beach sand (Defeo et al. 2009). Structures such as jetties around inlets restrict the natural movement of sand from north to south, starving beaches to the south of sand. The developed residential and tourism infrastructure of coastal areas has restricted natural dune and beach migration. Increasing sea-level rise associated with global climate change, will lead to more loss of beach, especially in developed areas where infrastructure such as seawalls, buildings and coastal roads restrict the potential for inland migration of the beach and dunes. Beach renourishment has been carried out on many beaches along the Carolina and Georgia coast. The use of sand for renourishment which does not match the grain size and composition of the beach to be restored can be a threat, especially where sand is applied deeply.

Invasive exotic plants which are threats include *Vitex rotundifolia* which can alter beach and dune sand vegetation dynamics. Invasive animals include imported red fire ants (*Solenopsis invicta*) and feral hogs (*Sus scrofa*) which prey on the eggs of sea turtles (Defeo et al. 2009). Feral house cats, dogs, and coyotes are a threat to nesting birds and other small animals which occur in coastal habitats. The beaches of the Atlantic coast provide important nesting habitat for sea turtles and shorebirds; certain restrictions on the timing and location of recreational uses may help accommodate nesting wildlife and promote nesting success.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of sand to erosion, especially in conjunction with engineered hard structures, and developed infrastructure on the shore side of the beach which restricts the inland migration of sand and dunes. There are many other threats which can contribute to ecosystem collapse. Ecosystem collapse is characterized by a large reduction of the width of the beach and the degradation and loss of beach ecosystem as habitat for various species, including shorebirds, sea turtles, and many invertebrates.

CES203.463 Texas Coast Beach

CES203.463 CLASSIFICATION

Concept Summary: This ecological system includes sparsely vegetated ocean beaches constituting the outermost zone of coastal vegetation ranging from and including Boliver peninsula south to include Padre Island in Texas. These beaches are typically located on barrier islands and peninsulas, and they are generally well-developed with an established dune system behind them. Examples generally extend seaward from foredunes but may include flats behind breached foredunes. Although these habitats are situated just above the mean high tide limit, they are constantly impacted by wind and salt spray and may be flooded by storm surges. Characteristic dominants are xerophytes and include the perennials *Ipomoea pes-caprae* and *Ipomoea imperati* and the annual *Cakile geniculata*.

Related Concepts:

- Coastal Beach (6100) [CES203.463] (Elliott 2011) =

Distribution: Outermost zone of coastal vegetation ranging from and including Boliver peninsula south to include Padre Island in Texas.

Nations: MX, US

Concept Source: J. Teague

Description Author: J. Teague, M. Pyne and L. Elliott

CES203.463 CONCEPTUAL MODEL

Environment: This ecological system includes the typically sparsely vegetated, back beach area of the mainland and barrier islands composed of sand and shell fragments in a microtidal environment (<0.5m) as it transitions into more stabilized coastal communities. These areas generally lie near mean sea level (~1 m) and are often found between foredunes and tidal waters. Examples are found on retreating, prograding and aggradating sandy barrier segments. In the case of beaches along bay margins, an active dune system is generally lacking and beaches lie between tidal waters and near-shore vegetation. Recently deposited sands are transported by gulf currents and distributed and redistributed by onshore winds. Landforms are very gently sloping and restricted to the margins of the Gulf of Mexico as well as interior bays. Soils are recently deposited sands.

Key Processes and Interactions: This system is dependent on highly dynamic coastal geomorphology. The process of sand movement due to the forces of wind and water are part of the natural dynamics of beach ecosystems. This includes transport of sand along the coast, and movement of sand by wind or water between the dunes, beach and subtidal areas. If not restricted by infrastructure or engineered hard structures, beaches and dunes can migrate as coastlines change over time in response to the action of wind and water. Some beaches in this system are eroding and some are accreting (Morton et al. 2004). Beaches require a supply of sand and in some cases this supply has been altered through control of river outflow into the Gulf of Mexico (e.g., the diversion of the mouth of the Brazos River). Loss of this supply of sand and sediments results in a lack of sand to replenish natural beach erosion and loss of beach systems.

Threats/Stressors: This system is threatened by alteration of sediment input through control of rivers entering the Gulf of Mexico, creating an imbalance between sediment input and natural erosion processes. Erosion in some areas can lead to significant loss of this system (Morton et al. 2004). Other threats include sea-level rise, coastal development, vehicle-use impacts, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009). Increasing sea-level rise associated with global climate change, will lead to more loss of beach, especially in developed areas where infrastructure such as seawalls, buildings and coastal roads restrict the potential for inland migration of the beach and dunes. The use of sand for renourishment which does not match the grain size and composition of the beach to be restored can be a threat, especially where sand is applied deeply. Invasive animals include imported red fire ants (*Solenopsis invicta*) and feral hogs (*Sus scrofa*) which prey on the eggs of sea turtles (Defeo et al. 2009). Feral house cats, dogs, and coyotes are a threat to nesting birds and other small animals which occur in coastal habitats. This system provides important nesting habitat for sea turtles and shorebirds; certain restrictions on the timing and location of recreational uses may help accommodate nesting wildlife and promote nesting success.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of sand to erosion, especially in conjunction with altered river outflow, engineered hard structures, and developed infrastructure on the shore side of the beach which restricts the inland migration of sand and dunes. There are many other threats which can contribute to ecosystem collapse. Ecosystem collapse is characterized by a large reduction of the width of the beach and the degradation and loss of beach ecosystem as habitat for various species, including shorebirds, sea turtles, and many invertebrates.

M057. Eastern North American Coastal Dune & Grassland

CES201.573 Acadian-North Atlantic Rocky Coast

CES201.573 CLASSIFICATION

Concept Summary: This system encompasses non-forested uplands along the immediate Atlantic Coast, from north of Cape Cod to the Canadian Maritimes. It is often a narrow zone between the high tide line and the upland forest; this zone becomes wider with increasing maritime influence. The substrate is rock, sometimes with a shallow soil layer, and tree growth is prevented by extreme exposure to wind, salt spray, and fog. Slope varies from flat rock to cliffs. Cover is patchy shrubs, dwarf-shrubs and sparse vascular vegetation, sometimes with a few stunted trees. Many coastal islands have graminoid-shrub areas that were maintained by sheep grazing and now persist even after grazing has ceased.

Related Concepts:

Distribution: Primary range is Maine eastward into the Canadian Maritimes, with peripheral occurrences southward along the New England rocky coast.

Nations: CA, US

CES203.500 East Gulf Coastal Plain Dune and Coastal Grassland

CES203.500 CLASSIFICATION

Concept Summary: This system includes vegetation of coastal dunes along the northern Gulf of Mexico, including the northwestern panhandle of Florida, southern Alabama, and southeastern Mississippi. The vegetation consists largely of herbaceous and embedded shrublands on barrier islands and other near-coastal areas where salt spray, saltwater overwash, and sand movement are important ecological forces. This vegetation differs from that of other regions of the Gulf, and this region forms a natural unit with similar climate and substrate. There are a number of diagnostic and endemic plant species which characterize this system, including *Ceratiola ericoides, Chrysoma pauciflosculosa, Schizachyrium maritimum, Paronychia erecta*, and *Helianthemum arenicola*.

Related Concepts:

- Southern Scrub Oak: 72 (Eyre 1980) **<**

Distribution: Coastal dunes along the northern Gulf of Mexico, including the northwestern panhandle of Florida, southern Alabama, and southeastern Mississippi.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans and C. Nordman

CES203.500 CONCEPTUAL MODEL

Environment: The vegetation consists largely of herbaceous vegetation and patches of shrublands on barrier islands and other near-coastal areas where salt spray, saltwater overwash, and sand movement are important ecological forces. This vegetation differs from that of other regions of the Gulf, and this region forms a natural unit with similar climate and substrate (Johnson 1997).

Key Processes and Interactions: The natural coastal dynamics include the movement of sand from wind, tides, and storm surge. This includes transport of sand along the coast (primarily from east to west), and movement of sand by wind or water between the dunes, beach and subtidal areas, and the movement of sand from the foredunes to the interior. If not restricted by infrastructure or engineered hard structures, beaches and dunes can migrate as coastlines change over time in response to the action of wind and water. The Gulf of Mexico coast is affected by one tide per day. Coastal grassland develops as a barrier island builds seaward, developing new dune ridges along the shore which protect the inland ridges from sand burial and salt spray, or as a beach recovers after storm overwash and a new foredune ridge builds up along the shore, protecting the overwashed area behind it from sand burial and salt spray (FNAI 2010a). Wrack and seaweed deposited along the shore is an important source of nutrients for the coastal ecosystem, and helps promote revegetation in newly disturbed areas (Defeo et al. 2009). Fire is rare and local to small areas.
Threats/Stressors: Threats include recreation, beach cleaning (removal of wrack), beach renourishment (if not planned and carried out in a way compatible with the beach ecosystem), sea-level rise, coastal development, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009). Many coastlines are starved of sand due to dams on rivers which restrict the transport of sand to coastal areas. This is the case for the Apalachicola-Chattahoochee River system and the Mobile-Tensaw River system. Coastal engineering hard structures reflect wave energy, constrain coastal sand migration and often lead to greater loss of beach and dune sand (Defeo et al. 2009). Structures such as jetties around inlets restrict the natural movement of sand, starving coastal ecosystems of sand. The developed residential and tourism infrastructure of coastal areas has restricted natural dune and beach migration. Increasing sea-level rise associated with global climate change will lead to more loss of beach, especially in developed areas where infrastructure such as seawalls, buildings and coastal roads restrict the potential for inland migration of the beach and dunes. Beach renourishment has been carried out on many beaches along the Florida coast. The use of sand for renourishment which does not match the grain size and composition of the beach to be restored can be a threat, especially where sand is applied deeply. This can be disruptive to the beach and dune ecosystem. Invasive exotic plants can alter beach and dune sand vegetation dynamics (FNAI 2010a). Oils spills associated with coastal and offshore oil drilling are a threat. Invasive animals include imported red fire ants (*Solenopsis invicta*) and feral hogs (*Sus scrofa*) which prey on the eggs of various animals (Defeo et al. 2009). Feral house cats, dogs, and coyotes are a threat to nesting birds and other small animals which occur in coastal habitats.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of sand to erosion, especially in conjunction with engineered hard structures, and developed infrastructure on the shore side of the dune which restricts the inland migration of sand and dunes. Tropical storms are a severe natural disturbance, but engineered hard coastal structures reduce the resilience of coastal ecosystems. There are many other threats which can contribute to ecosystem collapse. Ecosystem collapse is characterized by a large reduction of the width of the dunes and grasslands and the degradation and loss of habitat for various species.

CES201.026 Great Lakes Dune

CES201.026 CLASSIFICATION

Concept Summary: This system occurs along the Great Lakes shores region of the United States and Canada. Component plant communities vary from sparsely vegetated, active dunes to communities dominated by grasses, shrubs, and trees, depending on the degree of sand deposition, sand erosion, and distance from the lake. Many open dunes on Lake Michigan are considered "perched dunes" in that sands were deposited on top of glacial moraine located along the coast. In some instances, dunefields sit several hundred feet above current lake levels. Depositional areas, where Great Lakes beachgrass foredunes are found, are dominated by *Ammophila breviligulata* (or in the eastern part of the range *Ammophila champlainensis*); erosional areas, such as slacks in blowouts and dunefields, by *Calamovilfa longifolia*; and stabilized areas by *Schizachyrium scoparium*. In dunefields and on the most stable dune ridges, especially around northern Lake Michigan and Lake Huron, low evergreen shrubs (*Arctostaphylos uva-ursi, Juniperus communis, Juniperus horizontalis*) occupy dune crests and also the ground layer in the savanna edge of dunes; elsewhere, deciduous shrubs are dominant, including *Prunus pumila, Salix cordata*, and *Salix myricoides (= Salix glaucophylloides)*. Backdunes tend to succeed to forests and savanna indistinguishable from corresponding types found on sandy substrates further inland.

Related Concepts:

- Jack Pine: 1 (Eyre 1980) **<**

Distribution: This system occurs along the Great Lakes shores of the United States and Canada on stabilized foredunes, ranging from Wisconsin to Ontario and New York in the Great Lakes, and in isolated occurrences along the shores of Lake Champlain, Vermont.

CES203.264 Northern Atlantic Coastal Plain Dune and Swale

CES203.264 CLASSIFICATION

Concept Summary: This system consists of vegetation of barrier islands and other coastal areas, ranging from northernmost North Carolina northward to southern Maine (where extensive sandy coastlines are replaced by rocky coasts). A range of plant communities may be present, but natural vegetation is predominately herbaceous, with *Ammophila breviligulata* diagnostic. Shrublands resulting from succession from grasslands may occur in limited areas. Both dune uplands and non-flooded wetland vegetation of interdunal swales are included in this system. In the northern portion of the range, these swales are often characterized by *Vaccinium macrocarpon*, while south of New Jersey, swales are characterized by a variety of graminoids and forbs, usually including *Schoenoplectus pungens, Fimbristylis castanea, Fimbristylis caroliniana, Juncus* spp. and others. Small patches of natural woodland may also be present in limited areas, especially in the northern range of this system. Dominant ecological processes are those associated with the maritime environment, including frequent salt spray, saltwater overwash, and sand movement.

Related Concepts:

- Eastern Redcedar: 46 (Eyre 1980) **<**
- Loblolly Pine: 81 (Eyre 1980) **<**
- Pitch Pine: 45 (Eyre 1980) **<**

Distribution: This system ranges from northernmost North Carolina (EPA ecoregion 63d) and southeastern Virginia to southern Maine. The southern portion is a transition zone from around Kitty Hawk, North Carolina, to the Virginia-North Carolina border. The northern limit is Merrymeeting Bay, Maine.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne, S.C. Gawler and L.A. Sneddon

CES203.264 CONCEPTUAL MODEL

Environment: This system occurs on coastal strands and barrier islands, on sand dunes and sand flats. Strong salt spray is an important influence on vegetation in many parts. Overwash by sea water during storms is important on sand flats not protected by continuous dunes. On dunes, present or recent sand movement is an important factor. The combination of these factors prevents the dominance of woody vegetation. Sites may be either dry or saturated by freshwater from rainfall and the local water table. Areas connected to tidal influence are placed in other systems. Soils are sandy, with little organic matter and little or no horizon development. Soils may be excessively drained on the higher dunes. Soils are low in nutrient-holding capacity, but aerosol input of sea salt provides a continuous source of nutrients.

Key Processes and Interactions: The environment of this system is one of the most dynamic in existence for terrestrial vegetation. Reworking of sand by storms or by slower eolian processes may completely change the local environment in a short time, changing one association to another. Many of these sites are fairly early in the process of primary succession on recent surfaces. Chronic salt spray is an ongoing stress. Overwash and extreme salt spray in storms are frequent disturbances. Vegetation interacts strongly with geologic processes; the presence of grass is an important factor in the development of new dunes. Alteration of dynamic processes, such as artificial enhancement of dunes by planting or sand fencing, can have drastic effects on this system, causing large areas to succeed to woody vegetation. Fire is probably not a major natural factor in this system, but may have been important locally. Most vegetation is too sparse to carry fire well.

Threats/Stressors: Coastal development, disruption of sand deposition/erosion pattern; dune stabilization and repair, draining of overwash water, and driving on dunes. Coastal engineering hard structures reflect wave energy, constrain coastal sand migration and often lead to greater loss of beach and dune sand (Defeo et al. 2009). Invasive species such as *Elaeagnus umbellata, Rosa rugosa, Celastrus orbiculata, Pinus thunbergiana (= Pinus thunbergii)* (NYNHP 2013e).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur when the dynamic nature of coastal processes are interrupted by coastal development, hardened shorelines, and a lack of sufficient buffer to allow for dune migration.

CES203.895 Northern Atlantic Coastal Plain Heathland and Grassland

CES203.895 CLASSIFICATION

Concept Summary: Sandplain grasslands and heathlands of the southern New England / New York coast are areas of graminoid- and shrub-dominated vegetation maintained by periodic fire or other disturbance, as well as exposure to maritime influences. Developing on acidic, nutrient-poor, and very well-drained soils within a few kilometers of the ocean, they may occur as heathlands, grasslands, or support a patchwork of grass and shrub vegetation. Characteristic species include *Gaylussacia baccata, Arctostaphylos uva-ursi, Corema conradii, Amelanchier nantucketensis, Hudsonia ericoides, Hudsonia tomentosa, Vaccinium angustifolium, Deschampsia flexuosa, Schizachyrium scoparium*, and *Carex pensylvanica*. They provide habitat for several rare or uncommon forbs including *Liatris scariosa var. novae-angliae* and *Agalinis acuta*. They are important habitat for several bird and other animal species including the short-eared owl and regal fritillary, and (along with brushy plains and woodlands) provided habitat for the extinct heath hen.

Description Author: S.C. Gawler and L.A. Sneddon

CES203.895 CONCEPTUAL MODEL

Environment: Sandplain grasslands and heathlands of the southern New England / New York coast are areas of graminoid- and shrub-dominated vegetation maintained by extreme conditions and periodic fire or other disturbance. Developing on acidic, nutrient-poor, and very well-drained soils, they may occur as heathlands, grasslands, or support a patchwork of grass and shrub vegetation.

Key Processes and Interactions: The largely exposed locations experience extreme variations in temperature and moisture, and the sandy, nutrient-poor soils contribute to prevention of establishment of woody vegetation. Coastal occurrences maintain their open nature with the stress and killing of woody plant tissue caused by high winds, desiccation, and salt spray. Examples that developed in slight depressions are also maintained by frost that persists longer into the growing season (MNHESP 2010a, 2010b). Prior to European settlement, this system is believed to have occurred as small patches in limited areas near the coast (Motzkin and Foster 2002); there may also have been patches in the vicinity of Native American settlements, based on the prevalence of charcoal in some palynological cores (Dunwiddie 1989). Presettlement grasslands appear to have been more likely on portions of Long Island (Hempstead Plains and Montauk) and Martha's Vineyard than on Nantucket, Block Island, or Cape Cod (Motzkin and Foster 2002). This native vegetation is often confused with similar semi-natural grasslands and heathlands characterized by a mixture of native and exotic species developed as a result of agriculture; some natural occurrences may have resulted as expansions of original native vegetation. They have increased in extent and largely post-date land clearing following European settlement (Foster et al. 2002). In addition, some heathlands may have developed on severely disturbed soils following the abandonment of agriculture and grazing (Motzkin and Foster 2002). Efforts to reverse the conversion of these heathlands and grasslands to tall shrublands or woodlands have generally used a mixture of prescribed fire and mowing, and less commonly grazing.

Threats/Stressors: Hempstead Plains grasslands, once an extensive native grassland, have been reduced by 99% of their original extent. Other maritime grasslands and heathlands have been considerably reduced in extent as well, largely as a result of development and agriculture. Current threats include development, isolation from larger natural systems, loss of connectivity to other natural systems, invasive species encroachment (e.g., *Lespedeza cuneata, Artemisia vulgaris, Anthoxanthum odoratum, Celastrus orbiculata, Lonicera morrowii, Centaurea biebersteinii (= Centaurea maculosa)*), and fire suppression. Major threats to maritime heathlands include development and use of four-wheel drive vehicle and impacts of off-road vehicle use (NYNHP 2013f). Examples of this system in New England were naturally small but are threatened by fragmentation or outright destruction by development, off-road vehicle traffic, and incursion by non-native species. Examples in the maritime zone are also threatened by heightened storm intensity, sea-level rise, and erosion.

Ecosystem Collapse Thresholds: Reduction of extent to small isolated patches embedded in suburban matrix; >10% cover by exotic species, <50% native flora.

CES203.273 Southern Atlantic Coastal Plain Dune and Maritime Grassland

CES203.273 CLASSIFICATION

Concept Summary: This ecological system consists primarily of grasslands and related shrublands of Atlantic Coastal Plain barrier islands and related coastal areas from North Carolina south to northern and central Florida. On the Florida coast from south of Cape Canaveral to the sandy portions of the Florida Keys, this system occurs in a more attenuated fashion. This ecological system includes upland dune grasslands and maritime wet grasslands and shrublands, which are not tidal, but may be flooded for short periods of time from storm surge or heavy rain. The environment of this system is highly dynamic. Reworking of sand by storms or by slower eolian processes may completely change the local environment. Vegetation responds to these natural coastal processes through primary succession. The combined effects of chronic and extreme salt spray and periodic ocean overwash by seawater prevent or dramatically inhibit woody plant growth.

Related Concepts:

- Cabbage Palmetto: 74 (Eyre 1980) **<**
- Live Oak: 89 (Eyre 1980) **<**

Distribution: This system ranges on the Atlantic Coast from northern North Carolina (Omernik ecoregion 63g, Carolinian Barrier Islands and Coastal Marshes) to central Florida. The northern limit is a transition zone from around Kitty Hawk, North Carolina, to the Virginia-North Carolina border.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and C. Nordman

CES203.273 CONCEPTUAL MODEL

Environment: Occurs on barrier islands and similar coastal strands, on sand dunes and sand flats. Strong salt spray is an important influence on vegetation in many parts. Overwash by sea water during storms is important on sand flats not protected by continuous dunes. On dunes, present or recent sand movement is an important factor. The combination of these factors prevents the dominance of woody vegetation. Sites may be either dry or saturated by freshwater from rainfall and local water table. Areas connected to tidal influence and areas with ponded freshwater are placed in other ecological systems. Soils are sandy, with little organic matter and little or no horizon development. Soils may be excessively drained on the higher dunes. Soils are low in nutrient-holding capacity, but aerosol input of sea salt provides a continuous source of nutrients. North of the Sea Islands region of coastal Georgia and South Carolina, barrier islands that face south tend to have better developed dune fields, and often have extensive maritime forest systems, and east-facing barrier islands naturally have less continuous dunes and more overwash flats. On islands that face east, the northern portion tends to experience shoreline and dune erosion and the south end may experience accretion. Many of Georgia's barrier islands (known as Sea Islands) show this pattern.

Key Processes and Interactions: The environment of this system is one of the most dynamic in existence for terrestrial vegetation. Reworking of sand by storms or by slower eolian processes may completely change the local environment in a short time, changing one association to another or changing this system into a different system. Many of these sites are fairly early in the process of primary succession on recent surfaces. Chronic salt spray is an ongoing stress. Overwash and extreme salt spray in storms is a frequent disturbance. Vegetation interacts strongly with geologic processes; the presence of dune grass is an important factor in the development of new dunes. Artificial enhancement of dunes by sand fencing or planting off-site species, including *Ammophila breviligulata*, can alter the dynamic processes of the dunes. Fire is probably not a major natural factor in this system, but may have been important locally. Most vegetation is too sparse to carry fire well.

Threats/Stressors: Threats include recreation (vehicle traffic and excessive foot traffic), beach cleaning (removal of wrack), beach renourishment (if not planned and carried out in a way compatible with the beach ecosystem), sea-level rise, coastal residential and commercial development, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009). Coastal engineering hard structures reflect wave energy, constrain coastal sand migration and often lead to greater loss of beach and dune sand (Defeo et al. 2009). Structures such as jetties around inlets restrict the natural movement of sand, starving coastal ecosystems of sand. The developed residential and tourism infrastructure of coastal areas has restricted natural dune and beach migration. Increasing sea-level rise associated with global climate change will lead to more loss of beach, especially in developed areas where infrastructure such as seawalls, buildings and coastal roads restrict the potential for inland migration of the beach and dunes. Beach renourishment has been carried out on many beaches along the Florida coast. The use of sand for renourishment which does not match the grain size and composition of the beach to be restored can be a threat, especially where sand is applied deeply. This can be disruptive to the beach and dune ecosystem. Invasive exotic plants which are threats include (along the Florida coast) *Casuarina equisetifolia* and further north *Carex*

kobomugi and *Vitex rotundifolia* which can alter beach and dune sand vegetation dynamics (FNAI 2010a). Invasive animals include imported red fire ants (*Solenopsis invicta*) and feral hogs (*Sus scrofa*) which prey on the eggs of various animals (Defeo et al. 2009). Feral house cats, dogs, and coyotes are a threat to nesting birds and other small animals which occur in coastal habitats. Horses and other livestock can destabilize dunes by overgrazing the vegetation and tramping the dunes.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from coastal development and the loss of sand to erosion, especially in conjunction with engineered hard structures, and developed infrastructure on the shore side of the dune which restricts the inland migration of sand and dunes. Tropical storms are a severe natural disturbance, but engineered hard coastal structures reduce the resilience of coastal ecosystems. Collapse can also result from excessive vehicle and even foot traffic, which destroys dune and coastal grassland vegetation and can destabilize the sand. Collapse can also occur through unnatural succession, as shrubby vegetation grows up in sand flats that are cut off from natural overwash by artificial buildup of dunes. There are many other threats which can contribute to ecosystem collapse (Defeo et al. 2009). Ecosystem collapse is characterized by a large reduction of the width of the dunes and grasslands or by the loss of characteristic vegetation and species composition.

CES203.539 Southwest Florida Dune and Coastal Grassland

CES203.539 CLASSIFICATION

Concept Summary: This system occurs along the southwest coast of Florida, one of the four distinctive coastal regions of Florida. It includes herbaceous vegetation on dunes and just inland of the dunes, often on recently deposited sands. These are generally upland plant communities and less commonly non-flooded dune swale wetlands. Although the vegetation is mostly herbaceous, there are typically scattered shrubs of various heights present. The dune vegetation includes *Uniola paniculata, Panicum amarum var. amarulum*, and *Iva imbricata*. *Scaevola plumieri, Chamaesyce mesembrianthemifolia*, and *Coccoloba uvifera* help distinguish this system from similar dune and coastal grasslands found farther north.
Related Concepts:
Distribution: Found along the western coast of Florida south of the Big Bend region to the Florida Keys, one of the four distinctive coastal regions of Florida.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans and C.W. Nordman

CES203.539 CONCEPTUAL MODEL

Environment: The vegetation consists largely of herbaceous vegetation and patches of shrublands on barrier islands and other coastal areas where salt spray, saltwater overwash, and sand movement are important ecological forces. Soils are sandy, with little organic matter and little or no horizon development. Soils may be excessively drained on the higher dunes. Soils are low in nutrient-holding capacity, but aerosol input of sea salt provides a continuous source of nutrients. Winter low temperatures are warmer along the southwest coast of Florida, than along the coast further north. Killing frosts are more unusual further south along the coast of the Florida Peninsula.

Key Processes and Interactions: The natural coastal dynamics include the movement of sand from wind, tides, and storm surge along this low-energy coastline. This includes transport of sand along the coast, and movement of sand by wind or water between the dunes, beach and subtidal areas, and the movement of sand from the foredunes to the interior. If not restricted by infrastructure or engineered hard structures, beaches and dunes can migrate as coastlines change over time in response to the action of wind and water. The Gulf of Mexico coast is affected by one tide per day. Coastal grassland develops as a barrier island builds seaward, developing new dune ridges along the shore which protect the inland ridges from sand burial and salt spray, or as a beach recovers after storm overwash and a new foredune ridge builds up along the shore, protecting the overwashed area behind it from sand burial and salt spray (FNAI 2010a). Wrack and seaweed deposited along the shore is an important source of nutrients for the coastal ecosystem, and helps promote revegetation in newly disturbed areas. Fire is rare and local to small areas.

Threats/Stressors: Threats include recreation, beach cleaning (removal of wrack), beach renourishment (if not planned and carried in a way compatible with the beach ecosystem), sea-level rise, coastal development, and coastal engineering such as beach armoring, seawalls, jetties and other structures which interfere with sand movement and shoreline migration (Defeo et al. 2009). Coastal engineering hard structures reflect wave energy, constrain coastal sand migration and often lead to greater loss of beach and dune sand (Defeo et al. 2009). Structures such as jetties around inlets restrict the natural movement of sand, starving coastal ecosystems of sand. The developed residential and tourism infrastructure of coastal areas has restricted natural dune and beach migration. Increasing sea-level rise associated with global climate change will lead to more loss of beach, especially in developed areas where infrastructure such as seawalls, buildings and coastal roads restrict the potential for inland migration of the beach and dunes. Beach renourishment has been carried out on many beaches along the Florida coast. The use of sand for renourishment which does not match the grain size and composition of the beach to be restored can be a threat, especially where sand is applied deeply. This can be disruptive to the beach and dune ecosystem. Invasive exotic plants which are threats include *Casuarina equisetifolia* and *Scaevola sericea var. taccada (= Scaevola taccada)* which can alter beach and dune sand vegetation dynamics (FNAI 2010a). Invasive animals include imported red fire ants (*Solenopsis invicta*) and feral hogs (*Sus scrofa*) which prey on the eggs of various animals (Defeo et al. 2009). Feral house cats, dogs, and coyotes are a threat to nesting birds and other small animals which occur in coastal habitats.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from loss of sand to erosion, especially in conjunction with engineered hard structures, and developed infrastructure on the shore side of the dune which restricts the inland migration of sand and dunes. Tropical storms are a severe natural disturbance, but engineered hard coastal structures reduce the resilience of coastal ecosystems. There are many other threats which can contribute to ecosystem collapse. Ecosystem collapse is characterized by a large reduction of the width of the dunes and grasslands and the degradation and loss of habitat for various species.

CES203.465 Texas Coast Dune and Coastal Grassland

CES203.465 CLASSIFICATION

Concept Summary: This ecological system consists of wetland and upland herbaceous and shrubland vegetation of barrier islands, near-coastal areas, and the Coastal Sand Plain along the Texas coast in the northern Gulf of Mexico. Plant communities of primary and secondary dunes, interdunal swales, barrier flats, and adjacent mainland are included. Salt spray, saltwater overwash, and sand movement are important ecological forces. Some examples of this system naturally occurred as an open matrix of midgrass species within native mesquite - acacia shrublands dominated by *Prosopis glandulosa, Acacia farnesiana*, and *Acacia rigidula* but have become shrub-dominated due to the lack of fire.

- Coastal and Sandsheet: Dune and Coastal Grassland (6307) [CES203.465.7] (Elliott 2011) **<**

Distribution: This system is found in the northern Gulf of Mexico along the Texas coast.
Nations: US
Concept Source: R. Evans and J. Teague
Description Author: R. Evans, J. Teague, M. Pyne and L. Elliott

CES203.465 CONCEPTUAL MODEL

Environment: This system occupies deep eolian sands and Pleistocene barrier island and beach deposits that sit on top of underlying geologic formations, especially the Beaumont Formation. This includes deep sands well inland on the South Texas Sand Sheet, which represents by far the largest continuous patch of this type. It is found on primary and secondary dunes, as well as relatively level areas such as barrier flats, and on the mainland on deep sands of stranded beach ridges. Significant local topography, in the form of swales and pothole wetlands, may be present. Significant surface drainages are generally scarce. Soils are deep or coastal sands (Elliott 2011).
Key Processes and Interactions: Substrate, hydrology, drought, coastal processes (including tropical storms) and fire play a role in maintaining this ecological system (Lonard et al. 2004, Morton et al. 2004, Britton et al. 2010). Composition and structure vary depending on these processes.
Threats/Stressors: In some areas this system has been virtually eliminated due to conversion to tame pasture, cropland, urban and recreational development, dominance by invasive species, or due to woody plant encroachment because of lack of burning. Threats include habitat conversion, alteration of natural fire regime, sea-level rise, coastal development, habitat degradation from recreational vehicles, and coastal engineering that interferes with sand movement and shoreline migration (Defeo et al. 2009). Increasing sea-level rise associated with global climate change will lead to more loss of coastal grasslands, especially in developed areas where development restricts the potential for inland migration of the grasslands. Invasive plant threats include exotic pasture grasses (such as *Bothriochloa ischaemum var. songarica, Dichanthium annulatum*, and *Urochloa maxima (= Panicum maximum)*), *Triadica sebifera*, and off-site native shrubs such as *Baccharis* spp. Invasive animals such as imported red fire ants (*Solenopsis invicta*) and feral hogs (*Sus scrofa*) prey on the eggs of various animals (Defeo et al. 2009). Feral house cats, dogs, and coyotes are a threat to nesting birds and other small animals which occur in coastal habitats. The recent increase in prevalence of the native grass *Heteropogon contortus* has raised some concern (Bielfelt 2013).
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from habitat conversion and alteration of natural processes, including coastal processes and the natural fire regime. Ecosystem collapse is characterized by a loss and degradation of this system.

2.B.4.Nb. Pacific North American Coastal Scrub & Herb Vegetation

M059. Pacific Coastal Beach & Dune

CES302.003 Baja-Sonoran Coastal Dune

CES302.003 CLASSIFICATION

Concept Summary: This system is scattered along the coast of Baja California and Sonoran coast of the Gulf of California. Coastal dunes include beaches, foredunes, sand spits, and active to stabilizing backdunes and sandsheets derived from quartz or gypsum sands. The mosaic of sparse to dense vegetation in dune systems is driven by sand deposition, erosion, and lateral movement. Coastal dunes often front portions of inlets and tidal marshes. They may also occur as extensive dune fields dominating large coastal bays. Dune vegetation typically includes herbaceous, succulent, and low-shrub species with varying degrees of tolerance for salt spray, wind and sand abrasion, and substrate stability. Dune succession is highly variable, so species composition can vary significantly between occurrences. Common species include *Abronia maritima, Abronia villosa, Astragalus magdalenae, Croton californicus, Dicoria canescens, Euphorbia leucophylla, Helianthus niveus*, and *Jouvea pilosa*.

CES302.003 CONCEPTUAL MODEL

Environment: [from M059] This macrogroup occurs on sandy beaches and dunes, with or without salt spray, typically within 2 km of the coast. Soils are usually sandy and well-drained; some areas may have a cobble layer on top of sand. Forb communities are salt-tolerant and tend to occur just above mean high tide, while the grasslands tend to occur on cobble beaches and on dunes that become higher and further away from the beach. On the California Channel Islands, communities can be further interior where sand has been moved >2 km inland from high winds. Dwarf-shrub communities occur on older dunes, usually behind grassland-dominated dunes.
Key Processes and Interactions: [from M059] Processes that define the macrogroup include sand deposition, salt spray, wind erosion, long-shore transport, dune formation, and water erosion such as overwash from storm surges. Herbaceous species stabilize the sand deposits (dunes, beaches), and the older deposits support dwarf-shrubs mixed with herbaceous species.

The beach and open (shrub-herb) dune vegetation is but one part of the vegetation on dunes, including debris-line communities, herbaceous rhizomatous vegetation on oligotrophic habitats, consolidated dune scrubs, stabilized dune forests, willow shrubs on dune swales and deflation plains, terophytic sand communities and other specialized groups. The zonal and successional relationships among these communities are complicated and non-linear.

CES206.907 Mediterranean California Northern Coastal Dune

CES206.907 CLASSIFICATION

Concept Summary: This coastal system occurs in scattered locations from Point Conception, California, north to Coos Bay, Oregon. Coastal dunes include beaches, foredunes, sand spits, and active to stabilizing backdunes and sandsheets derived from quartz or gypsum sands. The mosaic of sparse to dense vegetation in dune systems is driven by sand deposition, erosion, and lateral movement. Coastal dunes often front portions of inlets and tidal marshes. They may also occur as extensive dune fields dominating large coastal bays. Dune vegetation typically includes herbaceous, succulent, and low-shrub species with varying degrees of tolerance for salt spray, wind and sand abrasion, and substrate stability. Dune succession is highly variable, so species composition can vary significantly between occurrences. Generally, these dune systems can be dominated by *Leymus mollis, Abronia latifolia, Ambrosia chamissonis, Baccharis pilularis, Calystegia soldanella, Artemisia pycnocephala, Ericameria ericoides, Eriogonum latifolium,* *Camissonia cheiranthifolia*, and *Carpobrotus chilensis (= Carpobrotus aequilateralus)*. Disturbance processes include dune blowouts caused by wind and occasional wave overwash during storm tidal surges.

CES206.907 CONCEPTUAL MODEL

Environment: Coastal dunes include beaches, foredunes, sand spits, and active to stabilizing backdunes and sandsheets derived from quartz or gypsum sands. The mosaic of sparse to dense vegetation in dune systems is driven by sand deposition, erosion, and lateral movement. Coastal dunes often front portions of inlets and tidal marshes. They may also occur as extensive dune fields dominating large coastal bays. Climate is both Mediterranean and maritime; temperatures are moderate year-round. Most precipitation occurs in the winter months, followed by summer drought, and mild winter temperatures permit growing season throughout most of the year (Wiedemann 1984, Christy et al. 1998, Pickart and Barbour 2007). Clouds and fog are present throughout much of the year, with fog becoming increasingly common to the south (Wiedemann 1984). The dune localities are generally associated with nearby rivers, estuaries or bays; rivers deposit sediment which is carried by ocean currents and wind and deposited on flat coastline areas with onshore winds (Pickart and Barbour 2007). Dune sands are very poor soils, with no organic matter accumulation (Wiedemann 1984). pH is about neutral and the nutrient status is so low as to be almost unmeasurable. Dune sands have poor moisture-holding capacity. A salinity gradient appears to be important in California dunes, and germination or emergence stages are more vulnerable to soil salinity or washover of saltwater than established plants. Pickart and Barbour (2007) provide a summary of studies of the physiological ecology of dune plants.

Key Processes and Interactions: Disturbance processes include dune blowouts caused by wind and occasional wave overwash during storm tidal surges. Cyclical dune activity is apparently triggered by cyclical changes in sea level associated with tectonic events (Wiedemann 1984, Christy et al. 1998, Pickart and Barbour 2007). Subsidence or uplift of 1.8 to 2.7 m (6-9 feet) associated with earthquakes would initiate new successional pathways after destruction of existing dune formations and vegetation (Thilenius 1995). Generally it appears that major earthquakes occur along this coastal region at 300- to 700-year intervals, and sometimes cause tsunamis (Carver et al. 1998, as cited in Pickart and Barbour 2007).

Wind is the other major disturbance process in this system. It drives seasonal movement of large dunes, in turn causing burial of forest vegetation along the eastern edge of the dune sheet and exhumation of previously buried vegetation in interdunal troughs. Storm winds lead to windthrow of many trees in exposed areas, and windfall is commonly seen in senescing stands of *Pinus contorta var. contorta*. Wind-driven sand and salt stunt and abrade plants, and can kill both buds and leaves of shrubs or conifers. Removal of vegetation exposes the sand to wind erosion, leading to the formation of blowouts or the complete destruction of stabilized dunes. Wind patterns are an important factor; in this system the northerly summer winds are associated with the North Pacific High and bring generally fair weather with occasional high-velocity land-sea breezes in the afternoon (Wiedemann 1984). In the winter, the low pressure systems commonly occurring further north are less important in this system. These wind patterns are modified by sheltering headlands and capes in places.

Fire, insects, and pathogens appear to have relatively minor roles in this system, although some *Pinus contorta var. contorta* stands are even-aged and result from stand-replacing fires; others result from primary succession (Christy et al. 1998). Pickart and Barbour (2007) provide a summary of recent work on plant-animal interactions and the roles of nitrogen-fixing plants in California dune ecosystems; they include topics such as rodent herbivory, the roles of ground-nesting bees in providing soil nutrients and pollination, cryptogamic soil crusts, obligate or facultative relationships between insects and plants, and others.

Threats/Stressors: Conversion of this type has commonly come from residential, industrial, and commercial development, extensive urban expansion along the coastline, stabilization programs (Pickart and Barbour 2007). Following WWII, vacation home development was combined with expansion of existing communities; other forms of coastal development that converted some occurrences include building of roads, highways, jetties, buildings, etc. Although inherently adapted to disturbances, dune systems have undergone, and continue to undergo, rapid and significant human-induced change and degradation. Recreation: off-road vehicles, horseback riding, hiking compact or displace sand, introduce weed seeds and fungal spores, or damage native plants. Intensive activity by recreational off-road vehicles has completely destroyed vegetation in some occurrences (Christy et al. 1998, Pickart and Barbour 2007), and caused severe erosion and disruption of dune processes; recreational hiking has been documented to cause declines in cover of vegetation and loss of the lichens altogether (Brown 1990). Agriculture and grazing of livestock disrupt sand and expose it to wind erosion; and introduce seeds or spores of exotic plants. Stabilization activities and planting to stabilize dunes - the synergy between erosive and stabilizing pressures is poorly understood, and has apparently benefited non-native plant species. Invasive/exotic species: some were planted and have expanded their distribution. *Ammophila arenaria* was introduced as a sand-binder and has spread in distribution, replacing native herbaceous species, especially native *Leymus mollis*, and causing complete stabilization of foredunes, reducing native species composition and abundance (Pickart and Barbour 2007). Another problematic exotic invader is *Carpobrotus edulis* and a hybrid of *Carpobrotus edulis* and *Carpobrotus chilensis*. This species was introduced from South Africa and has spread throughout the California dune systems. It displaces native herbaceous and even shrub species by direct overgrowth or indirectly through competition for resources. The impacts include changes to soil pH, buildup of organic matter, and loss of sand movement. It is also detrimental to burrowing dune insects and probably other invertebrates [see multiple citations in Pickart and Barbour (2007)]. Since the 1980s a suite of exotic annual grasses has begun to invade nearshore dune as well; in some places they are dominant and form large stands.

In northwestern California, regional climate models project mean annual temperature increases of 1.7-1.9°C (3.06-3.42°F) by 2070 (PRBO Conservation Science 2011). Regional climate models project a decrease in mean annual rainfall of 101 to 387 mm by 2070. Currently, there is greater uncertainty about the precipitation projections than for temperature in northwestern California, but with some evidence for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Potential climate change effects could include: increased fire frequency with warmer temperatures, lower precipitation may result in drier, more flammable fuels, which may exacerbate the fire intensity given changes to redwood forest structure, as noted above; less rainfall and higher temperatures may shift species composition to more drought-tolerant species, such as *Lithocarpus densiflorus*, and may also favor non-native species; in many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from (adapted from WNHP 2011) complete stabilization of the dunes in the occurrence because of invasive or planted exotics; native forbs and grasses have been mostly eliminated or are much reduced from expected abundance; the surrounding landscape is primarily in non-natural land uses; recreational vehicles have heavily impacted the occurrence, damaging native plants, deep ruts are found throughout the occurrence; foot traffic from hikers or livestock have eliminated native lichens and disrupted or compacted the sand surface. Coastal development and stabilization efforts have reduced or eliminated transport of sand along the coast. Native invertebrates and burrowing mammals no longer occur, or are much reduced in diversity and abundance.

Environmental Degradation (adapted from WNHP 2011): High-severity environmental degradation appears where much of the occurrence is surrounded by non-natural land uses, it is embedded in a landscape with <20% natural or semi-natural communities; connectivity within the occurrence and with other occurrences is gone; bare soil areas are substantial and contribute to long-lasting impacts, deep ruts from ORVs or machinery may be present, or trails are widespread; occurrence is very small (<0.3 mile/0.5 km long); much reduced from its original natural extent (<50% remains). Coastal development and stabilization efforts have reduced or eliminated transport of sand along the coast. Moderate-severity appears where some of the occurrence is surrounded by non-natural land uses, it is embedded in a landscape with 20-60% natural or semi-natural communities; connectivity within the occurrence and with other occurrences is generally low, but varies with the mobility of the species and arrangement on the landscape; there is moderate disruption of soil processes, shallow ruts from ORVs or machinery may be present, and bare soil areas due to human activity may be present; occurrence is small (0.3-1.25 miles/0.5-2 km long); reduced from its original natural extent (50-80% remains). Coastal development and stabilization efforts have reduced or eliminated transport of sand along the coast.

Disruption of Biotic Processes (adapted from WNHP 2011): High-severity disruption of biotic processes appears where open/migrating or native-anchored stages are absent and exotic-stabilized replacing native-stabilized on over 50% of total area (areas stabilized by raised groundwater may contribute here); *Ammophila* or *Carpobrotus* spp. cover is high, large patches are stabilizing dunes; other invasive exotics are abundant (>10% absolute cover); expected vegetation structure and composition has been highly altered, expected strata are absent or dominated by ruderal ("weedy") species, or comprised of planted stands of non-characteristic species, or unnaturally dominated by a single species; most or all indicator/diagnostic species are absent; native invertebrates no longer occur, or are much reduced in diversity and abundance. Moderate-severity appears where presence of open/migrating or native-anchored stages and exotic-stabilized replacing over 50% of total area OR open/migrating or native-anchored stage present and exotic-stabilized on less than 50% of total area; small patches of *Ammophila* or *Carpobrotus* spp. are stabilizing dunes; other invasive exotics are present (3-10% absolute cover); expected vegetation structure and composition has been somewhat altered, expected strata are reduced in abundance or codominated by ruderal ("weedy") species, many indicator/diagnostic species are absent; native invertebrates are present, but reduced in diversity and abundance.

CES206.908 Mediterranean California Southern Coastal Dune

CES206.908 CLASSIFICATION

Concept Summary: This coastal system occurs in scattered locations from Point Conception, California, south to north-central Baja California. Coastal dunes include beaches, foredunes, sand spits, and active to stabilizing backdunes and sandsheets derived from quartz or gypsum sands. The mosaic of sparse to dense vegetation in dune systems is driven by sand deposition, erosion, and lateral movement. Coastal dunes often front portions of inlets and tidal marshes. They may also occur as extensive dune fields dominating large coastal bays. Dune vegetation typically includes herbaceous, succulent, and low-shrub species with varying degrees of tolerance for salt spray, wind and sand abrasion, and substrate stability. Dune succession is highly variable, so species composition can vary significantly between occurrences. Generally, this dune system includes fewer perennial grasses and more suffrutescent plants than more northern dune systems. This system can be dominated by *Abronia maritima, Abronia umbellata, Atriplex leucophylla, Isocoma menziesii (= Haplopappus venetus), Distichlis spicata, Croton californicus, Lupinus chamissonis*, and *Carpobrotus chilensis (= Carpobrotus aequilateralus)*. Disturbance processes include dune blowouts caused by wind and occasional wave overwash during storm tidal surges.

Another problematic exotic invader is *Carpobrotus edulis* and a hybrid of *Carpobrotus edulis* and *Carpobrotus chilensis*. This species was introduced from South Africa and has spread throughout the California dune systems. It displaces native herbaceous and even shrub species by direct overgrowth or indirectly through competition for resources. The impacts include changes to soil pH, buildup of organic matter, and loss of sand movement. It is also detrimental to burrowing dune insects and probably other invertebrates [see multiple citations in Pickart and Barbour (2007)]. Since the 1980s a suite of exotic annual grasses has begun to invade nearshore dune as well; in some places they are dominant and form large stands.

In the southwest regions of California, regional climate models project mean annual temperature increases of 1.7-2.2°C by 2070. The projected impacts will be warmer temperatures in most months of the year, earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 51-184 mm by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a drier future climate relative to current conditions (PRBO Conservation Science 2011).

In many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain (PRBO Conservation Science 2011). Potential climate change effects could include (PRBO Conservation Science 2011): high temperature events will become more common and species with very narrow temperature tolerance levels may experience thermal stress; change in fire regime is uncertain, as the effects of climate change on the Santa Ana winds does not have any consensus in the models; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006); and increased competition for water from all users, and stresses on the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from (adapted from WNHP 2011) complete stabilization of the dunes in the occurrence because of invasive or planted exotics; native forbs and grasses have been mostly eliminated or are much reduced from expected abundance; the surrounding landscape is primarily in non-natural land uses; recreational vehicles have heavily impacted the occurrence, damaging native plants, deep ruts are found throughout the occurrence; foot traffic from hikers or livestock have eliminated native lichens and disrupted or compacted the sand surface. Coastal development and stabilization efforts have reduced or eliminated transport of sand along the coast. Native invertebrates and burrowing mammals no longer occur, or are much reduced in diversity and abundance.

Environmental Degradation (adapted from WNHP 2011): High-severity environmental degradation appears where much of the occurrence is surrounded by non-natural land uses, it is embedded in a landscape with <20% natural or semi-natural communities; connectivity within the occurrence and with other occurrences is gone; bare soil areas are substantial and contribute to long-lasting impacts, deep ruts from ORVs or machinery may be present, or trails are widespread; occurrence is very small (<0.3 mile/0.5 km long); much reduced from its original natural extent (<50% remains). Coastal development and stabilization efforts have reduced or eliminated transport of sand along the coast. Moderate-severity appears where some of the occurrence is surrounded by non-natural land uses, it is embedded in a landscape with 20-60% natural or semi-natural communities; connectivity within the occurrence and with other occurrences is generally low, but varies with the mobility of the species and arrangement on the landscape; there is moderate disruption of soil processes, shallow ruts from ORVs or machinery may be present, and bare soil areas due to human activity may be present; occurrence is small (0.3-1.25 miles/0.5-2 km long); reduced from its original natural extent (50-80% remains). Coastal development and stabilization efforts have reduced or eliminated transport of sand along the coast.

Disruption of Biotic Processes (adapted from WNHP 2011): High-severity disruption of biotic processes appears where open/migrating or native-anchored stages absent and exotic-stabilized replacing native-stabilized on over 50% of total area (areas stabilized by raised groundwater may contribute here); *Ammophila* or *Carpobrotus* spp. cover is high, large patches are stabilizing dunes; other invasive exotics are abundant (>10% absolute cover); expected vegetation structure and composition has been highly altered, expected strata are absent or dominated by ruderal ("weedy") species, or comprised of planted stands of non-characteristic species, or unnaturally dominated by a single species; most or all indicator/diagnostic species are absent; native invertebrates no longer occur, or are much reduced in diversity and abundance. Moderate-severity appears where Presence of open/migrating or native-anchored stages and exotic-stabilized replacing on over 50% of total area OR open/migrating or native-anchored stage present and exotic-stabilized on less than 50% of total area; small patches of *Ammophila* or *Carpobrotus* spp. are stabilizing dunes; other invasive exotics are present (3-10% absolute cover); expected vegetation structure and composition has been somewhat altered, expected strata are reduced in abundance or codominated by ruderal ("weedy") species, many indicator/diagnostic species are absent; native invertebrates are present, but reduced in diversity and abundance.

CES200.881 North Pacific Maritime Coastal Sand Dune and Strand

CES200.881 CLASSIFICATION

Concept Summary: Coastal sand dunes are found throughout the northern Pacific Coast, from south-central Alaska to the central Oregon coast (roughly Coos Bay). This system covers large areas of the southern Washington and central Oregon coasts, but coastal dunes in Alaska have been placed into a different system. Coastal dunes include beach strand (not the beach itself but sparsely or densely vegetated areas behind the beach), foredunes, sand spits, and active to stabile backdunes and sandsheets derived from quartz or gypsum sands. The mosaic of sparse to dense vegetation in dune systems is driven by sand deposition, erosion, and lateral movement. Disturbance processes include dune blowouts caused by wind and occasional wave overwash during storm tidal surges. Coastal dunes often front portions of inlets and tidal marshes. Dune vegetation typically includes herbaceous, succulent, shrub, and tree species with varying degrees of tolerance for salt spray, wind and sand abrasion, and substrate stability. Dune succession is highly variable, so species composition can vary significantly among occurrences. These dunes can be dominated by *Leymus arenarius (= Elymus arenarius), Festuca rubra, Leymus mollis*, or various forbs adapted to salty dry conditions. *Gaultheria shallon* and

Vaccinium ovatum are major shrub species. Forested portions of dunes are included within this system and are characterized (at least in the south) by *Pinus contorta var. contorta* early in succession, *Picea sitchensis* somewhat later in the sere, and in some cases *Tsuga heterophylla* later still. *Pseudotsuga menziesii* sometimes codominates in Oregon. In many cases, occurrences have thin, fragile layers of lichens and mosses covering the sand in between clumps of grasses or shrubs. Disturbance processes include dune blowouts caused by wind and occasional wave overwash during storm tidal surges. Late-sere forests, dominating stabilized dune systems where active dune processes are nearly absent and that compositionally represent the adjacent matrix system, are excluded from this dune system. Interdunal wetlands occur commonly within the matrix of this system and sometimes are extensive in deflation plains or old dune troughs, but are considered part of various separate wetland ecological systems depending on their hydrology, and are not part of this upland system.

Related Concepts:

- Lodgepole Pine: 218 (Eyre 1980) **><**
- Sitka Spruce: 223 (Eyre 1980) **><**

Distribution: This system is found throughout the northern Pacific Coast, including large inlets such as Puget Sound, from south-central British Columbia to the central Oregon coast (roughly Coos Bay).
