Environment: These dunes are found in about 23 localities along the North American Pacific Northwest Coast, from just north of Coos Bay, Oregon, north into Washington near the Copalis River (Wiedemann 1984). Coastal dunes include beach strand (not the beach itself but sparsely or densely vegetated areas behind the beach), foredunes, sand spits, and active to stabile backdunes and sandsheets derived from quartz or gypsum sands. Climate is both Mediterranean and maritime; temperatures are moderate year-round. Most precipitation occurs in the winter months, followed by summer drought, and mild winter temperatures permit growing season throughout most of the year (Wiedemann 1984, Christy et al. 1998). Clouds and fog are present throughout the year, with fog becoming increasingly common to the south (Wiedemann 1984). The dune localities are generally associated with nearby rivers, estuaries or bays (Wiedemann 1984); rivers deposit sediment which is carried by ocean currents and wind and deposited on flat coastline areas with on-shore winds. Dune sands are very poor soils, with no organic matter accumulation (Wiedemann 1984). pH is about neutral and the nutrient status is so low as to be almost unmeasurable. In this system, the rainfall is so high that, combined with rapid drainage, salinity is not an important factor even in areas just above the beach (Wiedemann 1984). Dune sands have poor moisture-holding capacity; however, these dunes are underlain by groundwater aquifers that maintain a high water table (Christy et al. 1998).

Key Processes and Interactions: The north Pacific coastal dunes are dynamic, transgressive, wind-controlled systems in their natural condition (citations in Zarnetske et al. 2010). These communities are dependent upon longshore drift and wind (WNHP 2011). Most occurrences are spits or berms behind sandy beaches. The mosaic of sparse to dense vegetation in dune systems is driven by sand deposition, erosion, and lateral movement. Disturbance processes include dune blowouts caused by wind and occasional wave overwash during storm tidal surges. Cyclical dune activity is apparently triggered by cyclical changes in sea level associated with glaciation and tectonic events (Wiedemann 1984, Christy et al. 1998). Subsidence or uplift of 1.8 to 2.7 m (6-9 feet) associated with earthquakes would initiate new successional pathways after destruction of existing dune formations and vegetation (Thilenius 1995). Generally it appears that major earthquakes occur along this coastal region at 300- to 700-year intervals (Christy et al. 1998), and sometimes cause tsunamis.

Wind is the major disturbance process in this system. It drives seasonal movement of large dunes, in turn causing burial of forest vegetation along the eastern edge of the dune sheet and exhumation of previously buried vegetation in interdunal troughs. Storm winds lead to windthrow of many trees in exposed areas, and windfall is commonly seen in senescing stands of *Pinus contorta var. contorta*. Wind-driven sand and salt stunt and abrade plants, and can kill both buds and leaves of shrubs or conifers. Removal of vegetation exposes the sand to wind erosion, leading to the formation of blowouts or the complete destruction of stabilized dunes. Wind patterns are an important factor; in this system northerly summer winds are associated with the North Pacific High and bring generally fair weather with occasional high-velocity land-sea breezes in the afternoon (Wiedemann 1984). In the winter low pressure systems dominate the weather patterns, bringing heavy rains and strong southerly winds. These wind patterns are modified by sheltering headlands and capes in places.

Fire, insects, and pathogens appear to have relatively minor roles in this system, although some *Pinus contorta var. contorta* stands are even-aged and result from stand-replacing fires; others result from primary succession (Christy et al. 1998).

Threats/Stressors: Conversion of this type has commonly come from residential and commercial development, stabilization programs (Pickart and Barbour 2007, WNHP 2011), lowering of groundwater table levels (Christy et al. 1998). Following WWII, vacation home development was combined with expansion of existing communities; other forms of coastal development that converted some occurrences include building of roads, highways, jetties, buildings, etc. Common stressors and threats include: Recreation: off-road vehicles, horseback riding, and hiking compact or displace sand, introduce weed seeds and fungal spores, or damage native plants. Recreational off-road vehicles have completely destroyed vegetation in some occurrences (Christy et al.

1998); recreational hiking has been documented to cause declines in cover of vegetation and loss of the reindeer lichens altogether (Brown 1990, as cited in Christy et al. 1998). Agriculture and grazing of livestock disrupt sand and expose it to wind erosion; and introduce seeds or spores of exotic plants. Stabilization activities and planting to stabilize dunes. Invasive/exotic species - some were planted and have expanded their distribution. *Ammophila arenaria* was introduced as a sand-binder, and has spread in distribution, replacing native herbaceous species, especially *Leymus arenarius* and *Leymus mollis*, and causing complete stabilization of foredunes, reducing native species composition and abundance (Pickart and Barbour 2007).

Quoted from WNHP (2011): Unstabilized sand is now a relatively rare condition primarily because of the effects of the introduction of this species. The physical form of dunes has also been altered by *Ammophila arenaria* from more sparsely vegetated, hummocky foredunes to a higher, steeper foredune that decreases sand flow to interior dunes (Weidemann 1984, Pickart 1997). It shortens the stabilization time, and drastically alters natural succession. Forests are probably forming at a greater rate than they did in the past because of increased stabilization. Zarnetske et al. (2010) summarize *Ammophila* impact as having changed Pacific Northwest coastal dunes from open, sparsely vegetated and low-lying, mobile systems to large, continuous, and highly stable foredunes. Exotic species, especially *Anthoxanthum odoratum* and *Holcus lanatus*, are now nearly ubiquitous components of herb-dominated communities (Zarnetske et al. 2010). The spread of such species may be related to past livestock grazing in many areas. *Cytisus scoparius* and *Ulex europaeus* are aggressive exotic shrub invaders that were planted for stabilization and have spread widely. Some logging has occurred, removing older trees (Christy et al. 1998); in some locations stands of tress have been logged 2 or 3 times, resulting in a significant shift in species composition.

Across the range of this ecosystem, there is consistent projected warming and decrease in regional precipitation patterns. In the Pacific Northwest, regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation are small (+1 to 2%), but some models project wetter autumns and winters and drier summers. Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models (Littell et al. 2009). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. Potential climate change effects could include: increased fire frequency due to warmer temperatures resulting in drier fuels the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009); less rainfall and higher temperatures may shift species composition, to more drought tolerant species, and which may favor non-native species; in many coastal regions, the interaction between oceanographic and terrestrial air masses may be ecologically important. Intensifying upwelling along the California coast under climate change may intensify fog development and onshore flows in summer months, leading to decreased temperatures and increased moisture flux over land (Snyder et al. 2003, Lebassi et al. 2009, as cited in PRBO Conservation Science 2011). Coastal terrestrial ecosystems could benefit from these changes. However, current trends in fog frequency along the Pacific coast from 1901-2008 have been negative (Johnstone and Dawson 2010, as cited in PRBO Conservation Science 2011), thus the effect of climate change on coastal fog remains uncertain. Summer time fog and its associated fog-drip and cooling effect may increase with warmer inland air temperatures (PRBO Conservation Science 2011), but this will depend on oceanic circulations and the complex interaction of the El Niño-Southern Oscillation and the Pacific Decadal Oscillation makes prediction of land/ocean interaction difficult and increases the uncertainty of regional climate modeling outcomes (Karl et al. 2009). However, regional climate model simulations generally predict increases in extreme high precipitation over the next half-century, particularly around Puget Sound (Littell et al. 2009).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from (from WNHP 2011) complete stabilization of the dunes in the occurrence because of invasive or planted exotics; native forbs and grasses have been mostly eliminated or are much reduced from expected abundance; the surrounding landscape is primarily in non-natural land uses; recreational vehicles have heavily impacted the occurrence, damaging native plants, deep ruts are found throughout the occurrence; foot traffic from hikers or livestock have eliminated native lichens and disrupted or compacted the sand surface. Coastal development and stabilization efforts have reduced or eliminated transport of sand along the coast.

Environmental Degradation (from WNHP 2011): High-severity environmental degradation appears where much of the occurrence is surrounded by non-natural land uses, it is embedded in a landscape with <20% natural or semi-natural communities; connectivity within the occurrence and with other occurrences is gone; bare soil areas are substantial & contribute to long-lasting impacts, deep ruts from ORVs or machinery may be present, or trails are widespread; occurrence is very small (<0.3 mile/0.5 km long); much reduced from its original natural extent (<50% remains). Coastal development and stabilization efforts have reduced or eliminated transport of sand along the coast. Moderate-severity appears where some of the occurrence is surrounded by non-natural land uses, it is embedded in a landscape with 20-60% natural or semi-natural communities; connectivity within the occurrence and with other occurrences is generally low, but varies with the mobility of the species and arrangement on the landscape; there is moderate disruption of soil processes, shallow ruts from ORVs or machinery may be present, and bare soil areas due to human activity may be present; occurrence is small (0.3-1.25 miles/0.5-2 km long); reduced from its original natural extent (50-80% remains). Coastal development and stabilization efforts have reduced or eliminated transport of sand along the coast.

Disruption of Biotic Processes (from WNHP 2011): High-severity disruption of biotic processes appears where open/migrating or native-anchored stages absent and exotic-stabilized replacing native-stabilized on over 50% of total area (areas stabilized by raised groundwater may contribute here); *Ammophila* cover is high, large patches are stabilizing dunes; other invasive exotics are abundant

(>10% absolute cover); expected vegetation structure and composition has been highly altered, expected strata are absent or dominated by ruderal ("weedy") species, or comprised of planted stands of non-characteristic species, or unnaturally dominated by a single species; most or all indicator/diagnostic species are absent. Moderate-severity appears where presence of open/migrating or native-anchored stages and exotic-stabilized replacing on over 50% of total area OR open/migrating or native-anchored stage present and exotic-stabilized on less than 50% of total area; small patches of *Ammophila* are stabilizing dunes; other invasive exotics are present (3-10% absolute cover); expected vegetation structure and composition has been somewhat altered, expected strata are reduced in abundance or codominated by ruderal ("weedy") species, many indicator/diagnostic species are absent.

M058. Pacific Coastal Cliff & Bluff

CES204.094 North Pacific Coastal Cliff and Bluff

CES204.094 CLASSIFICATION

Concept Summary: This ecological system includes unvegetated or sparsely vegetated rock cliffs and very steep bluffs of glacial deposits along the Pacific Ocean and associated marine and estuarine inlets. It is restricted to degrading slopes from southwestern British Columbia south into central Oregon. It is composed of barren and sparsely vegetated substrates, typically including exposed sediments, bedrock, and scree slopes. Exposure to waves, eroding and desiccating winds, slope failures and sheet erosion create gravelly to rocky substrates that are often unstable. There can be sparse cover of forbs, grasses, lichens and low shrubs.
Related Concepts:
Distribution: This system is found from central Oregon north along the immediate coast into British Columbia.
Nations: CA, US

2.C.2.Na. North American Bog & Fen

M877. North American Boreal & Sub-boreal Alkaline Fen

CES201.585 Laurentian-Acadian Alkaline Fen

CES201.585 CLASSIFICATION

Concept Summary: These fens, distributed across glaciated eastern and central North America, develop in open basins where bedrock or other substrate influence creates circumneutral to calcareous conditions. They are most abundant in areas of limestone bedrock, and widely scattered in areas where calcareous substrates are scarce. Shore fens, which are peatlands that are occasionally flooded along stream and lakeshores, are also included here because flooding tends to create moderately alkaline conditions. The vegetation may be graminoid-dominated, shrub-dominated, or a patchwork of the two; *Dasiphora fruticosa ssp. floribunda* is a common diagnostic shrub. The herbaceous flora is usually species-rich and includes calciphilic graminoids and forbs. *Sphagnum* dominates the substrate in many sites though in Michigan a patchy to continuous carpet of brown mosses is more typical; *Campylium stellatum* is an indicator bryophyte. The edge of the basin may be shallow to deep peat over a sloping substrate, where seepage waters provide nutrients.

Distribution: Scattered locations from New England and adjacent Canada west to the Great Lakes and northern Minnesota.
Nations: CA, US
Concept Source: S.C. Gawler
Description Author: S.C. Gawler and J. Drake

CES201.585 CONCEPTUAL MODEL

Environment: This system usually occurs where there is flat, highly calcareous bedrock near the surface. Water slowly moves along this bedrock and, where it comes to the surface, fens can form in the cold, mineral-rich, anoxic water. Soils are organic and saturated most or all of the growing season. Waterflow through this system is slow but greater than in bogs (Schwintzer and Tomberlin 1982). Some fens in this system occur on the shore of lakes or ponds where wave action is low.

Key Processes and Interactions: The presence of cold, mineral-rich, alkaline groundwater which promotes the formation of peat and marl is key to the formation and maintenance of this system. Where cold, mineral-rich groundwater emerges as diffuse seeps, decomposition of plant matter is slowed and peat can accumulate. Marl forms under sustained flow of calcium- and magnesium-rich water. Peat can form hummocks which have microenvironments that are drier and more acidic than the bulk of the fen. The hummock-and-hollow microtopography, which generates small-scale gradients in soil moisture and chemistry, contributes to fen floristic diversity. The high pH of the bulk of the fens strongly shapes the floristic composition.

Threats/Stressors: Alterations in wetland hydrology and physical destruction of sites are the prime threats to this system. These can occur due to ditching, road construction, or quarrying/mining that affect groundwater or surface waterflows into sites. Both reductions and increases in groundwater or surface water input can negatively affect this system. Partial drainage of a site can lead to increased fertility as peat decomposes; this allows species typical of richer swamps or uplands to colonize. Increased surface waterflow can flood the peatland and transform it to an inundated wetland rather than a saturated peatland and can transport sediment and higher nutrient loads. Logging of adjacent forests can negatively impact this system through increased water runoff and sedimentation. This system is slow to recover from perturbation so disturbance can accumulate over time. Invasive species that can reduce diversity and alter vegetative structure in fen systems include *Frangula alnus (= Rhamnus frangula), Lythrum salicaria, Phragmites australis*, and *Typha angustifolia*.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when hydrologic alterations result in excessive flooding or drying of this system or when physical damage occurs to the system. Severe environmental degradation occurs when the site has significantly increased or decreased water input; or when there is significant physical disturbance. Moderate environmental degradation occurs when the site has moderately increased surface water inputs or decreased groundwater flow; or when there is moderate physical disturbance. Severe disruption of biotic processes occurs when invasive exotic species become abundant (>10% cover) (Faber-Langendoen et al. 2011); or when cover by species typical of richer swamps is >50%. Moderate disruption of biotic processes occurs when invasive exotic species are common (3-10% cover) (Faber-Langendoen et al. 2011); or when cover by species typical of richer swamps is >25%.

CES306.831 Rocky Mountain Subalpine-Montane Fen

CES306.831 CLASSIFICATION

Concept Summary: This system occurs infrequently throughout the Rocky Mountains from Colorado north into Canada. It is confined to specific environments defined by groundwater discharge, soil chemistry, and peat accumulation of at least 40 cm. This system includes extreme rich fens and iron fens, both being quite rare. Fens form at low points in the landscape or near slopes where groundwater intercepts the soil surface. Groundwater inflows maintain a fairly constant water level year-round, with water at

or near the surface most of the time. Constant high water levels lead to accumulation of organic material. In addition to peat accumulation and perennially saturated soils, the extreme rich and iron fens have distinct soil and water chemistry, with high levels of one or more minerals such as calcium, magnesium, or iron. These fens usually occur as a mosaic of several plant associations dominated by *Carex aquatilis, Carex limosa, Carex lasiocarpa, Betula glandulosa, Kobresia myosuroides, Kobresia simpliciuscula*, and *Trichophorum pumilum*. *Sphagnum* spp. (peatmoss) is indicative of iron fens. The surrounding landscape may be ringed with other wetland systems, e.g., riparian shrublands, or a variety of upland systems from grasslands to forests.
Related Concepts:
- Tufted clubrush - Star moss (ESSFdc2/Wf11) (Steen and Coupé 1997) **><**

Distribution: This system occurs infrequently throughout the Rocky Mountains from Colorado north into Canada. In Montana, small fens included here are found in scattered locations in the plains and the small isolated mountain ranges of the central part of the state. Similarly, recent inventory in Wyoming has revealed the occurrence of small fens throughout the mountain ranges of that state.
Nations: CA, US

Description Author: G. Kittel

CES306.831 CONCEPTUAL MODEL

Environment: The montane fen ecological system is a small-patch system composed of mountain wetlands that support a unique ecology of rare plants not found in other types of wetlands. These fens are confined to specific environments defined by groundwater discharge, soil chemistry, and peat accumulation of at least 40 cm. Fens form at low points in the landscape or near slopes where groundwater intercepts the soil surface (CNHP 2010b). Groundwater inflows maintain a fairly constant water level year-round, with water at or near the surface most of the time. Constant high water levels lead to accumulations of organic material (CNHP 2010b).Within the region this system occurs at montane elevations ranging from 2440-3500 m (8000-11,480 feet) and is characterized by mosaics of plant communities. These communities typically occur in seeps and wet sub-irrigated meadows in narrow to broad valley bottoms. Surface topography is typically smooth to concave with slopes ranging from 0-10%. The soils within this system are organic Histosols with 40 cm or more of organic material. These Histosols range in texture from clayey-skeletal to loamy-skeletal and fine-loams. They may occur on a variety of parent materials including alluvial and colluvial deposits of granitic and gneiss origins. The pH of wetlands within this system in generally between 4.8 and 6.0-7.0.
Key Processes and Interactions: Groundwater inflows maintain a fairly constant water level year-round, with water at or near the surface most of the time. Constant high water levels lead to accumulations of organic material. Peatlands in the southern Rocky Mountains are fens that remain saturated primarily as a result of discharging groundwater, seasonal and/or perennial surface water input, or due to their location on the fringes of lakes and ponds (Cooper 1990). Thus, peatlands only occur in confining basins, near persistent groundwater-discharge sites, or near permanent waterbodies such as lakes, ponds, and streams. Due to the limited amount of precipitation and low humidity in the southern Rocky Mountains, true bogs do not occur in the region (Cooper 1990).

Snowmelt maintains high water tables through June in many wetland types (wet meadows, fens, riparian areas, etc.); however, only those areas with soil saturation or a water table within 30 cm of the soil surface through July and August accumulate peat (Cooper 1990, Chimner and Cooper 2003). Thus, a distinguishing characteristic between wet meadows and fens is the depth of the water table in these months. Even in fens, the water table begins to drop in late-July and August. However, late-summer precipitation often replenishes local aquifers thereby raising water tables, suggesting summer precipitation may be important to maintaining high water tables in Southern Rocky Mountain fens (Cooper 1990). In the Northern Rocky Mountains that lack late-summer rains, continuous groundwater discharge is important (Chadde et al. 1998).

Mountain fens function as natural filters cleaning ground and surface water. Fens also act as sponges by absorbing heavy precipitation, slowly releasing it downstream, minimizing erosion and recharging groundwater systems (Windell et al. 1986). The persistent groundwater and cold temperatures allow organic matter to accumulate (forming peat) which allows classification of wetlands within this system as fens. Fens in the Southern Rockies produce peat that accumulates at the rate of 20 to 28 cm (8-11 inches) per 1000 years, making peatlands a repository of 10,000 years of post-glacial history (Windell et al. 1986).
Threats/Stressors: Conversion of this type has commonly come from peat mining, groundwater withdrawal from aquifers discharging into fens; dewatering of supporting groundwater and surface water through upstream diversions usually for mining, road and recreational development can completely pave over occurrences. Water diversions and ditches can have a substantial impact on the hydrology as well as biotic integrity of slope fens (Johnson 1996, Chadde et al. 1998, Cooper et al. 1998, Woods 2001). Ditching and drainage, peat mining, livestock grazing, waterflow regulation and invasion of exotic species are direct impacts that may threaten the integrity of peatland ecosystems (Chadde et al. 1998).

In a study of calcareous fens, draining did not affect species diversity but did have an effect on community composition by favoring species more typical of mesic meadows (Johnson 1996). Once the water table is lowered, peat oxidization and subsequent decomposition occurs quickly thereby reducing peat depth, altering hydrological patterns, and resulting in a change of species composition (Cooper 1990; Chimner and Cooper 2003). As peat decomposes, changes in conductivity and bulk density of the peat results. Since this system is reliant on groundwater any disturbances that impact water quality or quantity are a threat. These threats include groundwater pumping, mining, and improper placement of septic systems, water diversions, dams, roads, etc. (CNHP 2010b).

Peat mining can have a substantial impact on fens. Given the slow accumulation rates of peat, once it is mined (i.e., removed) the fen cannot be restored to historic conditions in a time frame relevant to management activities. The removal of peat alters the subsurface hydrological storage capacity of the fen and tends to channelize surface flow which might result in further degradation of the fen (Johnson 1996). Peat mining has also been shown to significantly decrease species diversity and alter species composition (Johnson 1996).

Livestock management can impact peatlands by compacting peat, destroying hummocks and pugging (creation of pedestals by hooves) on the soil surface (Cooper 1993b). Cooper et al. (2005) also found that moderate to heavy grazing, and more than 20% bare ground can result in a negative carbon budget and therefore a net loss of peat. Cooper et al. (2005) noted that excessive trampling by recreational visitation on a floating mat fen may be resulting in an increase in bulk density from compaction which may reduce the ability of the peat mat to float. Recreational use of the area has also resulted in extensive bare areas due to the sensitivity of the Sphagnum growing on the mat to trampling. These bare areas could indicate a negative carbon budget and therefore loss of peat (Cooper et al. 2005). Jones (2003) found that timber management and roads were correlated to a decrease in species richness of vascular plants, an increase in soil nutrient levels, and possibly altered hydrology of peatlands in Montana. (CNHP 2010b).

The Colorado Plateau and surrounding areas are expected to undergo general warming over the entire region with as much as 2°C increase by 2060 in some locations. Average summer temperatures are expected to increase, but even greater increases are simulated for the winter months. Downscaled climate modeling for the southern Colorado Plateau by Garfin et al. (2010) predicted even greater warming of 4.7°C by the end of the century (Bryce et al. 2012). For the northern and southern Rocky Mountains, the average temperature has already increased roughly 1.5°F compared to the 1960-1979 baseline period. Predictions are for 3.5-5.5°F increase in temperatures by mid-century (Karl et al. 2009). Predictions suggest an increase in probability of droughts, and that droughts will be exacerbated by warmer temperatures. Increased temperatures will drive declines in spring snowpack and Colorado River flow (Karl et al. 2009). For the higher elevations, in areas where it snows, a warmer climate means major changes in the timing of runoff: streamflow increases in winter and early spring, and then decreases in late spring, summer, and fall. This shift in streamflow timing has already been observed over the past 50 years (Peterson et al. 2008), with the peak of spring runoff shifting from a few days earlier in some places to as much as 25 to 30 days earlier in others (Stewart et al. 2004). This trend is projected to continue, with runoff shifting 20 to 40 days earlier within this century. Reductions in summer water availability are expected to see reductions of about 10% in colder regions such as the Rocky Mountains (Karl et al. 2009). Moreover, increased flood risk in the southern Rocky Mountains is likely to result from a combination of decreased snow cover on the lower slopes of high mountains, and an increased fraction of winter precipitation falling as rain and therefore running off more rapidly (Knowles et al. 2006). The increase in rain on snow events will also result in rapid runoff and flooding (Bales et al. 2006).

Potential climate change effects could include: warmer temperatures and earlier snowmelt may result in less groundwater recharge; drop in groundwater table may reduce plant rigor as plants lose connection to groundwater and could cause oxidation of peat; and reduction in spring inflows to fen.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from peat mining that completely obliterates the wetland, any activity that cuts off groundwater discharge that feeds the wetland, either directly on site or more often through upstream or up-valley ditches, diversions, road building and other development that disrupts the flow of groundwater. Other collapse occurs through obliteration by development such as ski-areas, roads, parking lots and other recreational facilities or any development directly on top of fen location.

30 cm. Any of these conditions or combination of conditions rates as moderate-severity: Average water table depth in July and August is between 0 and 30 cm (CNHP 2010b); soil conditions show when there is >20% cover of bare peat exposed whether due to peat mining or grazing, oxidation of peat occurs (Cooper et al. 2005).

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: Forbs dominate. Graminoids, when present, are mostly non-native. Grasses (e.g., *Deschampsia caespitosa*) and rushes (e.g., *Juncus arcticus*) > sedges. <50% cover of native plant species. Floristic Quality Index Mean C <3.0. Any of these conditions or combination of conditions rates as moderate-severity: Cover of native graminoids <50%. Forbs dominate. Abundance of graminoid types: grasses (e.g., *Deschampsia caespitosa*) and rushes (e.g., *Juncus arcticus*) = or > sedges. There is 50-85% cover of native plant species.

M876. North American Boreal & Sub-boreal Bog & Acidic Fen

CES201.580 Acadian Maritime Bog

CES201.580 CLASSIFICATION

Concept Summary: These ombrotrophic acidic peatlands occur along the north Atlantic Coast from downeast Maine east into the Canadian Maritimes. When these form in basins, they develop raised plateaus with undulating sedge and dwarf-shrub vegetation. *Trichophorum cespitosum* may form sedge lawns on the raised plateau. The system may also occur as "blanket bogs" over a sloping rocky substrate in extreme maritime settings; here, dwarf-shrubs and *Sphagnum* are the dominant cover. Species characteristic of this maritime setting include *Empetrum nigrum* and *Rubus chamaemorus*. Typical bog heaths such as *Kalmia angustifolia, Kalmia polifolia, Gaylussacia baccata, Ledum groenlandicum*, and *Gaylussacia dumosa* are also present. Morphological characteristics and certain coastal species distinguish these from more inland raised bogs. The distribution is primarily Canadian, and these peatlands are rare in the U.S.

Related Concepts:

CES201.583 Boreal-Laurentian-Acadian Acidic Basin Fen

CES201.583 CLASSIFICATION

Concept Summary: This peatland system ranges over a broad geographic area across the glaciated Northeast to the Great Lakes and upper Midwest. The fens have developed in open or closed, relatively shallow basins with nutrient-poor and acidic conditions. Many occur in association with larger lakes or streams. Some occur as kettlehole fens (usually called kettlehole "bogs") associated with eskers or other glacial deposits. The substrate is *Sphagnum*, and vegetation typically includes areas of graminoid dominance and dwarf-shrub dominance. *Chamaedaphne calyculata* is usually present and often dominant. Scattered stunted trees may be present. These fens often develop adjacent to open water and may form a floating mat over water.

Particularly distinctive are the ribbed bogs or fens in which a pattern of narrow (2- to 3-m wide), low (less than 1 m deep) ridges are oriented at right angles to the direction of the drainage (National Wetlands Working Group 1988). Wet pools or depressions occur between the ridges. These patterned peatlands may include string bog, Atlantic ribbed fen, or northern ribbed fen (National Wetlands Working Group 1988). They develop almost entirely north of 46°N latitude in east-central Canada and the adjacent U.S. They are minerotrophic peatlands in which the vegetation has developed into a pattern of strings (raised, usually linear features) and flarks (wet depressions separating the strings). The substrate chemistry is entirely acidic in some peatlands; in others, where bedrock or other substrate influence creates circumneutral to calcareous conditions, peatland chemistry may be entirely calcareous or vary from acidic to calcareous within the same peatland. In acidic portions, typical bog heaths predominate mixed with sedges. *Dasiphora fruticosa ssp. floribunda* is diagnostic of circumneutral to calcareous conditions. These peatlands usually develop in open basins and flat plains, and the patterned portion may occupy only a fraction of the entire peatland. The edge of the basin may be shallow to deep peat over a sloping substrate, where seepage waters provide nutrients.

CES202.606 North-Central Interior and Appalachian Acidic Peatland

CES202.606 CLASSIFICATION

Concept Summary: These *Sphagnum* and shrub peatlands occur in basins south of the Laurentian-Acadian region down to near the glacial boundary in the northeastern and north-central U.S. Unlike the true raised bogs of boreal regions, the vegetation is not raised above the groundwater level. They are found in colder regions, mostly in areas where glacial stagnation left coarse deposits and glacial depressions (many are "kettleholes"). The basins are generally closed, i.e., without inlets or outlets of surface water, and typically small in area. The nutrient-poor substrate and the reduced throughflow of water create oligotrophic conditions fostering the development of *Sphagnum* peat and the growth of peatland vegetation. In deeper basins, the vascular vegetation grows on a *Sphagnum* mat over water, with no mineral soil development. Ericaceous shrubs and dwarf-shrubs (e.g., *Chamaedaphne calyculata*) dominate, with patches of graminoid dominance. Some peatlands may have a sparse tree layer. Although these are often called bogs, in most cases they are technically fens (albeit nutrient-poor ones), as the vegetation remains in contact with the surface water.

Related Concepts:

- Black Spruce - Tamarack: 13 (Eyre 1980) <
- Red Maple: 108 (Eyre 1980) <

Distribution: This system is found from central New England to the Great Lakes and south-central Minnesota southward, generally associated with the glacial terminus or stagnation zones, and interior from the Coastal Plain.
Nations: CA, US
Concept Source: S.C. Gawler
Description Author: S.C. Gawler, J. Drake and M. Pyne

CES202.606 CONCEPTUAL MODEL

Environment: These peatlands occur in kettle depressions on pitted outwash and moraines and in flat areas and shallow depressions on glacial outwash and glacial lakeplain. Groundwater and surface water feed these temperate peatlands. It is not strongly calcareous and may be acidic in some places but not as much as boreal sites. These peatlands occurred in landscapes dominated by either forest or grassland/savanna. The fire regime is not well known but periodic surface fires likely helped limit the cover by trees. The basins in which these occur tend to be small and, where open water is still present, these peatlands form where wave energy is low (Swinehart 1997). These peatlands are characterized by organic soils composed of saturated peat that contains partially decomposed sphagnum mosses and frequently fragments of sedges and wood. The peat soils are acidic, cool, and characterized by low nutrient availability and oxygen levels. The water-retaining capacity of sphagnum peat is tremendous and as a result these are saturated, anoxic systems with water tables near the surface (Kost et al. 2007).
Key Processes and Interactions: The cool, nutrient-poor water which feeds into this system favors peat development. This water can come from surface runoff or groundwater. Basins in which these peatlands occur are small, which limits the amount of nutrients that can be brought in by surface water. Groundwater sources flow through nutrient-poor, neutral to somewhat acidic substrates. Once peat begins to develop, it tends to create conditions favorable for continued peat development by contributing to the acidic, anoxic character of the water.
Threats/Stressors: Alterations in wetland hydrology and agricultural development can threaten examples of this system. These can occur due to ditching, road construction, quarrying/mining, or development of crop fields or pastures that affect groundwater or surface waterflows into sites. Both reductions and increases in groundwater or surface water input can negatively affect this system. Partial drainage of a site can lead to increased fertility as peat decomposes; this allows species typical of richer swamps or uplands to colonize (Swinehart and Starks 1994). Increased surface waterflow can flood the peatland and transform it to an inundated wetland rather than a saturated peatland and can transport sediment and higher nutrient loads. Periodic fires infrequently help keep woody plants in check, and a reduction in this frequency will result in increased growth by these species. However, fires that occur when the peat has dried out (due to prolonged drought or a reduction in water input) can burn the peat and create mineral soil wetlands. Invasive species tend to increase after perturbations to other processes that maintain peatlands but can invade without changes, as well. Particularly aggressive invasive species that may threaten the diversity and vegetative structure of this peatland system include *Frangula alnus (= Rhamnus frangula), Phalaris arundinacea, Phragmites australis, Typha angustifolia*, and *Typha x glauca*. Disturbance near this system, whether crop fields, road building, urban development, or other activities, can serve as seed sources for invasive species.
Ecosystem Collapse Thresholds: Ecological collapse tends to occur when hydrologic alterations result in excessive flooding or drying of this system, when exotic species or species typically of richer forested or shrub swamps become abundant, or when agricultural or urban development physically degrades the sites. Severe environmental degradation occurs when the site has significantly increased or decreased water input; when trees or tall shrubs typical of richer swamps become abundant; or when there is significant physical or chemical disturbance to the site (increased sedimentation, pesticides, herbicides, etc.). Moderate environmental degradation occurs when the site has moderately increased surface water inputs or decreased groundwater flow; or when there is moderate physical or chemical disturbance to the site (increased sedimentation, pesticides, herbicides, etc.). Severe disruption of biotic processes occurs when invasive exotic species become abundant (>10% cover) (Faber-Langendoen et al. 2011); or when cover by species typical of richer swamps is >50%. Moderate disruption of biotic processes occurs when invasive exotic species are common (3-10% cover) (Faber-Langendoen et al. 2011); or when cover by species typical of richer swamps is >25%.

M063. North Pacific Bog & Fen

CES206.953 Mediterranean California Serpentine Fen

CES206.953 CLASSIFICATION

Concept Summary: This ecological system is found uncommonly throughout coastal lowlands and high mountains of the Klamath Mountains and surrounding landscapes where serpentine soils are common in cool and moist environments. This system includes unique assemblages of wetlands species restricted to serpentine and ultramafic substrates. These sites remain moist or wet throughout the year and may have substantial *Sphagnum* accumulation. Some may be bogs in the sense of nutrients and moisture primarily coming from rainfall, or more commonly they are seeps or fens maintained by groundwater discharge. Soils are acidic and often derived from ultramafic parent materials. The acidic (6.5-6.7 pH) and nutrient-poor substrates produce severe nitrogen deficiency which favors insectivorous plants. Characteristic plant species include *Darlingtonia californica, Drosera rotundifolia, Eleocharis quinqueflora, Calliscirpus criniger, Carex californica*, and *Deschampsia cespitosa*. Around the edges of these fens *Chamaecyparis lawsoniana* can occur and form part of the fen. Burning is essential to maintain healthy stands. *Darlingtonia* fens are important habitat for rare species that respond positively to burning. Burning at least eliminates some of the tree invaders (*Pinus jeffreyi, Pseudotsuga menziesii, Chamaecyparis lawsoniana*) and maintains a high water table, essential for the fen-dependent plants.

Related Concepts:

Distribution: This system is found uncommonly throughout coastal lowlands and high mountains of the Klamath Mountains of California and Oregon and surrounding landscapes where serpentine soils are common in cool and moist environments.

Nations: US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.953 CONCEPTUAL MODEL

Environment: This system comprises wetlands located on serpentine soils, where a layer of sphagnum moss overlays serpentine soils and parent material. Soils are acidic and often derived from ultramafic parent materials. The acidic (6.5-6.7 pH) and nutrient-poor substrates produce severe nitrogen deficiency.

Key Processes and Interactions: Consistently high water table and spring flows to maintain wet soils, water quantity and quality are very important, and stable groundwater, surface water, or precipitation inputs are crucial for continual integrity of these organic soils.

Threats/Stressors: Conversion of this type has commonly come from upstream or landscape activity that completely dries up the stream or spring feeding the fen. Direct impacts also come from development and road building. Conversion to agriculture is not a factor as the soil types are not conducive to agricultural use. Wetlands and fens are threatened by similar human activities throughout the world. In California fens are stressed by moderate to heavy cattle grazing which causes direct physical damage to the fen surface, changes to water quality and nutrient levels, as well as direct impact on vegetative growth (Cooper and Wolf 2005, 2006a, 2006b, 2006c, Sikes et al. 2010, 2011, 2012, 2013). Physical disturbance from cows, hikers, roads or off-road vehicles have a similar effect by exposing the peat to oxygen which allows for decomposition, and may also hinder plant growth and therefore peat development. Grazing can shift vegetation composition away from peat-forming species (Cooper and Wolf 2005, 2006a, 2006b, 2006c, Sikes et al. 2013).

The following treats and stressors are taken from ~North Pacific Bog and Fen (CES204.063)$$, which occurs just north of this Mediterranean California serpentine fen ecosystem geographically, and all of the same threats and stressors apply. The following text is from WNHP (2011): "Reservoirs, water diversions, ditches, roads, and human land uses in the contributing watershed (fens)or surrounding landscape can also have a substantial impact on the hydrological regime. Direct alteration of hydrology (i.e., channeling, draining, damming) or indirect alteration (i.e., road building or removing vegetation on adjacent slopes) results in changes in species composition and wetland extent. Water diversions and ditches can have a substantial impact on the hydrology as well as biotic integrity of peatland. For example, if the water table is lowered, peat oxidization and subsequent decomposition occurs thereby reducing peat depth, altering hydrological patterns, and resulting in a change of species composition. Conversely, increased surface flow into a fen could result in the site being converted into a new wetland type that reflects the new hydrology, e.g., marsh. Since fens are reliant on groundwater any disturbances that impact water quality or quantity are a threat. These threats include groundwater pumping, mining, and improper placement of septic systems, water diversions, dams, roads, etc.

Human land uses in adjacent upland areas have reduced connectivity between wetland patches and upland areas. Land uses in contributing the watershed (e.g., logging, roads, development, etc.) have the potential to contribute excess nutrients into to the system which could lead to the establishment of non-native species and/or dominance of native increasing species. In general, excessive livestock or native ungulate use leads to a shift in plant species composition. Non-native plants or animals, which can have wide-ranging impacts, also tend to increase with these stressors. Although most wetlands receive regulatory protection at the national, state, and county level, many wetlands have been and continued to be filled, drained, grazed, and farmed extensively.

Peat mining can have a substantial impact on fens. Given the slow accumulation rates of peat, once it is mined (i.e., removed) the fen cannot be restored to historic conditions in a time frame relevant to management activities. The removal of peat alters the subsurface hydrological storage capacity of the peatland and tends to channelize surface flow which might result in further degradation. Peat mining can also decrease species diversity and alter species composition.

When upland forest areas adjacent to fens are logged, decreases in evaporation rates and increased surface flow from such areas can contribute excess water into the peatland. Such impacts could have negative consequences to hydrological regime of the peatland resulting in changes of decomposition and species composition. Likewise, roads within the peatland watershed can have similar deleterious effects on the hydrological regime as well as increasing sediment, contaminant, and nutrient inputs into a peatland. Increased nutrients (wherever the source) can alter species composition and, in *Sphagnum*-dominated peatlands, result in the loss of *Sphagnum*."

The projected impacts of climate change on thermal conditions in northwestern California (where most but not all serpentine fens are located, and this region is a good representation of the type of projected change for much of California) will be warmer winter temperatures, earlier warming in the spring, and increased summer temperatures. Currently, there is greater uncertainty about the precipitation projections than for temperature in Northwestern California, but with some evidence for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Potential climate change effects could include: warmer temperatures and earlier snowmelt may result in less groundwater recharge; drop in groundwater table may reduce plant rigor as plants lose connection to groundwater; reduction in spring inflows to fen; and increased fire frequency due to warmer temperatures resulting in drier fuels; the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009). This may be beneficial to fens in areas where fire suppression has been the rule, as fire generally eliminates tree invader species such as *Pinus jeffreyi, Pseudotsuga menziesii*, and *Chamaecyparis lawsoniana* and helps to maintain a high water table, essential for the fen-dependent plants.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from complete destruction by peat mining and/or agricultural conversion. Peat has dried up and decomposed due to complete drying up of wetland hydrologic source. Source of hydrologic cutoff may not be at the wetland location but in the surrounding landscape.

All of the following criteria and thresholds are from WNHP (2011), whose criteria and thresholds for Washington state fens work just as well for California fens. Environmental Degradation: Any of these conditions or combination of conditions rates as high-severity: Waterflow has been substantially diminished by human activity, Site is greatly altered by greater increased inflow from runoff, or experiences large drawdown or drying, as compared to more natural wetlands (e.g., ditching). Surface organic horizons are present. The thickness of the organic horizon has been reduced by >50%. The moss layer (when present) has been mostly removed. Any of these conditions or combination of conditions rates as moderate-severity: Source is primarily urban runoff, direct irrigation, pumped water, artificially impounded water, or other artificial hydrology. Site is somewhat altered by greater increased inflow from runoff, or experiences moderate drawdown or drying, as compared to more natural wetlands (e.g., ditching). Surface organic horizons are present. The thickness of the organic horizon has been reduced by >25%. The moss layer (when present) has been partially removed.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: Cover of native plants <50, Invasive species abundant (>10% absolute cover). Relative cover native increasers >20% cover; Native species that increase with disturbance or changes in hydrology/nutrients are prominent to dominant. Any of these conditions or combination of conditions rates as moderate-severity: Cover of native plants 50 to <79%. Invasive species prevalent (3-10% absolute cover). Relative cover native increasers 10-20% cover. Native species that increase with disturbance or changes in hydrology/nutrients may be very prominent, even in communities adapted to nutrient-poor conditions (sphagnum bogs).

CES206.952 Mediterranean California Subalpine-Montane Fen

CES206.952 CLASSIFICATION

Concept Summary: This system is found in montane to subalpine elevations confined to specific environments defined by groundwater discharge, soil chemistry, and peat accumulation. This system includes extreme rich fens which are quite rare. Fens form at low points in the landscape or near slopes where groundwater intercepts the soil surface. Groundwater inflows maintain a fairly constant water level year-round, with water at or near the surface most of the time. Constant high water levels lead to accumulation of organic material. In addition to peat accumulation and perennially saturated soils, the extreme rich fens have distinct soil and water chemistry, with high levels of one or more minerals such as calcium and/or magnesium. They usually occur as a mosaic of several plant associations dominated by species of *Carex, Betula, Kobresia*, or *Schoenoplectus*. The surrounding landscape may be ringed with other wetland systems, e.g., riparian shrublands, or a variety of upland systems from grasslands to forests.

Related Concepts:

CES204.063 North Pacific Bog and Fen

CES204.063 CLASSIFICATION

Concept Summary: This wetland system occurs in peatlands along the Pacific Coast from British Columbia south to northern California, in and west of the coastal mountain summits but including the Puget Sound lowlands. Elevations are mostly under 457 m (1500 feet), and annual precipitation ranges from 890-3050 mm (35-120 inches). These wetlands are relatively abundant in British Columbia but diminish rapidly in size and number farther south. They occur in river valleys, around lakes and marshes, or on slopes. The organic soils are characterized by an abundance of sodium cations from oceanic precipitation. Poor fens and bogs are often intermixed except in a few calcareous areas in British Columbia where rich fen vegetation may dominate. *Sphagnum* characterizes poor fens and bogs (pH <5.5), and the two are lumped here, while "brown mosses" and sedges characterize rich fens (pH >5.5). Mire profiles in British Columbia may be flat, raised (domed), or sloping, but most occurrences in Washington and Oregon are flat with only localized hummock development. Vegetation is usually a mix of conifer-dominated swamp, shrub swamp, and open sphagnum or sedge mire, often with small lakes and ponds interspersed. Vegetation includes many species common to boreal continental bogs and fens, such as *Ledum groenlandicum, Vaccinium uliginosum, Myrica gale, Andromeda polifolia, Vaccinium oxycoccos, Equisetum fluviatile, Comarum palustre*, and *Drosera rotundifolia*. However, it is also distinguished from boreal continental bogs and fens by the presence of Pacific coastal species, including *Callitropsis nootkatensis, Pinus contorta var. contorta, Picea sitchensis, Tsuga heterophylla, Ledum glandulosum, Thuja plicata, Gaultheria shallon, Spiraea douglasii, Carex aquatilis var. dives, Carex lyngbyei, Carex obnupta, Carex pluriflora, Darlingtonia californica, Sphagnum pacificum, Sphagnum henryense*, and *Sphagnum mendocinum*.

Distribution: This system occurs along the Pacific Coast from British Columbia south to northern California, west of the coastal mountain summits but including the Puget Sound lowlands. Occurrences diminish rapidly in size and number south of British Columbia.
Nations: CA, US
Concept Source: J.C. Christy
Description Author: M.S. Reid, K. Boggs, J. Christy, C. Chappell

CES204.063 CONCEPTUAL MODEL

Environment: Elevations are mostly under 457 m (1500 feet), and annual precipitation ranges from 890-3050 mm (35-120 inches). These wetlands are relatively abundant in British Columbia but diminish rapidly in size and number farther south. They occur in river valleys, around lakes and marshes, or on slopes. The organic soils are characterized by an abundance of sodium cations from oceanic precipitation. Poor fens and bogs are often intermixed except in a few calcareous areas in British Columbia where rich fen vegetation may dominate. *Sphagnum* characterizes poor fens and bogs (pH <5.5), and the two are lumped here, while "brown mosses" and sedges characterize rich fens (pH >5.5). Mire profiles in British Columbia may be flat, raised (domed), or sloping, but most occurrences in Washington and Oregon are flat with only localized hummock development.
Key Processes and Interactions: Successional patterns of wet meadows to fens to bogs in Alaska have been documented as follows, and are likely to be similar in this ecological system. Species that dominate the early stages of succession in newly formed ponded basins include *Equisetum variegatum, Equisetum fluviatile*, and *Comarum palustre*. *Sphagnum* species invade the surface and help in forming peat. Acidic and nutrient-poor-tolerant vascular species eventually dominate the sites, such as *Myrica gale, Empetrum nigrum, Vaccinium uliginosum, Andromeda polifolia*, and *Vaccinium oxycoccos*. The late-successional stage of a peatland supports various community types, depending on the pH, waterflow, and nutrient status of a site such as *Myrica gale / Empetrum nigrum* and *Picea sitchensis / Sphagnum* plant associations. Peat buildup, patterned ground, and changes in water table are recurrent aspects of peatland development rather than unidirectional successional events. It is unlikely that any of the late-seral peatland communities are stable in the sense of climax vegetation.

2.C.2.Nb. Atlantic & Gulf Coastal Plain Pocosin

M065. Southeastern Coastal Bog & Fen

CES203.893 Atlantic Coastal Plain Northern Bog

CES203.893 CLASSIFICATION

Concept Summary: This system comprises dwarf-shrub sphagnum bogs dominated by *Chamaedaphne calyculata* occurring on Cape Cod (Massachusetts), Long Island (New York), and the Coastal Plain and near-coastal areas of northern New Jersey. North of the glacial border, this system typically occurs in isolated glacial kettleholes and in New Jersey in similar isolated basins, generally in regions of deep sands. The system is characterized by acidic, tannic water supporting a floating or grounded *Sphagnum* mat over which *Chamaedaphne calyculata, Gaylussacia dumosa*, and other dwarf-shrubs have rooted. Taller shrubs such as *Vaccinium corymbosum* may occur at the periphery of the bog, and *Decodon verticillatus* often forms a distinct zone adjacent to open water. Scattered individuals of *Pinus rigida, Pinus strobus*, or less often *Chamaecyparis thyoides* or *Picea mariana* may form a partial and stunted tree layer. Rooted hydromorphic plants such as *Nymphaea odorata* occur in open water.

CES203.267 Atlantic Coastal Plain Peatland Pocosin and Canebrake

CES203.267 CLASSIFICATION

Concept Summary: This system includes wetlands of organic soils, occurring on broad flats or gentle basins, primarily on the outer terraces of the Atlantic Coastal Plain of the Carolinas and southeastern Virginia. Under current conditions, the vegetation is predominantly dense shrubland and very shrubby open woodlands. A characteristic suite of primarily evergreen shrubs, *Smilax* species, and *Pinus serotina* dominates. These shrubs include *Cyrilla racemiflora, Ilex coriacea, Ilex glabra, Lyonia lucida*, and *Zenobia pulverulenta*, along with *Smilax laurifolia*. *Pinus serotina* is the characteristic tree, along with *Gordonia lasianthus, Magnolia virginiana*, and *Persea palustris*. Herbs are scarce and largely limited to small open patches. Under pre-European settlement fire regimes, stands of *Arundinaria tecta* (canebrakes) would have been more common and extensive. Soil saturation, sheet flow, and peat depth create a distinct zonation, with the highest stature woody vegetation on the edges and lowest in the center. Catastrophic fires are important in this system, naturally occurring at moderate frequency. Fires generally kill all above-ground shrubs in large patches. Mortality of *Pinus serotina* varies, creating a shifting mosaic. Vegetation structure and biomass recover rapidly in most of the burned areas, primarily by sprouting. *Pinus serotina* can regenerate from serotinous cones if killed.

Nations: US
Concept Source: M. Schafale and R. Evans
Description Author: M. Schafale, R. Evans, M. Pyne and C. Nordman

CES203.267 CONCEPTUAL MODEL

Environment: This system occurs on broad interfluvial flats and in small to large, very gentle basins and swales, largely on the outermost terraces of the Outer Coastal Plain. Some occurrences are in large to small peat-filled Carolina bays (Bennett and Nelson 1991, Nifong 1998). Smaller patches occur in shallow swales associated with relict coastal dune system or other irregular sandy surfaces. Soils range from wet mineral soils with mucky surface layers to peats several meters deep. Most of the largest occurrences are domed peatlands with the deepest peat associated with topographic highs in the center, but deep peats are also associated with buried drainage channels. Hydrology is driven by rainfall and sheet flow. The low hydraulic conductivity of the organic material limits interaction with the groundwater. The raised center of domed peatlands is fed only by rainwater and is therefore a true ombrotrophic bog. More peripheral portions are fed by sheet flow from the center, and so receive only acidic water low in nutrients. Occurrences in Carolina bays and other basins appear to be similarly isolated from surface or groundwater inflow from adjacent areas. Soils are normally saturated throughout the winter and well into the growing season, though the organic material may dry enough to burn during droughts. Standing water is limited to local depressions and disturbed areas. Soil saturation and peat depth, with its corresponding nutrient limitation, are the primary drivers of vegetational zonation as well as the distinction between this system and adjacent ones, but their effect may be modified by drainage patterns.

Key Processes and Interactions: Fire is an important factor in these systems, with the pre-settlement fire regime probably being very different from that observed under current conditions. Natural fire-return intervals are not well known, but are probably on the order of a decade or two in the wettest areas. Peripheral areas may be subject to fire as often as the surrounding vegetation burns, which may naturally have been an average of 3 years. Fires are typically intense due to density and flammability of the vegetation; all above-ground vegetation is often killed, though *Pinus serotina* are resilient to fire and may survive. Fires are followed by vigorous root sprouting by shrubs and hardwoods, leading to recovery of standing biomass within a few years. *Pinus serotina* recovers by epicormic sprouting or by regeneration from seeds released from serotinous cones. Fires during droughts may ignite peat, forming holes that take longer to recover. Herb-dominated openings in pocosins may depend on peat fires for their creation, though this is not well documented. Natural fires occur in large patches, creating a shifting patch structure in the system that interacts with the vegetational zonation created by peat depth. The intensity of fire in these systems makes fire control difficult; prescribed burning is seldom done, and wildfires during drought continue to be a significant influence. The larger peatlands are believed to have been created by paludification following natural blocking of drainage (Otte 1981). Peat buildup raises the water table in the center, creating the domed structure of the largest peatlands and allowing the wetland to spread out as wetness is increased at the edges. Many of the deeper pocosin peats contain fossil logs that indicate dominance by a swamp forest in past millennia. Otte (1981) noted that peat fires likely limit the height to which the peat can accumulate, in proportion to how high it can raise the local water table.

Threats/Stressors: Alterations to the natural hydrology threaten this habitat, especially drainage. Some extensive peatland pocosin areas have been converted to intensively managed pine plantations, or cleared for agriculture. Drainage is used for both plantation forestry and agriculture. Peat can decompose more rapidly when it is drained and exposed to aerobic conditions.

Altered fire regimes are a threat to most remaining areas. These habitats are naturally prone to fire spreading from the adjacent pinelands, and from lightning strike fires which start within the pocosins. The occasional burning of patches provides for habitat diversity. Prescribed burning is difficult to conduct in pocosins. Due to land development and the associated fragmentation of natural lands in the vicinity of pocosins, the risks, complexity, and costs of prescribed fire are increased. Uncontrollable wildfires occur mainly during droughts, and if the peat is ignited, it can burn for months. Certain firefighting practices sometimes can be very destructive, resulting in extensive soil disturbance and sometimes in pumping of salt-containing water. Altered hydrology interacts with wildfires. Artificially drained peats are more subject to deep and prolonged burning. Deep peat fires can lower the land surface and kill roots so that pocosin vegetation does not sprout.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from drainage, conversion to intensive forestry plantations, and fragmentation of remaining pocosin habitat. By shortening the duration of saturation and exposing peat to oxygen for longer periods of time, drainage allows accumulated peat to decompose. This lessens the ability of the pocosin to retain water and slowly release it. Deep peat burns made possible by artificial drainage can lead to rapid collapse, with natural vegetation being replaced by ruderal herbaceous plants or shallow open-water areas lacking vegetation. Ecosystem collapse is characterized by the drying and decomposition of accumulated peat, transition of the vegetation structure away from shrubland or open *Pinus serotina* woodland dominated by native wetland shrubs. This includes transition to forest dominated by *Pinus taeda* with hardwood trees, and may include invasive exotic plants.

CES411.286 South Florida Everglades Sawgrass Marsh

CES411.286 CLASSIFICATION

Concept Summary: This marsh system was a dominant type throughout much of the Everglades region of southeastern Florida. It consists largely of herbaceous marsh vegetation across a range of soil and hydrologic conditions, i.e., hydroperiod of 225-275 days per year, maximum wet-season water level of 40 cm, and occurrence on peat soils. Several individual marsh community associations have been recognized based on species composition, structure, and aspect. Variations are largely due to the interrelated effects of fire, soils, and hydroperiod. Sawgrass beds or "glades" may have been the single most extensive component of this system, and large areas may have the appearance of nearly monotypic stands of *Cladium mariscus ssp. jamaicense*. However, local variation in composition and stature are also often apparent. For example, two broad aspect types of *Cladium* marsh are often recognized based on density and/or height with denser and taller stands typically occurring on higher topographic positions and deeper organic soils, while sparser, shorter stands occur in lower topography on shallower soils. In addition, other marsh types are also interfingered in the sawgrass matrix where wetter depressions are found and/or where fires have burned away peat soils.

Related Concepts:

Distribution: This system is endemic to south Florida.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans and M. Pyne

CES411.286 CONCEPTUAL MODEL

Environment: A range of conditions are present, but generally falls within conditions outlined by Duever et al. (1986). Soils vary from shallow marl to relatively deep peat. Hydroperiod ranges from 5-12 months, with maximum wet-season water level of 40 cm. The effect of fire is influenced by both factors and affects them in turn. For example, peat accumulates in the absence of fire, but under certain conditions, fires may burn away accumulated sawgrass peat resulting in a thin, residual, marly soil and relative increase of effective water depth (resulting in community change).

Key Processes and Interactions: In the absence of fire, portions of stands will become dominated by *Salix caroliniana*. If fire continues to be absent, these areas may succeed to *Acer rubrum* until a replacement fire or mechanical activity restores the marsh.

CES411.485 South Florida Slough, Gator Hole and Willow Head

CES411.485 CLASSIFICATION

Concept Summary: This ecological system includes a series of wetlands of southern Florida, ranging in physiognomy from open and herbaceous-dominated to tree-dominated patches, including nearly monospecific stands of *Salix caroliniana*. These wetlands hold water for much of the year and have some of the longest hydroperiods (8-12 months) in a region characterized by wetlands. Most are maintained, at least historically, by American alligators. Alligators were such a dominant disturbance force in many plant communities of southern Florida that their role has been compared with that of bison in the prairies. Through constant movement, they create numerous small pools and ponds (analogous to buffalo wallows), as well as trails to and from these pools through sawgrass marshes. These paths eventually widen and deepen into creeks. Many of these small freshwater creeks have been invaded by mangroves and hardwoods, including *Salix caroliniana*, in the absence of fire and with decreases in alligator populations. Some emergent wetlands included within the concept of this system may also have originated from soil and topographic changes in former sawgrass marshes following severe fires that consume organic substrate and decrease soil elevation. One component of this system ("heads") may originate as circular or oval-shaped solution holes or basins, being maintained and possibly enhanced by the alligator activity. Without this activity, there would be a tendency for the hole or basin to fill with organic material and succeed to other systems. Soils are mucky peats. In addition, *Salix caroliniana* seeds are readily dispersed by wind and may rapidly colonize wet depressions and disturbed areas. In the absence of fire and disturbance, these areas may remain in a forested condition. Otherwise, they would cycle between different physiognomic states, including sawgrass marsh.

Related Concepts:

- Cabbage Palmetto: 74 (Eyre 1980) **<**

Distribution: This system is endemic to south Florida.

Nations: US

Concept Source: R. Evans and C. Nordman

Description Author: R. Evans, C. Nordman, M. Pyne

CES411.485 CONCEPTUAL MODEL

Environment: Examples of this system may originate as solution holes in sawgrass marsh, with a longer hydroperiod, but expand and contract in size and extent with disturbance, including fire and American alligator activity. Some examples are directly caused by alligator activity and/or the effect of severe fire in sawgrass marshes, ~South Florida Everglades Sawgrass Marsh (CES411.286)$$ (Craighead 1971, Hilsenbeck et al. 1979). At least some examples attributed to this system occupy "marshes" with long hydroperiods (8-12 months) and deep organic soils (Hilsenbeck et al. 1979).

Key Processes and Interactions: The American alligators was a dominant force that helped maintain this system, at least historically. Their role has been compared with that of bison in the prairies (Craighead 1971). Through constant movement they create numerous small pools and ponds (analogous to buffalo wallows) as well as trails to and from these pools through sawgrass marshes. These paths eventually widen and deepen into creeks. Many of these small freshwater creeks have been invaded by mangroves and hardwoods in the absence of fire and decrease in alligator populations (Craighead 1971). Some emergent wetlands included within the concept of this system may also have originated from soil and topographic changes in former sawgrass marshes following severe fires that consume organic substrate and decrease soil elevation (Gunderson and Loope 1982b).

CES411.370 South Florida Wet Marl Prairie

CES411.370 CLASSIFICATION

Concept Summary: This system includes marl prairies of the southern Florida Everglades region and related vegetation of the Florida Keys. This system occurs only on shallower soils with bedrock close to the surface. Composition and variability in this system is heavily influenced by hydrology. Especially unusual are small-patch communities found on elevated areas of oolitic rocks referred to as pinnacle rock or table rock. This system also includes embedded solution holes (depressions formed from limestone collapse).

Related Concepts:

Distribution: Southern Florida Everglades region and related vegetation of the Florida Keys. Marl prairies with scattered dwarf cypress cover large areas of Big Cypress National Preserve in Collier and Monroe counties. In the Everglades region, marl prairie forms the border between the Miami Rock Ridge and the lower slough and glades marsh and occurs in the narrow finger glades on Long Pine Key (FNAI 2010a).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans and C. Nordman

CES411.370 CONCEPTUAL MODEL

Environment: This system occurs only on shallower soils with bedrock close to the surface (Gunderson and Loftus 1993). Composition and variability in this system are heavily influenced by hydrology, with the predominant community types occurring on marl substrates which are seasonally inundated (2-4 months per year). With diminished hydroperiod, species composition changes (Hilsenbeck et al. 1979). Examples of this ecological system can include elevated areas of oolitic rocks referred to as pinnacle rock (Gunderson and Loftus 1993) or table rock (Hilsenbeck et al. 1979), and also include embedded solution holes (depressions formed from limestone collapse).

Key Processes and Interactions: Composition and variability in this system are heavily influenced by hydrology; with shortened hydroperiod, species composition changes (Hilsenbeck et al. 1979). Marl prairie depends on a hydroperiod of two to four months. Longer hydroperiods favor the development of peat and the dominance of *Cladium mariscus ssp. jamaicense*; shorter hydroperiods

permit the invasion of woody species (FNAI 2010a). Marl prairie normally dries out during the winter and is subject to fires at the end of the dry season, in late spring. These late-spring fires promote flowering of the dominant grasses (FNAI 2010a). Biomass recovers to pre-fire levels after two years. The natural fire frequency may be once every two to six years, or up to ten years for marl prairies with sparse herbaceous vegetation, such as is found on shallow soils (FNAI 2010a).
Threats/Stressors: Hydrological modifications have produced an increase in sawgrass marsh at the expense of marl prairie; drainage and lack of fire have allowed invasion of exotic plants; and rock plowing for agriculture on the eastern edge of Everglades National Park has permanently changed the physical environment that formerly supported it (Hilsenbeck et al. 1979, FNAI 2010a). The buildup of leaf litter in marl prairie lowers the nesting frequency of the Cape Sable seaside sparrow (*Ammodramus maritimus mirabilis)*, an endangered bird which only occurs in a small area. Prescribed fire can reduce the leaf litter and help control some invasive plant species. Invasive plants which threaten the marl prairie include *Schinus terebinthifolius, Casuarina equisetifolia*, and *Melaleuca quinquenervia* (Hilsenbeck et al. 1979, FNAI 2010a). Water releases too soon after a fire can kill resprouting grasses. Water releases and prescribed fires need to be coordinated according to the nesting needs of the Cape Sable seaside sparrow where it occurs in the in marl prairie in the southeastern portion of Big Cypress National Preserve and in the vicinity of Taylor Slough in Everglades National Park (FNAI 2010a). Marl prairies are subject to damage from off-road vehicles (FNAI 2010a). The Burmese python has become a severe threat to the diversity of native wildlife in these habitats.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from drainage and a resulting shorter duration of flooding, long-term lack of fire (such as more than 20 years), and the dominance by invasive exotic plants and exotic animals such as the Burmese python. Areas in the eastern Everglades have been drained in order to be converted to agriculture. Ecosystem collapse is characterized by the loss of the high diversity of herbaceous plants and animals characteristic of marl prairie. This can be accompanied by the increasing dominance of trees and shrubs other than *Taxodium ascendens*. These include the invasive exotic plants *Schinus terebinthifolius, Casuarina equisetifolia*, and *Melaleuca quinquenervia* (Hilsenbeck et al. 1979, FNAI 2010a). Ecosystem collapse is also characterized by a transformation to sawgrass marsh, due to too much flooding.

M711. Mesoamerican Freshwater Marsh, Wet Meadow & Shrubland

CES402.589 Meso-American Palustrine Vegetation

CES402.589 CLASSIFICATION

Concept Summary: Este sistema es un complejo de comunidades herbáceas acuáticas enraizadas o que rodean cuerpos de agua, sobre todo en orillas de cauces lentos y planicies inundables. Las diferentes comunidades tienden a ser claramente dominadas por una especie. La fisonomía es variable, desde pantanos herbáceos dominados por *Gynerium sagittatum* hasta carrizales pantanosos. En partes de su distribución pueden encontrarse también arbustos o arbolitos creciendo entre las herbáceas. Este sistema ecológico es a menudo adyacente con bosques higrófilos y pantanosos y por eso, algunas de las especies leñosas, salpican su fisonomía herbácea predominante. Los suelos son saturados hidromórficos y puede formarse una capa de turba. La siguiente lista de especies es diagnóstica para este sistema:*Thalia geniculata, Aeschynomene sensitiva, Ipomoea aquatica (= Ipomoea reptans), Heliconia* spp., Marantaceae spp., *Calathea* spp., *Hymenachne amplexicaulis, Agrostis danaefolia, Cyperus ligularis, Cyperus odoratus, Rhynchospora macrostachya, Typha latifolia, Typha domingensis, Polygonum hispidum, Polygonum acuminatum, Myrica mexicana, Cyrilla racemiflora, Camnosperma panamensis, Clusia* sp., *Sabal* sp., *Montrichardia arborescens, Blechnum serrulatum, Thelypteris* sp., *Scleria pterota, Scleria secans, Panicum* sp., and *Acrostichum aureum*.

M888. Arid West Interior Freshwater Marsh

CES304.059 Inter-Mountain Basins Interdunal Swale Wetland

CES304.059 CLASSIFICATION

Concept Summary: This ecological system occurs within dune fields in the Intermountain western U.S. as small (usually less than 0.1 ha) interdunal wetlands that occur in wind deflation areas, where sands are scoured down to the water table. Small ponds may be associated. The water table may be perched over an impermeable layer of caliche or clay or, in the case of the Great Sand Dunes of Colorado, a geologic dike that creates a closed basin that traps water. These wetland areas are typically dominated by common emergent herbaceous vegetation such as species of *Eleocharis, Juncus*, and *Schoenoplectus*. Dune field ecological processes distinguish these emergent wetlands from similar non-dune wetlands.

Related Concepts:

Distribution: The system occurs in some dune fields across the Intermountain western U.S., including the Great Sand Dunes in southern Colorado and the Pink Coral Dunes in Utah. Interdunal wetlands may also occur in dune fields in northeastern Arizona and the Great Basin, as well as in southwestern Wyoming in the Killpecker Dunes and Ferris Dunes, and southern Idaho.

Nations: US

Concept Source: D.J. Hammond (1998)

Description Author: K.A. Schulz

CES304.059 CONCEPTUAL MODEL

Environment: Occurs in wet interdunal swales.

Key Processes and Interactions: The dunes are shaped by the wind and continue to change. The size and exact location of the wet swales may change as the sand dunes shift, due to active dune migration. Dune "blowouts" and subsequent stabilization through succession are characteristic processes of the active dunes which surround the interdunal swales.

Threats/Stressors:

Ecosystem Collapse Thresholds:

CES300.729 North American Arid West Emergent Marsh

CES300.729 CLASSIFICATION

Concept Summary: This widespread ecological system occurs throughout much of the arid and semi-arid regions of western North America, typically surrounded by savanna, shrub-steppe, steppe, or desert vegetation. Natural marshes may occur in depressions in the landscape (ponds, kettle ponds), as fringes around lakes, and along slow-flowing streams and rivers (such riparian marshes are also referred to as sloughs). Marshes are frequently or continually inundated, with water depths up to 2 m. Water levels may be stable, or may fluctuate 1 m or more over the course of the growing season. Water chemistry may include some alkaline or semi-alkaline situations, but the alkalinity is highly variable even within the same complex of wetlands. Marshes have distinctive soils that are typically mineral, but can also accumulate organic material. Soils have characteristics that result from long periods of anaerobic conditions in the soils (e.g., gleyed soils, high organic content, redoximorphic features). The vegetation is characterized by herbaceous plants that are adapted to saturated soil conditions. Common emergent and floating vegetation includes species of *Scirpus* and/or *Schoenoplectus, Typha, Juncus, Potamogeton, Polygonum, Nuphar*, and *Phalaris*. This system may also include areas of relatively deep water with floating-leaved plants (*Lemna, Potamogeton*, and *Brasenia*) and submerged and floating plants (*Myriophyllum, Ceratophyllum*, and *Elodea*).

CES300.729 CONCEPTUAL MODEL

Environment: Natural marshes may occur in depressions in the landscape (ponds, kettle ponds), as fringes around lakes, and along slow-flowing streams and rivers (such riparian marshes are also referred to as sloughs). Marshes are frequently or continually inundated, with water depths up to 2 m. Water chemistry may include some alkaline or semi-alkaline situations, but the alkalinity is highly variable even within the same complex of wetlands. Marshes have distinctive soils that are typically mineral, but can also accumulate organic material. Soils have characteristics that result from long periods of anaerobic conditions in the soils (e.g., gleyed soils, high organic content, redoximorphic features).

Key Processes and Interactions: Water levels may be stable, or may fluctuate 1 m or more over the course of the growing season. Some marshes draw down completely on an annual or semi-annual cycle, or longer 5-20 year cycle. During the "dry" period, different plant species may become established, encouraging seedlings and discouraging others, in fact, allowing for natural changes in water levels leads to higher diversity of structure and composition of the marsh ecosystems (Mitsch and Gosselink 2000). Fire also has profound effects on marsh vegetation (Kirby et al. 1988). Literature on the specifics of natural fire frequency and effects in western U.S. non-tidal wetlands is very limited (Kirby et al. 1988, Clark and Wilson 2001).

Threats/Stressors: Conversion of this type has commonly come from draining and filling of marsh wetland for roads, parking lots and other development, complete desiccation by diversion of inflow from surface waters or by lowering the groundwater level from pumping or agriculture or industry. Common stressors and threats include dredging to deepen pond levels for waterfowl management, increased occurrence of prescribed fire, not allowing ponds to periodically drain, alterations to the natural hydrology either by increasing water levels or lowering water levels and/or groundwater levels.

For the Great Basin ecoregion, which is representative of predicted climate change for a large portion of the range of the interior arid west ecosystem, with higher warming in the southern region, warming but slightly less in the northern parts of that ecoregion: "By 2060, models forecasts substantial increases in maximum temperatures for all months of the year, with the greatest increases concentrated during the summer. July and August monthly maximum temperatures are projected to increase by 5.5° and 6.5°F, respectively, more than two standard deviations above the average values from the 80-year baseline (1900-1979), whereas November and December minimum temperatures only increase by one standard deviation beyond the baseline values" (Comer et al. 2013a).

From PRBO Conservation Science (2011): "Lakes, ponds, and other standing water provides important habitat for many wildlife species. Already, many lakes are impacted by introduced fish (Knapp et al. 2001, Pope et al. 2009, as cited in PRBO Conservation Science 2011). Climate change may exacerbate these stresses and further climate change may exacerbate stresses through the altering of invertebrate communities (Porinchu et al. 2010, as cited in PRBO Conservation Science 2011) or changing water levels or changes to water chemistry (e.g., concentration of elements as ponds reduce in size) (Melack et al. 1997, Parker et al. 2008, as cited in PRBO Conservation Science 2011). If ponds are fed by snowmelt and/or streams, they may dry out or be more ephemeral during the non-winter months."

In addition, increased demand for water for human use may increase groundwater pumping, which may impact wetland marshes through the lowering of the groundwater table, shrinking marsh size and buffering capacity, as happened to Camas National Wildlife Refuge (Kittel et al. 2012b). As closed-basin marsh systems shrink due to increased evaporation and decreased rainfall, salinity levels can increase beyond the tolerance of some or all plants, altering or killing the emergent plant community. On a much larger scale, Walker and Pyramid lakes are a good example (J. Johnson pers. comm. 2013). As smaller water sources dry and become unusable, wildlife, domestic livestock, and humans will increase use of larger or more stable water sources.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from dewatering of the site, continuous heavy grazing, increasing pond levels. The following criteria and thresholds are from WNHP (2011), whose information applies throughout the range of this arid west marsh ecosystem: Environmental Degradation: Any of these conditions or combination of conditions rates as high-severity: Marsh has shrinking by more than 50% of its original size, or water levels have increased beyond tolerance for emergent plants for >75% of the marsh. Hydrology patterns of inundation and draw down/drying of site deviate from natural conditions (either increase or decrease in the magnitude and/or duration). Site is 90% cut off from surrounding upland and there is essentially no longer a hydrologic connection. Any of these conditions or combination of conditions rates as moderate-severity: Marsh size has decreased by >10%, or water levels have risen above tolerance for emergent vegetation for part of the marsh. Hydrologic pattern of inundation and drawdown/drying follow natural patterns, but are subject to more rapid or extreme flooding/levels or longer duration of either inundation or drying periods. Source of water may be restricted by barriers to drainage or is augmented by more rapid runoff being delivered to site.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: Loss of emergent vegetation by>75% either through desiccation or permanent increased water levels. Aquatic Invasive species present. Cover of native plants is <50%; non-native invasive species >10% absolute cover; species diversity/abundance different from reference standard, many indicator/diagnostic species absent. Any of these conditions or combination of conditions rates as moderate-severity: Cover of native plants 50-85%, invasive species 3-10% absolute cover; some native species reflective of past anthropogenic degradation present and some indicator/diagnostic species may be absent.

CES302.747 North American Warm Desert Cienega

CES302.747 CLASSIFICATION

Concept Summary: This ecological system occurs at low elevations (<2000 m) across the warm deserts of western North America. "Ciénegas" are freshwater spring-fed wetlands, characterized by non-fluctuating shallow surface water; the term ciénega was applied to riparian marshlands by Spanish explorers. Ciénegas are characterized by permanently saturated, highly organic, reducing soils and a relatively simple flora dominated by low-statured herbaceous hydrophytes (water-loving plants), with only occasional patches of trees. Evaporation often creates saline conditions especially on the margins as evidenced by salt-tolerant species such as *Distichlis spicata* and *Sporobolus airoides*. Typically, low-elevation examples are too warm to accumulate a deep organic layer. The type of vegetation depends on depth of water. In shallow margins, emergent plants typical of riparian vegetation are present including species of *Carex, Juncus*, and *Schoenoplectus*. In adjacent deeper waters, emergent marsh can be characteristic. The hydrology is controlled by permanently saturated hydrosols, with reducing conditions limiting the type of plant life that may grow there. The dense vegetation can slow surface waterflow, reducing the erosive power of flood waters and increase sedimentation within the ciénega. Soils can have many meters of organic deposition. Plant life is limited to low shallow-rooted semi-aquatic sedges such as *Eleocharis* spp., *Juncus* spp., *Carex* spp., a few grasses, and more rarely, *Typha* spp. Forbs include *Hydrocotyle verticillata* and *Ludwigia repens*, which can be rooted in patches of gravel below organic root zone in pool bottoms. Few trees and shrubs may be present but may include *Salix gooddingii, Populus fremontii, Fraxinus velutina*, and *Cephalanthus occidentalis*.

Description Author: G. Kittel

CES302.747 CONCEPTUAL MODEL

Environment: This spring-fed marsh ecosystem occurs at mid to low elevations (<2000 m [6562 feet]) across the warm deserts of western North America. "Ciénegas" are freshwater spring-fed wetlands, characterized by non-fluctuating shallow surface water (PAG 2001, Stromberg et al. 2009). Ciénegas are characterized by permanently saturated, highly organic, reducing soils (Hendrickson and Minckley 1984, Stromberg et al. 2009, Stevens et al. 2012).

Key Processes and Interactions: Ciénegas described here are isolated spring-fed wetlands found at the outer edge of floodplains and valley floors. Therefore, they have very stable surface hydrologic dynamics. As such they are entirely dependent on groundwater flow to their source spring, and are sensitive to changes in groundwater levels (Hendrickson and Minckley 1984, Stromberg et al. 1996, 1997, 2009, Bagstad et al. 2005, Noonan 2013). Overland surface flow from intense monsoon rains in the summer may deliver sediments into the ciénega, depending on the amount of vegetation and exposed soils on hillslopes above. Winter storms are less intense and are more likely to result in soil moisture absorption, groundwater recharge, and less surface runoff. Groundwater level stability is key to maintaining ciénegas (Hendrickson and Minckley 1984, Stromberg et al. 1996, 1997, 2009, Bagstad et al. 2005, Noonan 2013)

Threats/Stressors: Conversion of this type has commonly come from recreational use, cutting of woody vegetation, development for roadways/railways, mining and land development, altered watershed ground cover, spring development /alteration, diversion of flows, point-source pollution, watershed non-point-source pollution, withdrawals of groundwater, wildfire suppression, and invasive exotic terrestrial and aquatic plants and animals.

Continual heavy livestock grazing results in removal of native vegetation, changes in native vegetation composition and structure, possibly favoring invasion of non-native vegetation; disruption of spring structure, associated pools and outflow channels (Stevens and Meretsky 2008); and increased water pollution (sediment, manure), which can be very harmful to fish (Calamusso 2005). Recreational use results in elimination and disturbance of ciénega habitat; increased soil erosion; soil compaction, non-point source pollution, reduction spring-upland trophic linkage, potential fire starts (Debinski and Holt 2000, Stevens and Meretsky 2008). Cutting of woody vegetation removes native vegetation, possibly favoring invasion of non-native vegetation (Patten 1998, Stromberg et al. 2009), thus altering native vegetation assemblage and overall ecological function (Faber-Langendoen et al. 2008b) which can impact the amount of woody debris important for fish habitat (Calamusso 2005).

Development of roadways/railways eliminates and fragments spring habitat; alters surface flow paths; and increases non-point source pollution (Comer and Hak 2009). Mining activities eliminate spring habitat; alter alluvial/channel geomorphic dynamics; alter longitudinal groundwater flow paths in alluvial aquifers; and are a source of pollution and sedimentation (Berkman and Rabeni 1987, Mol and Ouboter 2004). Altered watershed ground cover results in alteration of runoff and recharge at both the watershed scale and immediately surrounding the ciénega buffer area; altered sediment inputs from watershed during runoff events; and altered non-point source pollution (Webb and Leake 2006, Anning et al. 2009, Poff et al. 2010). Land development reduces alluvial recharge during rainfall/runoff; and increases soil erosion and non-point source pollution (McKinney and Anning 2009).

Spring development/alteration results in the direct local elimination of natural spring geomorphic structure, reduction in soil moisture absorption, physical disruption of pool/bank ratio (Stevens and Meretsky 2008). Post-orifice diversion is also common, particularly for livestock watering and development of ponds. Spring flows are commonly captured into open troughs or into covered tanks and then piped to troughs or ponds. These alterations often eliminate spring channel and ciénega (wet meadow) functions (Stevens and Meretsky 2008). Diversion of flows results in loss of surface flows, both baseflow and runoff, with consequent loss of natural alluvial groundwater recharge/discharge dynamics, which can come from activities far removed from spring location (Poff et al. 2010, Shafroth et al. 2010, Theobald et al. 2010). Point-source pollution alters water quality of groundwater sources (Anning et al. 2009). Groundwater and surface water pollution strongly alters springs ecosystem integrity and is a common phenomenon in agricultural and urban areas. Agricultural groundwater pollution may shift ecosystem nutrient dynamics to entirely novel trajectories creating conditions to which few native species may be able to adapt (Stevens and Meretsky 2008). Local contamination may also affect springs microhabitats by polluting surface waters. Such impacts are abundant at springs on the southern Colorado Plateau where springs sources are often fenced and concentrate ungulate use (Stevens and Meretsky 2008). Decrease in water quality degrades habitat for fish (Calamusso 2005). Non-point-source pollution alters water quality in surface storm runoff into the ciénega itself, which can come from agricultural and urban areas within the watershed, also detrimental to fish habitats (Abell et al. 2000, Calamusso 2005). Withdrawals of groundwater results in loss of baseflow (magnitude and spatial extent) and lowering of alluvial water table (Stromberg et al. 1996, Calamusso 2005, Poff et al. 2010).

Wildfire suppression leads to changes in vegetation succession dynamics, possibly also favoring invasion of non-native vegetation (Unnash et al. 2008). Also, changes in land use by fire suppression or grazing can change the role of plant water use in a watershed and subsequently recharge to the aquifer (Stevens and Meretsky 2008).

Introduction of exotic terrestrial plants and animals can lead to the replacement of native vegetation, altering ciénega habitat suitability for terrestrial fauna; alteration of shading of channel affecting water temperature and habitat quality; alteration of fire risk; alteration of soil and ground-litter chemistry; and alteration of evapotranspiration rates and timing (Stromberg 1998). Exotic aquatic plants and animals can remove or reduce native aquatic species due to competition, predation, and alteration of water quality (Rinne 1995, Calamusso 2005, EPA 2005).

According to the U.S. Global Change Research Program, recent warming in the Southwest has been significantly higher than the global average (USCCSP 2009, IPCC 2007c). The global average temperature has risen 1°F over the past 150 years, while in the southwest it has risen by more than 2°F (AFRTF 2010). According to the IPCC's Fourth Assessment report, the Southwestern region of the U.S. will continue to experience warming at a faster rate than most of the U.S. with warming likely to be greatest during the summer months. This increase in summer month maximum temperatures was also observed in the Mojave Basin and Range Rapid Ecoregional Assessment (Comer et al. 2013b). To date, climate in the western U.S. has warmed an average of 1.4°F over the past 50 years. IPCC climate models predict these areas will continue to warm a further 3.6° to 9.0°F by 2040 to 2069 in the summer months (ACCAG 2006). This warmer climate is expected to increase the rate of water evaporation, leading to lower levels in streamflows. These trends are also affecting processes including plant production and soil respiration (Weltzin et al. 2003, ACCAG 2006). Warmer temperatures are also expected to affect precipitation, as described below.

It is anticipated that critical changes in precipitation due to climate change - including alterations in the amount, pattern, and type of precipitation (i.e., snow versus rain) - will have a direct effect on ecosystem processes in the Southwest (Archer and Predick 2008, Stromberg and Tellman 2009). However, there is less agreement among models about how precipitation will change when compared to other climatic temperature predictions.

Despite some uncertainties the following forecasts for the Southwest are generally understood by scientists, as summarized in the Heinz Center report (2011): More high-intensity storms: High-intensity storms will likely become common in the Southwest during summer months, resulting in more erosive events and an increase in the likelihood of flash flooding (Archer and Predick 2008). Changes in snowfall and snowmelt: In general, there is expected to be less winter snowfall, more winter rain, and a faster, earlier snowmelt in Arizona's mountains (ACCAG 2006). Trends over the last 50 years show earlier spring snowmelt and declining winter snowpack (AFRTF 2010). Montane areas may see less snowfall and more rain in the winter due to changes in the spatial patterns of precipitation as well as warmer temperatures at higher elevations. Warmer temperatures may lead to earlier snowmelt, which will alter peak runoff in streams and rivers, may result in higher magnitude floods (ACCAG 2006), and may result in streams becoming intermittent sooner in the season, with an increase in the spatial extent of intermittent stream reaches in summer months (Solomon et al. 2009, USCCSP 2009).

Decreased annual precipitation: Drier months: There is a greater agreement among models regarding less precipitation amounts during the dry season than during the wet months (Christensen et al. 2007, Dominguez et al. 2009). Solomon et al. (2009) showed that over 90% of the regional climate models indicate increased drying during dry seasons. Wetter months (The North American Monsoon System): Approximately 60% of the MAR's precipitation comes during the wet monsoon season. Complicating effects of climate change are changes in oceanic circulation and regional wind patterns, whose changes may decrease the amount of atmospheric moisture being delivered inland to the MAR. Summer-time decadal trends have been observed in the San Pedro River, where abrupt shifts in flood type have occurred over the twentieth century precipitation (Hirschboeck 2009). Since 1965 peak annual flows (annual floods) floods are more often produced by winter cyclonic and tropical storms and with less frequency by summer convective storms. The same trend has been documented in the Santa Cruz River. The reason for this shift is under debate but some research points to an increase of the frequency and strength of El Niño years that tend to result in greater winter months precipitation over summer months be wetter-than-normal winter precipitation (Hirschboeck 2009).

Potential climate change effects could include alteration of precipitation and evapotranspiration rates and timing, resulting in direct alteration of soil moisture, runoff (surface flows) and recharge (groundwater quantity) at both the watershed scale and immediately within ciénega and buffer. Impacts may also occur through changes in human consumption of surface water and groundwater in response to climate change (Price et al. 2005).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from arroyo formation. Historically, ciénegas were much more abundant across the Southwest; after 1870 and the influx of European setters, their livestock and coincidental drought cycle, severe changes occurred in the hydrology and plant cover with ciénega wetlands, causing arroyo formation and the loss of many ciénegas (Hendrickson and Minckley 1984, Noonan 2013).

The following is based on threats noted in literature cited above, applied through standard criteria of landscape condition, size and physical/biologic condition, as described in NatureServe's Ecological Integrity Assessment (Faber-Langendoen et al. 2008b) and Heritage Program Ecological Occurrences Specifications [see WNHP (2011) and CNRA (2009) for example criteria). Suggested thresholds are by the author. Environmental Degradation: Any of these conditions or combination of conditions rates as high-severity: A poor condition/non-functioning ecosystem is highly fragmented, or much reduced in size from its historic extent; the surrounding landscape is in poor condition either with highly eroding soils, or a large percentage of the surrounding landscape has been converted to pavement or highly maintained agriculture (row crops, irrigated crops, etc.); abiotic condition is poor with high soil erosion, high sediment loads into water bodies, hill and gullies present, streambanks are broken down, stream channels are not as sinuous as expected for the stream bed downstream gradient. Any of these conditions or combination of conditions rates as moderate-severity: A moderate condition/just functioning ecosystem is somewhat fragmented, or reduced in size from its historic extent; the surrounding landscape is in moderate to poor condition either with highly eroding soils, or a large percentage of the surrounding landscape has been converted to pavement or highly maintained agriculture (row crops, irrigated crops, etc.); abiotic condition is moderate with high soil erosion in places, providing a source of sediment loads into water bodies, hill and gullies present, streambanks are broken down in some places, stream channels are not as sinuous as expected for the stream bed downstream gradient.

Disruption of Biotic Processes; Any of these conditions or combination of conditions rates as high-severity: The biotic condition is at the limit or beyond natural range of variation, i.e., very few native species expected for this ecosystem are present or are in poor physical condition and are barely able to reproduce; many invasives and non-native species are in greater abundance than the natives; birds, mammals, reptiles and amphibian species expected are not present or the ratio of species shows an imbalance of predator to prey populations, or have more opportunistic species and a lack of interior, poor competitor species (i.e., species guilds are not within the normal range of variation). Any of these conditions or combination of conditions rates as moderate-severity: The biotic condition is at the lower limits of the natural range of variation, i.e., some of the native species expected for this ecosystem are not present or are in poor physical condition and are barely able to reproduce; many invasives and non-native species are abundant; birds, mammals, reptiles and amphibian species expected are not present or the ratio of species shows an imbalance of predator to prey populations, or have more opportunistic species and a lack of interior, poor competitor species (i.e., species guilds are at the lower limits of their normal range of variation).

M073. Vancouverian Lowland Marsh, Wet Meadow & Shrubland

CES204.854 North Pacific Avalanche Chute Shrubland

CES204.854 CLASSIFICATION

Concept Summary: This tall shrubland system occurs throughout mountainous regions of the Pacific Northwest, from the southern Cascades and Coast Ranges north into the mountains of British Columbia. This system occurs on sideslopes of mountains on glacial till or colluvium. These habitats range from moderately xeric to wet and occur on snow avalanche chutes at montane elevations. In the mountains of Washington, talus sites and snow avalanche chutes very often coincide spatially. On the west side of the Cascades, the major dominant species are *Acer circinatum, Alnus viridis ssp. sinuata, Rubus parviflorus*, and small trees, especially *Callitropsis nootkatensis*. Forbs, grasses, or other shrubs can also be locally dominant. *Prunus virginiana, Amelanchier alnifolia, Vaccinium membranaceum* or *Vaccinium scoparium*, and *Fragaria* spp. are common species on drier avalanche tracks on the east side of the Cascades. The main feature of this system is that it occurs on steep, frequently disturbed (snow avalanches) slopes. Avalanche chutes can be quite long, extending from the subalpine into the montane and foothill toeslopes.

CES204.865 North Pacific Shrub Swamp

CES204.865 CLASSIFICATION

Concept Summary: Swamps vegetated by shrublands occur throughout the Pacific Northwest Coast, from Cook Inlet and Prince William Sound, Alaska, to the southern coast of Oregon. These are deciduous broadleaf tall shrublands that are located in depressions, around lakes or ponds, or river terraces where water tables fluctuate seasonally (mostly seasonally flooded regime), in areas that receive nutrient-rich waters. These depressions are poorly drained with fine-textured organic, muck or mineral soils and standing water common throughout the growing season. *Alnus viridis ssp. sinuata* often dominates the shrub layer, but many *Salix* species may also occur. The shrub layer can have many dead stems. However, various species of *Salix, Spiraea douglasii, Malus fusca, Cornus sericea, Alnus incana ssp. tenuifolia (= Alnus tenuifolia), Alnus viridis ssp. crispa (= Alnus crispa)*, and/or *Alnus viridis ssp. sinuata (= Alnus sinuata)* can be the major dominants. They may occur in mosaics with marshes or forested swamps, being on average more wet than forested swamps and more dry than marshes. However, it is also frequent for them to dominate entire wetland systems. Hardwood-dominated stands (especially *Fraxinus latifolia*) may be considered a shrub swamp when they are not surrounded by conifer forests but do not occur in Alaska. Typical landscape for the *Fraxinus latifolia* stands were very often formerly dominated by prairies and now by agriculture. Wetland species, including *Carex aquatilis var. dives (= Carex sitchensis), Carex utriculata, Equisetum fluviatile*, and *Lysichiton americanus*, dominate the understory. On some sites, *Sphagnum* spp. are common in the understory (Stikine, Yakutat Forelands, Copper River Delta).

CES200.877 Temperate Pacific Freshwater Emergent Marsh

CES200.877 CLASSIFICATION

Concept Summary: Freshwater marshes are found at all elevations below timberline throughout the temperate Pacific Coast and mountains of western North America. In the Pacific Northwest, they are mostly small-patch, confined to limited areas in suitable floodplain or basin topography. They are mostly semipermanently flooded, but some marshes have seasonal hydrologic flooding. Water is at or above the surface for most of the growing season. Soils are muck or mineral (in Alaska typically muck over a mineral soil), and water is high-nutrient. Occurrences of this system typically are found in a mosaic with other wetland systems. It is often found along the borders of ponds, lakes or reservoirs that have more open basins and a permanent water source throughout all or most of the year. Some of the specific communities will also be found in floodplain systems where more extensive bottomlands remain. By definition, freshwater marshes are dominated by emergent herbaceous species, mostly graminoids (*Carex, Scirpus* and/or *Schoenoplectus, Eleocharis, Juncus, Typha latifolia*) but also some forbs. Common emergent and floating vegetation includes species of *Scirpus* and/or *Schoenoplectus, Typha, Eleocharis, Sparganium, Sagittaria, Bidens, Cicuta, Rorippa, Mimulus*, and *Phalaris*. Maritime Alaska freshwater marshes are described as having *Carex rostrata, Equisetum fluviatile* (often pure stands), *Carex aquatilis var. dives, Menyanthes trifoliata, Comarum palustre, Eleocharis palustris*, and *Schoenoplectus tabernaemontani*. In relatively deep water, there may be occurrences of the freshwater aquatic bed system, where there are floating-leaved genera such as *Lemna, Potamogeton, Polygonum, Nuphar, Hydrocotyle*, and *Brasenia*. A consistent source of freshwater is essential to the function of these systems.

CES200.878 Temperate Pacific Freshwater Mudflat

CES200.878 CLASSIFICATION

Concept Summary: Freshwater mudflats are found scattered throughout the temperate regions of the Pacific Coast of North America. In the Pacific Northwest, they occur primarily in seasonally flooded shallow lakebeds on floodplains, especially along the lower Columbia River. During any one year, they may be absent because of year-to-year variation in river water levels. Mudflats must be exposed before the vegetation develops from the seedbank. They are dominated mainly by low-stature annual plants. They range in physiognomy from sparsely vegetated mud to extensive sods of herbaceous vegetation. The predominant species include *Eleocharis obtusa, Lilaeopsis occidentalis, Crassula aquatica, Limosella aquatica, Gnaphalium palustre, Eragrostis hypnoides*, and *Ludwigia palustris*.

CES204.874 Willamette Valley Wet Prairie

CES204.874 CLASSIFICATION

Concept Summary: This system is largely restricted to the Willamette Valley of Oregon and adjacent Washington. It is nearly extirpated from the Puget Trough of Washington. These are high-nutrient wetlands that are temporarily and seasonally flooded.

They are dominated primarily by graminoids, especially *Deschampsia cespitosa, Camassia quamash, Carex densa*, and *Carex unilateralis*, and to a lesser degree by forbs (e.g., *Isoetes nuttallii*) or shrubs (e.g., *Rosa nutkana*). Wet prairies historically covered large areas of the Willamette Valley where they were maintained by a combination of wetland soil hydrology and frequent burning. They have been reduced to tiny fragments of their former extent.

Related Concepts:

Distribution: Restricted to the Willamette Valley of Oregon and adjacent Washington.

Nations: US

Concept Source: C. Chappell

Description Author: C. Chappell and G. Kittel

CES204.874 CONCEPTUAL MODEL

Environment: This ecosystem occurred in areas with seasonally high water tables often perched on clay-rich soils (e.g., local depressions, swales and low-gradient riparian areas) within the matrix of a fire-maintained prairie landscape.

Key Processes and Interactions: Given their location within a fire-maintained, open grassland landscape, these wet prairies experienced periodic fire, which is what distinguishes them from similar wetland types found elsewhere in western Washington and Oregon. This system was productive and likely dynamic due to frequency of fire.

Threats/Stressors: Due to their productive nature, many wet prairies were converted to agricultural use, others were overgrazed, and others experienced invasion of woody vegetation due to fire suppression (WNHP 2011). Wet prairies have been lost and/or degraded due to numerous anthropogenic land uses and activities. Many other sites have been altered by draining, roads, and groundwater withdrawal. Due to these impacts, wet prairies have been nearly extirpated in the South Puget Sound region. The hydrologic regime of remaining wet prairie sites has likely been altered by draining and/or recession of the water table (Easterly et al. 2005). Fire suppression, attenuation of salmon runs, and altered hydrology of the current landscape have likely had a profound influence on the ecological processes and dynamics, such as nutrient cycling and successional status, of remaining wet prairie sites (Easterly et al. 2005).

In the Pacific Northwest Regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation, averaged over all models, are small (+1 to +2%), but some models project wetter autumns and winters and drier summers. Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models (Littell et al. 2009). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. This change will result in: Less winter snow accumulation, Higher winter streamflows, Earlier spring snowmelt, Earlier peak spring streamflow and lower summer streamflows in rivers that depend on snowmelt (most rivers in the Pacific Northwest) (Littell et al. 2009). Potential climate change effects could include: further reduction in summer flows (Littell et al. 2009); however, regional climate model simulations generally predict increases in extreme high precipitation over the next half-century, particularly around Puget Sound (Littell et al. 2009); drop in groundwater table; and increased fire frequency due to warmer temperatures resulting in drier fuels the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from the lack of flooding, and lack of fire during the dry season (WNHP 2011). All of the following criteria and thresholds come from WNHP (2011): Environmental Degradation: Any of these conditions or combination of conditions rates as high-severity: Waterflow has been substantially diminished by human activity Both the filling/inundation and drawdown/drying of the site deviate from natural conditions (either increased or decreased in magnitude and/or duration). Soils are either never saturated to the surface during the rainy season, or are completely inundated for more than 120 continuous hours (5 days) at least once in a five year period. Lateral excursion of rising waters is partially restricted by unnatural features, such as levees or excessively high banks, and 50-90% of the site is restricted by barriers to drainage. Flood flows may exceed the obstructions, but drainage back to the wetland is incomplete due to impoundment. Any of these conditions or combination of conditions rates as moderate-severity: Water source is mostly natural, but site directly receives occasional or small amounts of inflow from anthropogenic sources; The filling or inundation patterns in the site are of greater magnitude (and greater or lesser duration than would be expected under natural conditions, but thereafter, the site is subject to natural drawdown or drying. Lateral excursion of rising waters is partially restricted by unnatural features, such as levees or excessively high banks, but Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: Encroachment of woody species, especially Douglas-fir seedlings/saplings/small trees (10-25% cover); native cover <90%; invasive increasers 5-30% absolute cover; composition of high fidelity wet prairie species drops to only 5-10 species. Any of these conditions or combination of conditions rates as moderate-severity: Douglas-fir density <4 /acre; shrub cover <10%.; native species cover is >90%; composition of high fidelity wet species is 10-15 species.

M075. Western North American Montane-Subalpine-Boreal Marsh, Wet Meadow & Shrubland

CES304.084 Columbia Plateau Silver Sagebrush Seasonally Flooded Shrub-Steppe

CES304.084 CLASSIFICATION

Concept Summary: This ecological system includes sagebrush communities occurring at lowland and montane elevations in the Columbia Plateau-northern Great Basin region, east almost to the Great Plains. These are generally depressional wetlands or non-alkaline playas, occurring as small- or occasionally large-patch communities, in a sagebrush or montane forest matrix. Climate is generally semi-arid, although it can be cool in montane areas. This system occurs in poorly drained depressional wetlands, the largest characterized as playas, the smaller as vernal pools, or along seasonal stream channels in valley bottoms or mountain meadows. *Artemisia cana ssp. bolanderi* or *Artemisia cana ssp. viscidula* are dominant, with *Artemisia tridentata ssp. tridentata, Artemisia tridentata ssp. wyomingensis*, or *Artemisia tridentata ssp. vaseyana* occasionally codominant; *Dasiphora fruticosa ssp. floribunda* can also be codominant. Understory graminoids and forbs are characteristic, with *Poa secunda, Poa cusickii, Festuca idahoensis, Muhlenbergia filiformis, Muhlenbergia richardsonis*, and *Leymus cinereus* dominant at the drier sites; *Eleocharis palustris, Deschampsia cespitosa*, and *Carex* species dominate at wetter or higher-elevation sites.

CES306.812 Rocky Mountain Alpine-Montane Wet Meadow

CES306.812 CLASSIFICATION

Concept Summary: These are high-elevation communities found throughout the Rocky Mountains and Intermountain regions, dominated by herbaceous species found on wetter sites with very low-velocity surface and subsurface flows. They range in elevation from montane to alpine (1000-3600 m). These types occur as large meadows in montane or subalpine valleys, as narrow strips bordering ponds, lakes, and streams, and along toeslope seeps. They are typically found on flat areas or gentle slopes, but may also occur on sub-irrigated sites with slopes up to 10%. In alpine regions, sites typically are small depressions located below late-melting snow patches or on snowbeds. Soils of this system may be mineral or organic. In either case, soils show typical hydric soil characteristics, including high organic content and/or low chroma and redoximorphic features. This system often occurs as a mosaic of several plant associations, often dominated by graminoids, including *Calamagrostis stricta, Caltha leptosepala, Cardamine cordifolia, Carex illota, Carex microptera, Carex nigricans, Carex scopulorum, Carex utriculata, Carex vernacula, Deschampsia cespitosa, Eleocharis quinqueflora, Juncus drummondii, Phippsia algida, Rorippa alpina, Senecio triangularis, Trifolium parryi*, and *Trollius laxus*. Often alpine dwarf-shrublands, especially those dominated by *Salix*, are immediately adjacent to the wet meadows. Wet meadows are tightly associated with snowmelt and typically not subjected to high disturbance events such as flooding.

Nations: CA, US

Concept Source: M.S. Reid

Description Author: NatureServe Western Ecology Team

CES306.812 CONCEPTUAL MODEL

Environment: Moisture for these wet meadow community types is acquired from groundwater, stream discharge, overland flow, overbank flow, and on-site precipitation. Salinity and alkalinity are generally low due to the frequent flushing of moisture through the meadow. Depending on the slope, topography, hydrology, soils and substrate, intermittent, ephemeral, or permanent pools may be present. These areas may support species more representative of purely aquatic environments. Standing water may be present during some or all of the growing season, with water tables typically remaining at or near the soil surface. Fluctuations of the water table throughout the growing season are not uncommon, however. On drier sites supporting the less mesic types, the late-season water table may be one meter or more below the surface.

Soils typically possess a high proportion of organic matter, but this may vary considerably depending on the frequency and magnitude of alluvial deposition (Kittel et. al. 1999b). Organic composition of the soil may include a thin layer near the soil surface or accumulations of highly sapric material of up to 120 cm thick. Soils may exhibit gleying and/or mottling throughout the profile. Wet meadow ecological systems provide important water filtration, flow attenuation, and wildlife habitat functions.

Key Processes and Interactions: Wet meadows are tightly associated with snowmelt and typically not subjected to high disturbance events such as flooding. Associations in this ecological system are adapted to soils that may be flooded or saturated throughout the growing season. They may also occur on areas with soils that are only saturated early in the growing season, or intermittently. Typically these associations are tolerant of moderate-intensity surface fires and late-season livestock grazing (Kovalchik 1987). Most appear to be relatively stable types, although in some areas these may be impacted by intensive livestock grazing.

CES306.832 Rocky Mountain Subalpine-Montane Riparian Shrubland

CES306.832 CLASSIFICATION

Concept Summary: This system is found throughout the Rocky Mountain cordillera from New Mexico north into Montana and northwestern Alberta, and also occurs in mountainous areas of the Intermountain West region and Colorado Plateau. These are montane to subalpine riparian shrublands occurring as narrow bands of shrubs lining streambanks and alluvial terraces in narrow to wide, low-gradient valley bottoms and floodplains with sinuous stream channels. Generally, the system is found at higher elevations, but can be found anywhere from 1500-3475 m, and may occur at even lower elevations in the Canadian Rockies. Occurrences can also be found around seeps, fens, and isolated springs on hillslopes away from valley bottoms. Many of the plant associations found within this system are associated with beaver activity. This system often occurs as a mosaic of multiple communities that are shrub-and herb-dominated and includes above-treeline, willow-dominated, snowmelt-fed basins that feed into streams. The dominant shrubs reflect the large elevational gradient and include *Alnus incana, Betula glandulosa, Betula occidentalis, Cornus sericea, Salix bebbiana, Salix boothii, Salix brachycarpa, Salix drummondiana, Salix eriocephala, Salix geyeriana, Salix monticola, Salix planifolia*, and *Salix wolfii*. Generally the upland vegetation surrounding these riparian systems are of either conifer or aspen forests.

CES200.998 Temperate Pacific Subalpine-Montane Wet Meadow

CES200.998 CLASSIFICATION

Concept Summary: Montane and subalpine wet meadows occur in open wet depressions, basins and flats among montane and subalpine forests from California's Transverse and Peninsular ranges north to British Columbian coastal forests at varying elevations depending on latitude. Sites are usually seasonally wet, often drying by late summer, and many occur in a tension zone between perennial wetlands and uplands, where water tables fluctuate in response to long-term climatic cycles. They may have surface water for part of the year, but depths rarely exceed a few centimeters. Soils are mostly mineral and may show typical hydric soil characteristics, and shallow organic soils may occur as inclusions. This system often occurs as a mosaic of several plant associations with varying dominant herbaceous species that may include *Camassia quamash, Carex bolanderi, Carex utriculata, Carex exsiccata, Dodecatheon jeffreyi, Glyceria striata, Carex nigricans, Calamagrostis canadensis, Juncus nevadensis, Caltha leptosepala ssp. howellii, Veratrum californicum*, and *Scirpus* and/or *Schoenoplectus* spp. Trees occur peripherally or on elevated microsites and include *Picea engelmannii, Abies lasiocarpa, Abies amabilis, Tsuga mertensiana*, and *Callitropsis nootkatensis*. Common shrubs may include *Salix* spp., *Vaccinium uliginosum, Betula glandulosa*, and *Vaccinium macrocarpon*. Wet meadows are tightly associated with snowmelt and typically are not subjected to high disturbance events such as flooding.

Distribution: This system is found from California's Transverse and Peninsular ranges north to British Columbian coastal forests at varying elevations depending on latitude.
Nations: CA, US
Concept Source: P. Comer
Description Author: P. Comer, G. Kittel and C. Chappell

CES200.998 CONCEPTUAL MODEL

Environment: Deep mineral soils (often overlain with organic soil that is <40 cm thick) and seasonal high water table are the driving forces of this system. Soil oxygen levels can be low for much of the growing season, and in mature stands, graminoid root density provides extreme competition for seedling establishment. Soils can dry out by the end of the growing season. Prolonged drought will lower the water table and reduce plant vigor.
Key Processes and Interactions: Wet meadows are tightly associated with snowmelt and typically are not subjected to high disturbance events such as flooding.
Threats/Stressors:
Ecosystem Collapse Thresholds:

M074. Western North American Vernal Pool

CES304.057 Columbia Plateau Vernal Pool

CES304.057 CLASSIFICATION

Concept Summary: This system includes shallow ephemeral waterbodies found in very small (3 m2 to 1 acre) to large depressions (1500 m2 to a square mile, average size of vernal pools is 1600 m2, while average size on non-alkaline playa lakes is 5-10 acres) throughout the exposed volcanic scablands of the Columbia Plateau in Washington, Oregon, and northern Nevada. Most of these pools and lakes are located on massive basalt flows exposed by Pleistocene floods; southward they also occur on andesite or rhyodacite caprock. Inundation is highly irregular, sometimes not occurring for several years. Depressions usually (but not always) fill with water during winter and spring. They are generally dry again within 9 months, though in exceptional times they can remain inundated for two years in a row. Water is from rainfall and snowmelt in relatively small closed basins, on average probably no more than 5-15 times the area of the ponds themselves. Because these pools and playas are perched above the general surrounding landscape, they are not generally subject to runoff from major stream systems. They typically have silty clay soils, sometimes with sandy margins. Pools are often found within a mounded or biscuit-swale topography with *Artemisia* shrub-steppe or rarely *Pinus ponderosa* savanna. In the northern Columbia Plateau, characteristic species are predominantly annual and diverse. Floristically akin to California vernal pool flora (one-third), however, many of the most abundant species are not reported in Californian pools. The Columbia Plateau vernal pools have many floristic similarities to their California counterparts. In one study, it was found that 34% of the native taxa and 65% of the genera also occurred in a comprehensive listing of California vernal pool. Characteristic species of these vernal pools include *Callitriche marginata, Camissonia tanacetifolia, Cuscuta californica var. breviflora, Elatine californica, Elatine chilensis, Elatine rubella, Juncus uncialis, Myosurus minimus, Plagiobothrys* spp., *Polygonum polygaloides ssp. confertiflorum, Polygonum polygaloides ssp. polygaloides, Psilocarphus brevissimus, Psilocarphus elatior, Psilocarphus oregonus*, and *Trifolium cyathiferum*. *Artemisia ludoviciana ssp. ludoviciana* can occur on better developed soils. In northern Nevada, most of the species by biomass are perennials and include *Polygonum, Rumex, Juncus arcticus ssp. littoralis, Eleocharis, Carex douglasii, Muhlenbergia richardsonis*, and *Polyctenium* species, in addition to *Camissonia tanacetifolia* and *Psilocarphus brevissimus*. Endemic plant species *Navarretia leucocephala ssp. diffusa* and *Polyctenium williamsiae* may occur.

Related Concepts:

Distribution: This system is restricted to the northern Columbia Plateau ecoregion commonly called the Columbia Basin and perhaps the Okanagan Valley in British Columbia, and to the western Great Basin.

Nations: CA?, US

Concept Source: R. Crawford

Description Author: R. Crawford, J. Morefield and G. Kittel

CES304.057 CONCEPTUAL MODEL

Environment: This system includes shallow ephemeral waterbodies found in very small (3 m2 to 1 acre) to large depressions (1500 m2 to a square mile; average size of vernal pools is 1600 m2, while average size on non-alkaline playa lakes is 5-10 acres) throughout the exposed volcanic scablands of the Columbia Plateau in Washington, Oregon, and northern Nevada. Most of these pools and lakes are located on massive basalt flows exposed by Pleistocene floods; southward they also occur on andesite or rhyodacite caprock. Inundation is highly irregular, sometimes not occurring for several years. Depressions usually (but not always) fill with water during winter and spring. They are generally dry again within 9 months, though in exceptional times they can remain inundated for two years in a row. Water is from rainfall and snowmelt in relatively small closed basins, on average probably no more than 5-15 times the area of the ponds themselves. Because these pools and playas are perched above the general surrounding landscape, they are not generally subject to runoff from major stream systems. They typically have silty clay soils, sometimes with sandy margins. Pools are often found within a mounded or biscuit-swale topography with *Artemisia* shrub-steppe or rarely *Pinus ponderosa* savanna. Winters are colder (coldest average median temperature month in the high 20°F) than California vernal pools and are climatically defined by wet winters (November through January, sporadically so southward) and severe summer drought (July-September), although May or June can be wet. The northernmost vernal pools are adapted to cold spring and long summer days (18 hours).

Key Processes and Interactions: Vernal pools are precipitation-filled seasonal wetlands inundated during the growing season, allowing for plant growth, followed by a brief water-logged terrestrial stage and culminating in complete drying of surface and subsurface soils. Inundation during the growing season eliminates establishment of upland species in the pool basins, and the dry period prevents the establishment of many typical wetland taxa (Keeley and Zedler 1998). Pool filling is a combination of direct precipitation and lateral flow among pools within a complex of pools and subsurface flow from uplands which buffers pool volume, keeping them filled into the dry season (Hanes and Stromberg 1998). Soils are relatively shallow (10-30 cm) underlain by basalt bedrock that prevents drainage (Crowe et al. 1994, Bjork and Dunwiddie 2004). What is unique about vernal pools is the seasonality of the wetting period followed by the desiccation period, which generally is supported by a Mediterranean climate (Crowe et al. 1994, Keeley and Zedler 1998), resulting in the development of diverse and highly endemic vegetation (Barbour et al. 2003, 2005, Solomeshch et al. 2007). Natural fire regimes for vernal pools are generally unknown, but are assumed to be similar to their surrounding upland grassland fire regimes (Wills 2006). Fire can have a positive effect on vernal pool vegetation as it can results in robust response by native grasses and can reduce non-native invasive woody and non-native herbaceous species (Pollak and Kan 1998).

Threats/Stressors: There has been little outright eradication of pools on the Columbia Plateau, as basalt-bedrock landscapes are impractical for agricultural or development activities (Bjork and Dunwiddie 2004). Only a small percentage have been heavily impacted by non-natives (Bjork and Dunwiddie 2004). However, continuous heavy grazing can have a negative affect on native plant rigor and introduce non-native species (Brown 1999, Dlugolecki 2010). The ratio of annual/perennial species can shift due to heavy, long-term grazing, and upland or wetland perennial species are favored over specialist vernal pool annuals. This impact varies with intensity of grazing. Research in the Columbia Basin (Brown 1999, Dlugolecki 2010) and personal observations (J. Rocchio pers. comm. 2013) suggest grazing often has detrimental effects that result in reduced annual species diversity and abundance, an increase in perennial species, and a reduction of biotic crust (when present).

Regional climate models project mean annual temperature increases of 1.5-4.7°C. The projected impacts will be warmer winter temperatures, with the greatest season increase in summer temperatures of 1.9-5.2°C. Precipitation scenarios show a larger range, with increases in annual, winter, spring and fall amounts by +2.8 to +7.2 inches (mean values), but summer time (June, July and August) predictions are more dire, with decrease of 5.6 to 7.5 inches (mean values) with min and max ranging from -33.6 to +12.4 inches of moisture (Dalton et al. 2013). Less precipitation in summer combined with warmer summer-time temperatures can mean shallower pool depths, reducing growing season impacted native plant and native aquatic species reproductive cycles. Some pools may disappear altogether, or remain in a dry state for more years.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from continuous heavy grazing which results in a complete change in the vegetative composition and disruption of hydrologic regime. Environmental Degradation (from "success criteria" for vernal pool monitoring, Solomeshch et al. 2007): Any of these conditions or combination of conditions rates as high-severity: Vernal pool complex has been significantly reduced in size; soil disturbance evident throughout occurrence; hydrology has been altered either through reduction in lateral flow or too much flow from artificial runoff. Any of these conditions or combination of conditions rates as moderate-severity: Vernal pool complex has been somewhat reduced in size; soil disturbance is evident in only part of the occurrence; hydrology is intact to slightly altered.

Disruption of Biotic Processes (from Brown 1999, J. Rocchio pers. comm. 2013): Any of these conditions or combination of conditions rates as high-severity: significant reduction of native annual cover, loss of native annual vascular diversity and >10% absolute cover of non-native plant species. Any of these conditions or combination of conditions rates as moderate-severity: moderate reduction of native annual cover, loss of native annual vascular diversity and >2-5% absolute cover of non-native plant species.

CES206.948 Northern California Claypan Vernal Pool

CES206.948 CLASSIFICATION

Concept Summary: These systems are shallow ephemeral waterbodies found in depressions (up to several hectares in size) among grasslands and open woodlands throughout the northern Central Valley of California. Northern claypan vernal pools include a clay hardpan that retains water inputs throughout some portion of the spring, but typically the depression dries down entirely into early summer months. They tend to be circumneutral to alkaline and slightly saline wetlands with characteristic plant species including *Downingia bella, Downingia insignis, Cressa truxillensis, Plagiobothrys leptocladus (= Allocarya leptoclada), Pogogyne douglasii, Eryngium aristulatum, Veronica peregrina, Lasthenia ferrisiae, Lasthenia glaberrima*, and *Spergularia salina (= Spergularia marina)*. Due to draw-down characteristics, vernal pools typically form concentric rings of similar forb-rich vegetation. Given their relative isolation in upland-dominated landscapes, many endemic and Federally-listed plant species are common in California vernal pools.

CES206.948 CONCEPTUAL MODEL

Environment: These systems are shallow ephemeral waterbodies found in depressions (up to several hectares in size) among grasslands and open woodlands throughout the northern Central Valley of California. Northern claypan vernal pools include a clay hardpan that retains water inputs throughout some portion of the spring, but typically the depression dries down entirely into early summer months. They tend to be circumneutral to alkaline and slightly saline wetlands. Pool depth rarely exceeds 50 cm (Solomeshch et al. 2007).

Key Processes and Interactions: Vernal pools are precipitation-filled seasonal wetlands inundated during the growing season, allowing for plant growth, followed by a brief water-logged terrestrial stage and culminating in complete drying of surface and subsurface soils. Inundation during the growing season eliminates establishment of upland species in the pool basins and the dry period prevents the establishment of many typical wetland taxa (Keeley and Zedler 1998). Pool filling is a combination of direct precipitation and lateral flow among pools within a complex of pools and subsurface flow from uplands which buffers pool volume, keeping them filled into the dry season (Hanes and Stromberg 1998). Subsurface soils have a hard pan of clay that prevents drainage. What is unique about vernal pools is the seasonality of the wetting period followed by the desiccation period, which generally is supported by a Mediterranean climate (Keeley and Zedler 1998) and resulted in development of diverse and highly endemic vegetation (Barbour et al. 2003, 2005, Solomeshch et al. 2007). Natural fire regimes for vernal pools are generally unknown, but are assumed to be similar to their surrounding upland grassland fire regimes (Wills 2006). Fire can have a positive effect on vernal pool vegetation as it can results in robust response by native grasses and can reduce non-native invasive woody and non-native herbaceous species (Pollak and Kan 1998).

Threats/Stressors: Agricultural conversion, urban development have resulted in widespread loss of vernal pools throughout California. Losses also result from mining disturbance, altered hydrology, inappropriate livestock grazing, contaminants in the water, disruptive recreational use (off-road vehicles and pathways), decline of specialist pollinators (Holland 1998, 2009, Solomeshch et al. 2007). Common stressors and threats include land use that disturbs or disrupts the hardpan nature of the soils changing soil drainage, continuous heavy grazing, introduction of and dominance by non-native species, fragmentation by agriculture, storm-water runoff, sedimentation and modified fire regimes (Barbour 1998, Robins and Vollmar 2002, Calderaro 2011). Grazing too little should be considered as a threat to these systems as well as overgrazing (Marty 2005).

In the Central Valley, regional climate models project mean annual temperature increases of 1.4-2.0°C (1.8-3.6°F) by 2070. The projected impacts will be warmer winter temperatures; earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 47-175 mm (1-7 inches) by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Less precipitation and warmer temperatures can mean shallower pool depths, reducing growing season impacted native plant and native aquatic species reproductive cycles. Some pools may disappear altogether, or remain in a dry state for more years, making more susceptible to conversion.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from reduction of vernal pool complex size by encroaching agricultural, which removes the buffering capacity of the pools, land use that disrupts lateral subsurface flow into and between pools, and damage to clay pan such that water no longer stays on the surface, eliminating pool filling. Environmental Degradation (from "success criteria" for vernal pool monitoring, Solomeshch et al. 2007): Any of these conditions or combination of conditions rates as high-severity: Vernal pool complex has been significantly reduced in size; soil disturbance evident throughout occurrence; hydrology has been altered either through reduction in lateral flow or too much flow from artificial runoff. Any of these conditions or combination of conditions rates as moderate-severity: Vernal pool complex has been somewhat reduced in size; soil disturbance is evident in only part of the occurrence; hydrology is intact to slightly altered.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: invasive species are abundant; cover and number of endemic species is at or below minimum found in reference sites, mosaic of community types is reduced to only 1 or 2 communities. Any of these conditions or combination of conditions rates as moderate-severity: invasive species present but not in higher cover than native species in cover; number and cover of endemic species near minimum values found in reference sites; mosaic of community types is near the minimum of reference sites.

2.C.4.Nc. Southwestern North American Warm Desert Freshwater Marsh & Bosque

M076. Warm Desert Lowland Freshwater Marsh, Wet Meadow & Shrubland

CES302.752 North American Warm Desert Riparian Mesquite Bosque

CES302.752 CLASSIFICATION

Concept Summary: This ecological system consists of low-elevation (<1100 m) riparian corridors along perennial and intermittent streams in valleys of the warm desert regions of the southwestern U.S. and adjacent Mexico. Rivers include the lower Colorado (within and downstream of the Grand Canyon), Gila, Santa Cruz, Salt, lower Rio Grande, Pecos (up to near its confluence with Rio Hondo), and their tributaries that occur in the desert portions of their range. Dominant trees include *Prosopis glandulosa* and *Prosopis velutina*. Shrub dominants include *Baccharis salicifolia, Pluchea sericea*, and *Salix exigua*. Woody vegetation is relatively dense, especially when compared to drier washes. Vegetation, especially the mesquites, tap groundwater below the streambed when surface flows stop. Vegetation is dependent upon annual rise in the water table for growth and reproduction.

Related Concepts:

Distribution: This system is found along perennial and intermittent streams in valleys of southern Arizona, southern Nevada, southeastern California, New Mexico, western Texas, and adjacent Mexico. M061. Eastern North American Cool Temperate Seep

CES202.300 Southern and Central Appalachian Bog and Fen

CES202.300 CLASSIFICATION

Concept Summary: This system consists of wetlands associated with flat sites in the Southern Blue Ridge, Central Appalachians, Cumberland Mountains, and possibly upper Piedmont and adjacent Ridge and Valley. These sites occur at elevations below 1220 m (4000 feet) in poorly drained bottomlands on soils which are often saturated and mucky. Wetness results from a combination of groundwater input, seepage from adjacent slopes, rainfall and impeded drainage. The amount of seepage water input is variable among examples, and these wetlands are typically primarily depressional. Vegetation is at least partially open, with herbaceous-dominated areas as well as shrub thickets and often forested zones. Vegetation is a complex of zones or patches with a mix of physiognomies. The wettest areas have herbaceous vegetation dominated by *Carex* spp., usually with abundant *Sphagnum*. Scattered trees and shrubs may be present in the herbaceous zones. Most examples also have a dense shrub zone around the edges. Some examples have forested zones as well, around the edges or as a matrix in which numerous small herbaceous openings are embedded. Characteristic tree species are *Tsuga canadensis, Acer rubrum, Nyssa sylvatica*, and *Pinus rigida*. Characteristic shrubs include *Rhododendron maximum, Alnus serrulata, Viburnum nudum var. cassinoides*, and *Toxicodendron vernix*.

Distribution: This system ranges from the southern Appalachians of northern Georgia and South Carolina north to Virginia. It is also found in the Cumberland Mountains of Kentucky.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, M. Pyne, S.C. Gawler and C. Nordman

CES202.300 CONCEPTUAL MODEL

Environment: This system occurs in patches in flat valley bottoms, usually on the outer edges of stream floodplains at elevations below 1220 m (4000 feet). The soil is saturated most or all of the year, at least in the wettest parts, and may be very mucky. Although sites rarely flood, wetness results from a combination of groundwater input, rainfall, seepage from adjacent slopes, and impeded drainage. The groundwater is usually highly acidic and low in dissolved bases, but one or a few examples have somewhat calcareous water input because groundwater flows through mafic rock substrates. Overland flow and stream flooding are presumably only rare events. The geologic substrate is usually alluvium. Often, but not always, there is an adjacent slope with a seep at its base or some visible microtopographic feature, such as a stream levee or ridge, that impedes water drainage out of the area. Some occurrences have substantial microtopography of abandoned stream channels or ridge-and-swale systems that pond water in low areas.

Key Processes and Interactions: The natural dynamics of this system are not well known and are subject to debate. The factors that created and naturally maintain this system are unclear. Most examples show a strong tendency at present for shrubs and trees to increase in density in the open areas, threatening to eliminate the characteristic herb species. This suggests that an important process has been altered or lost. One hypothesis is that bogs are an ephemeral feature developing from abandoned beaver ponds. Another hypothesis is that they result from a narrow combination of moisture and nutrient conditions, which have been widely altered in an obscure way that has changed ecosystem stability. The cattle grazing that was nearly universal in examples of this system in the past appears to have delayed woody succession but may also have altered the natural characteristics. Fire is sometimes considered as a factor, but most examples do not appear flammable enough to burn. Besides woody encroachment, bogs may be altered by changes in adjacent drainage, such as entrenchment by streams.

Threats/Stressors:

Ecosystem Collapse Thresholds:

M069. Eastern North American Marsh, Wet Meadow & Shrubland

CES205.687 Eastern Great Plains Wet Meadow-Prairie-Marsh

CES205.687 CLASSIFICATION

Concept Summary: This system is found along creeks and streams from Nebraska and Iowa to Illinois, and from Minnesota to Texas. It is also found in depressions and along lake borders, especially in the northern extension of its range into Minnesota. It is often adjacent to a floodplain system but is devoid of trees and riparian vegetation. It is also distinguished from upland prairie systems by having more hydrology, especially associated with silty, dense clay soils that are often hydric, classified as Vertic Haplaquolls. The landform is usually floodplain or poorly drained, relatively level land. The vegetation is dominated by *Spartina pectinata, Tripsacum dactyloides*, numerous large sedges, such as *Carex frankii* and *Carex hyalinolepis*, and in wetter areas, *Eleocharis* spp. Other emergent marsh species such as *Typha* spp. can be associated with this system. Forbs can include *Helianthus grosseserratus, Vernonia fasciculata*, and *Physostegia virginiana*. Some parts of this system may be saline and have species such as *Distichlis spicata* and *Bolboschoenus maritimus (= Schoenoplectus maritimus)*. Fire has been the primary influence in keeping these wet areas free of trees. Other dynamic processes include grazing and flooding (often in late spring). Many areas have been converted to agricultural, but this usually requires some sort of drainage.

Related Concepts:

- Eastern Great Plains Wet-Meadow, Prairie and Marsh (Rolfsmeier and Steinauer 2010) =

Distribution: This system is found throughout the northeastern Great Plains ranging from eastern Kansas to western Illinois and north into Minnesota.

Nations: US

Concept Source: S. Menard and K. Kindscher

Description Author: S. Menard and K. Kindscher

CES205.687 CONCEPTUAL MODEL

Environment: This system is found primarily on silty and/or dense clay, hydric soils, usually classified as Vertic Haplaquolls. It is found within poorly drained, relatively level areas.

Key Processes and Interactions: Fire and grazing can affect this system. Fire could spread from adjacent upland prairie, especially in the fall when water levels tended to be low and vegetation was driest. The wet prairie/wet meadow zone burned most frequently, but in the fall, dense, dry tall emergent vegetation in shallow or deep marshes could carry fire, as well. These fires could remove standing dead vegetation, allowing more light to reach the ground and returning nutrients to the soil, but they did not result in a conversion to a different system. In the eastern portion of this system's range, fire was more important in keeping woody species from invading. Native ungulates grazed the margins of potholes and used them as water sources. Muskrats live in larger, wetter potholes and, when populations get high, can have significant effects on the vegetation by eating *Typha* spp. and substantially reducing its cover. Flooding or saturation of sites for part of the growing season is required for the dominant species to survive over time. Grazing during the late summer or other dry periods can result in significant reduction in herbaceous cover but, in general, grazing is of lower importance than fire and flooding in maintaining this system.

Threats/Stressors: The primary threat to this system is drainage followed by conversion to agriculture or urban/infrastructure development. In addition to the direct effects of conversion of this system, landscape fragmentation from conversion of this or other related natural systems affects remaining stands by further reducing the opportunities for landscape-level fires, increasing the opportunities for exotic species to invade from nearby populations, and reducing the amount of suitable habitat that can be converted to this system as part of the natural fluid response to fire and precipitation. A lack of fire quickly results in invasion by shrubs and trees and conversion to a shrub swamp or swamp.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from alteration of the hydrologic regime which usually creates an upland setting not affected by periodic inundation. This allows native woody species and exotic herbaceous and woody species to expand. The fragmented nature of the landscape furthers this transformation by providing nearby seed sources for weedy species, and the lack of fire means species not adapted to periodic burning are able to grow on these sites. Severe environmental degradation occurs when the hydrologic regime is altered to the point that sites are no longer inundated during the growing season; the fire-return intervals are increased to the point that woody vegetation can become abundant. Moderate environmental degradation occurs when the hydrologic regime is altered such that growing-season inundation is reduced; the fire-return intervals are increased to the point that woody vegetation becomes common (10-25%). Severe disruption of biotic processes occurs when woody vegetation is >25% canopy; when exotic species are abundant. Moderate disruption of biotic processes occurs when woody vegetation is 10-25% canopy; when exotic species are common.

CES202.033 Great Lakes Freshwater Estuary and Delta

CES202.033 CLASSIFICATION

Concept Summary: This system is found throughout the southern Great Lakes Basin in the United States and Canada. It can include many associated wetlands occurring along portions of tributary rivers and streams that are directly affected by Great Lakes water regimes. It also forms much of the St. Clair River delta. Species distributions and community patterns are determined by multiple abiotic factors, including the type of aquatic system (major river channels, smaller tributary rivers, major deltas, or estuarine), Great Lakes water-level fluctuations, surficial bedrock, glacial landform, climate, and land use. Although wetland species are generally widely distributed, those of more temperate prairie regions are found in the southern parts of the basin. Vegetation types found across this diverse set of abiotic factors can be placed into a number of zones, though not all are present at a given site. The first four zones are typically inundated directly by lake waters: (a) submergent marsh; (b) emergent marsh; (c) shore fen; and (d) shoreline or strand. The next set of zones are inland from the water's edge and include (e) herbaceous and shrubby wet meadows and (f) shrub or wooded swamps.

This system can be divided into a number of geographical variants, based on the various community types found across the range of the system: (1) Lake Michigan Lacustrine Estuary; (2) Lake Erie-St. Clair Lakeplain Marsh; (3) Lake Ontario Lagoon Marsh; and (4) St. Lawrence River Estuary.

Related Concepts:

Distribution: Throughout the southern Great Lakes Basin in the United States and Canada.

Concept Source: D. Albert and L. Minc

Description Author: D. Albert, L. Minc

CES202.033 CONCEPTUAL MODEL

Environment: Species distributions and community patterns are determined by multiple abiotic factors. Great Lakes water-level fluctuations, surficial bedrock, glacial landform, climate, and land use. Great Lakes water level fluctuate over at least three temporal time scales: first, short-term fluctuations caused by winds or barometric pressures; second, seasonal fluctuations reflecting the annual hydrologic cycle in the basin; and third, interannual fluctuations in lake level as a result of variable precipitation and evaporation within the drainage basin. Interannual fluctuations can be as much as 1.3-2.5 m, with apparently little or no periodicity. These fluctuations, which also alter turbidity, nutrient availability, ice scour zones, etc., cause locational shifts in vegetation zones, but also in the composition of these zones, as species have individual tolerance limits.

The major bedrock distinction in the Great Lakes Basin is between igneous and metamorphic bedrock of the Precambrian period and younger (Paleozoic) sedimentary bedrock. The igneous and metamorphic bedrock form the rugged north shore of Lake Superior and Georgian Bay, and line much of the St. Lawrence River; they are locally present on the south shore of western Lake Superior. They lack the shallow protected waters and fine-textured substrates that support broad coastal wetlands. Where such bedrock is at or near the surface, it forms soils that are nutrient-poor and acidic. The rest of the basin is dominated by softer, sedimentary bedrock, which, with its broad, horizontal depositions, favors broad zones of shallow waters. The sedimentary rocks are typically more alkaline (calcareous), forming soils that are nutrient- and moisture-rich loams and clays. Bedrock patterns are overlaid by glacial landforms that, in combination with recent long-shore transport processes, create the prevalent physiographic features of the shorelines. In the lakes themselves, sand lakeplains, clay lakeplains, and moraines are shaped by currents, and the long-shore transportation of sediments has created sand-spit embayments and swales, dune-swale complexes, and tombolos. Channels and rivers contain channel-side wetlands, embayments, and deltas, and estuaries form as either open or barred river mouths. It is this diversity of landforms that has given rise to a diverse set of vegetation types.

Finally, regional patterns of climate affect the basin. The strong latitudinal gradient from southern Lake Erie to northern Lake Superior creates marked differences in length of growing season and solar radiation. Although wetland species are generally widely distributed, those of more temperate and prairie regions are found in the southern parts.

CES202.027 Great Lakes Wet-Mesic Lakeplain Prairie

CES202.027 CLASSIFICATION

Concept Summary: This system is found on the lakeplain near the southern central Great Lakes of the United States and Canada. Stands occur on level, sandy glacial outwash, sandy glacial lakeplains, and deposits of dune sand in silty/clayey glacial lakeplains. The soils are sands and sandy loams, loams with poor to moderate water-retaining capacity, typically occurring over less permeable silty clays . There is often temporary inundations after heavy rains or in the spring, followed by dry conditions throughout much of the remaining growing season. The vegetation of this system is dominated by graminoid species typically 1-2 m high. Trees and shrubs are very rare. There is very little bare ground. *Andropogon gerardii, Calamagrostis canadensis, Carex* spp. (*Carex aquatilis, Carex bicknellii, Carex buxbaumii, Carex pellita*), *Panicum virgatum, Spartina pectinata, Schizachyrium scoparium*, and *Sorghastrum nutans* are the most abundant graminoid species. Many of the sites that this system formerly occupied are now urban and/or agricultural. Areas around Chicago and Detroit were likely in this system but are heavily converted now and few sites remain. Remnant sites have been impacted by woody encroachment of native and non-native species.

Related Concepts:

Distribution: This system is found near the southern central Great Lakes of the United States and Canada, from southeastern Wisconsin and northeastern Illinois to southern Michigan and southwestern Ontario. This does not go farther east than northwestern Ohio (glacial Lake Maumee).

Nations: CA, US

CES202.027 CONCEPTUAL MODEL

Environment: Stands occur on level, sandy glacial outwash, sandy glacial lakeplains, and deposits of dune sand in silty/clayey glacial lakeplains. The soils are sands, sandy loams, and loams with poor to moderate water-retaining capacity and typically occur over less permeable silty clays. The shallow, less permeable silty clays and the flat landscape combine to favor temporary inundations after heavy rains or in the spring. The coarser surface soils then dry out throughout much of the remaining growing season. These occurred in a patchy landscape of both drier oak woodland/savanna and more mesic beech-maple forest. Pin oak depressions were common in these prairies.

Key Processes and Interactions: The cycle of soils being temporarily inundated and then drying out during the growing season is important for this system. Great Lakes water levels also affected this system with longer-term increases and decreases creating wetter and drier baseline conditions, respectively. Graminoids and forbs can thrive under these conditions but woody species are inhibited. The dry conditions and abundance of herbaceous vegetation creates conditions well-suited for burning and fires further reduced woody vegetation. Drier sites and those in a drier landscape burned more frequently. Fires were most likely in dry years after a productive year(s) when biomass was higher. Fire regime was probably related to the adjacent oak savannas but likely a little less frequent. Water levels were highly variable and boundaries of this system probably shifted across the landscape in response to fire, Great Lakes water levels, and wetter or drier climatic cycles.

Threats/Stressors: The primary threat to this system is drainage followed by conversion to agriculture or urban/infrastructure development. This system was concentrated in highly developed areas of the Midwest near what is now metropolitan Detroit, Chicago, Milwaukee, and northern Indiana. From the early 1800s to the 1990s, more than 99% of presettlement ~Great Lakes Wet-

Mesic Lakeplain Prairie (CES202.027)$$ was destroyed (Comer et al. 1995b). Expanding urban infrastructure and alterations to drainage patterns continue to threaten remaining sites. In addition to the direct effects of conversion of this system, landscape fragmentation from conversion of this or other related natural systems affects remaining stands by further reducing the opportunities for landscape-level fires, increasing the opportunities for exotic species to invade from nearby populations, and reducing the amount of suitable habitat that can be converted to this system as part of the natural fluid response to fire, Great Lakes water levels, and precipitation. Invasive species that threaten the diversity and vegetative structure in lakeplain wet-mesic prairie include *Elaeagnus umbellata, Frangula alnus (= Rhamnus frangula), Lythrum salicaria, Phalaris arundinacea, Phragmites australis, Rhamnus cathartica, Rosa multiflora, Typha angustifolia*, and *Typha x glauca* (Kost et al. 2007).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from alteration of the hydrologic regime which usually creates an upland setting not affected by periodic inundation. This allows native woody species and exotic herbaceous and woody species to expand. The fragmented nature of the landscape furthers this transformation by providing nearby seed sources for weedy species, and the lack of fire means species not adapted to periodic burning are able to grow on these sites. Severe environmental degradation occurs when the hydrologic regime is altered to the point that sites are no longer inundated during the growing season; the fire-return intervals are increased to the point that woody vegetation can become abundant. Moderate environmental degradation occurs when the hydrologic regime is altered such that growing-season inundation is reduced; the fire-return intervals are increased to the point that woody vegetation becomes common (10-25%?); the landscape is fragmented. Severe disruption of biotic processes occurs when woody vegetation is >25% canopy; when exotic species are abundant. Moderate disruption of biotic processes occurs when woody vegetation is 10-25% canopy; when exotic species are common.

CES201.594 Laurentian-Acadian Freshwater Marsh

CES201.594 CLASSIFICATION

Concept Summary: These freshwater emergent and/or submergent marshes are dominated by herbaceous vegetation. They are common throughout the northeastern United States and adjacent Canadian provinces. Freshwater marshes occur in closed or open basins that are generally flat and shallow. They are associated with lakes, ponds, slow-moving streams, and/or impoundments or ditches. The herbaceous vegetation does not persist through the winter. Scattered shrubs are often present and usually total less than 25% cover. Trees are generally absent and, if present, are scattered. The substrate is typically muck over mineral soil. Examples of vegetation in the Delaware Estuary freshwater marsh communities include *Typha latifolia, Typha angustifolia, Phragmites australis, Schoenoplectus americanus, Thelypteris palustris, Impatiens capensis, Carex* spp., *Vallisneria americana, Potamogeton perfoliatus, Nuphar advena (= Nuphar lutea ssp. advena)*, and *Nymphaea odorata*.

CES201.582 Laurentian-Acadian Wet Meadow-Shrub Swamp

CES201.582 CLASSIFICATION

Concept Summary: This system encompasses shrub swamps and wet meadows on mineral soils of the Northeast and upper Midwest. They are often associated with lakes and ponds, but are also found along streams, where the water level does not fluctuate greatly. They are commonly flooded for part of the growing season but often do not have standing water throughout the season. The size of occurrences ranges from small pockets to extensive acreages. The system can have a patchwork of shrub and graminoid dominance; typical species include *Salix* spp., *Cornus amomum, Alnus incana, Spiraea alba, Calamagrostis canadensis*, tall *Carex* spp., and *Juncus effusus*. Trees are generally absent and, if present, are scattered.

CES202.899 North-Central Interior Freshwater Marsh

CES202.899 CLASSIFICATION

Concept Summary: This system is found throughout the northern Midwest ranging into southern Canada. It is typically found on glacial potholes, along small streams, ponds, channels in glacial outwash and on lakeplains. This system contains a deep to shallow area of freshwater marsh dominated by emergent and submergent species. Stands may be open ponds with floating or rooted aquatics, or deep marsh with bulrush or cattails, and range from fairly small to several acres. It contains hydric soils flooded by water ranging from several centimeters to over 1 meter for most of the growing season. Emergent marsh species such as *Typha* spp. and *Schoenoplectus* spp. dominate this system with an occasional scattering of tall *Carex* spp. and forbs that can vary from dense to open cover. Trees are generally absent and, if present, are scattered. Submergent wetlands include a variety of macrophytes.

CES202.701 North-Central Interior Wet Meadow-Shrub Swamp

CES202.701 CLASSIFICATION

Concept Summary: This system is found throughout the northern Midwest ranging into southern Canada. It is typically found on glacial potholes, river valleys, ponds, channels in glacial outwash, and on lakeplains. This system contains a deep to shallow area of freshwater marsh dominated by emergent species surrounded by a zone of wet meadow. The emergent marsh zone within this system contains hydric soils flooded by water ranging from several centimeters to over 1 meter for most of the growing season. Emergent marsh species such as *Typha* spp. and *Schoenoplectus* spp. dominate the core of this system. Wet meadows can surround the emergent marsh core along wet mineral soils or shallow peat with the water table typically just below the surface for most of the growing season. The vegetation in this zone of the system is dominated by sedges (*Carex* spp.) and grasses such as *Calamagrostis canadensis*. This system also can contain a zone of wet prairie species such as *Spartina pectinata*. Shrub swamps can also be associated with the wet meadows within this system. Typical shrub species include *Cornus* spp., *Salix* spp., and/or *Cephalanthus occidentalis*. Trees are generally absent and, if present, are scattered. Fire originating in adjacent uplands, as well as hydrology, can influence this system. In the absence of fire, drought and/or ditching can increase the proportion of shrubs compared to the wet meadow or prairie species.

CES201.722 Northern Great Lakes Coastal Marsh

CES201.722 CLASSIFICATION

Concept Summary: This system is found throughout the northern Great Lakes Basin in the United States and Canada. This system, which can include many associated wetlands, occurs along the Great Lakes shoreline directly affected by Great Lakes water regimes. Species distributions and community patterns are determined by multiple abiotic factors, including Great Lakes water-level fluctuations, surficial bedrock, glacial landform, climate, and land use. Although wetland species are generally widely distributed, those of more boreal and subarctic regions are found in the northern parts of the basin.

Vegetation types found across this diverse set of abiotic factors vary in any number of ways, but they can be placed into a number of zones, though not all are present at a given site. The first four zones are typically inundated directly by lake waters: (a) submergent marsh; (b) emergent marsh; (c) shore fen; and (d) shoreline or strand. The next set of zones are inland from the water's edge and include (e) herbaceous and shrubby wet meadows and (f) shrub or wooded swamps.

This system can be divided into a number of geographical variants, based on the various community types found across the range of the system: (1) Lake Superior Poor Fen; (2) Northern Rich Fen; (3) Northern Great Lakes Marsh; (4) Green Bay Disturbed Marsh; (5) Lake Michigan Lacustrine Estuary; (6) Saginaw Bay Lakeplain Marsh; (7) Lake Erie-St. Clair Lakeplain Marsh; (8) Lake Ontario Lagoon Marsh; and (9) St. Lawrence River Estuary.

Related Concepts:
Distribution: This system is found throughout the northern Great Lakes Basin in the United States and Canada.
Nations: CA, US
Concept Source: D. Albert
Description Author: D. Albert

CES201.722 CONCEPTUAL MODEL

Environment: Species distributions and community patterns are determined by multiple abiotic factors. Great Lakes water-level fluctuations, surficial bedrock, glacial landform, climate, and land use. Great Lakes water level fluctuate over at least three temporal time scales: first, short-term fluctuations caused by winds or barometric pressures; second, seasonal fluctuations reflecting the annual hydrologic cycle in the basin; and third, interannual fluctuations in lake level as a result of variable precipitation and evaporation within the drainage basin. Interannual fluctuations can be as much as 1.3-2.5 m, with apparently little or no periodicity. These fluctuations, which also alter turbidity, nutrient availability, ice scour zones, etc., cause locational shifts in vegetation zones, but also in the composition of these zones, as species have individual tolerance limits.

The major bedrock distinction in the Great Lakes Basin is between igneous and metamorphic bedrock of the Precambrian period and younger (Paleozoic) sedimentary bedrock. The igneous and metamorphic bedrock form the rugged north shore of Lake Superior and Georgian Bay, and line much of the St. Lawrence River; they are locally present on the south shore of western Lake Superior. They lack the shallow protected waters and fine-textured substrates that support broad coastal wetlands. Where such bedrock is at or near the surface, it forms soils that are nutrient-poor and acidic. The rest of the basin is dominated by softer, sedimentary bedrock, which, with its broad, horizontal depositions, favors broad zones of shallow waters. The sedimentary rocks are typically more alkaline (calcareous), forming soils that are nutrient- and moisture-rich loams and clays. Bedrock patterns are overlaid by glacial landforms that, in combination with recent long-shore transport processes, create the prevalent physiographic features of the shorelines. In the lakes themselves, sand lakeplains, clay lakeplains, and moraines are shaped by currents, and the long-shore transportation of sediments has created sand-spit embayments and swales, dune-swale complexes, and tombolos. Channels and rivers contain channel-side wetlands, embayments, and deltas, and estuaries form as either open or barred river mouths. It is this diversity of landforms that has given rise to a diverse set of vegetation types.

Finally, regional patterns of climate affect the basin. The strong latitudinal gradient from southern Lake Erie to northern Lake Superior creates marked differences in length of growing season and solar radiation. Although wetland species are generally widely distributed, those of more boreal and subarctic regions are found in the northern parts of the basin, whereas those of more temperate and prairie regions are found in the southern parts.

M881. Eastern North American Riverscour Vegetation

CES202.036 Cumberland Riverscour

CES202.036 CLASSIFICATION

Concept Summary: Examples of this riverscour-influenced system may occur on high-gradient and very high-gradient streams in the gorges of the Cumberland Plateau, the Cumberland Mountains, and the more rugged parts of the Ridge and Valley in Kentucky, Tennessee, and Alabama, and possibly in Georgia. The succession of woody plants (particularly trees) is retarded by the force of "flashy," high-velocity water traveling down the stream channels. This system may occur on flood-scoured acidic or calcareous bedrock, cobble, pebble, or sandbar substrates of sandstone, limestone, dolomite, and possibly other sedimentary and weakly metamorphosed geologies. The most distinctive parts of the system are dominated by shrubs, perennial grasses, and forbs. In some areas, a riparian woodland composed of *Betula nigra* and *Platanus occidentalis* may be a component association. Some common shrubs include *Alnus serrulata, Betula nigra, Cephalanthus occidentalis, Cornus amomum, Fothergilla major, Itea virginica, Salix caroliniana, Rhododendron arborescens, Toxicodendron radicans*, and *Juniperus virginiana var. virginiana*. Some grasses (typical of prairies) include *Andropogon gerardii, Sorghastrum nutans, Schizachyrium scoparium, Chasmanthium latifolium, Tripsacum dactyloides*, and/or *Panicum virgatum*. Forbs are diverse and variable from occurrence to occurrence. This system is affected by flood-scouring in some areas and deposition in others. There is typically a gradient from dry, nutrient-poor conditions upslope to moist and relatively enriched conditions downslope. A variety of these conditions may exist at any one site. Some areas are prone to severe drought periods that may stress or kill some (particularly woody) vegetation. Flood-scouring is a powerful and ecologically important abrasive force along the riverbanks where this system is found.

Environment: Examples may occur on high-gradient and very high-gradient streams in the gorges of the Cumberland Plateau, the Cumberland Mountains, and rugged parts of the Ridge and Valley, in Kentucky, Tennessee, and Alabama, and possibly in Georgia. The succession of woody plants (particularly trees) is retarded by the force of "flashy," high-velocity water traveling down the stream channels. This system may occur on flood-scoured acidic or calcareous bedrock, cobble, pebble, or sandbar substrates of sandstone, limestone, dolomite, and possibly other sedimentary and weakly metamorphosed geologies. It is presumably more extensive and better developed in materials derived from sandstone, where the erodibility creates more material circulating in the stream to create the sandbar/gravelbar areas where the system may occur in extensive patches, and where the extremely well-drained qualities of the coarse sediments further help to retard woody plant succession.

Key Processes and Interactions: This system is prone to flooding in the upper regions and deposition in the topographically lower areas. There is typically a gradient from dry acidic conditions higher on the bank to moist, fairly enriched conditions lower down may exist at any one site. It is prone to severe drought periods that may stress or kill some vegetation. Flood scouring is a powerful and ecologically important abrasive force along the riverbanks where this system is found. Soils in sandstone areas are rapidly drained Psamments, and may be restricted to the narrow interstices of tightly packed boulders, or to small crevices in bedrock exposures. Within the system the various species are distributed patchily probably due to microsite conditions.

CES202.703 Ozark-Ouachita Riparian

CES202.703 CLASSIFICATION

Concept Summary: This system is found along streams and small rivers within the Ozark and Ouachita regions. In contrast to larger floodplain systems, this system has little to no floodplain development and often contains cobble bars and steep banks. It is higher gradient than larger floodplains and experiences periodic, strong flooding. It is often characterized by a cobble bar with forest immediately adjacent with little to no marsh development. Canopy cover can vary within examples of this system, but typical tree species include *Liquidambar styraciflua, Platanus occidentalis, Betula nigra, Acer* spp., and *Quercus* spp. The richness of the herbaceous layer can vary significantly, ranging from species-rich to species-poor. Likewise, the shrub layer can vary considerably, but typical species may include *Lindera benzoin, Alnus serrulata*, and *Hamamelis vernalis*. Small seeps and fens can often be found within this system, especially at the headwaters and terraces of streams. These areas are typically dominated by primarily wetland obligate species of sedges (*Carex* spp.), ferns (*Osmunda* spp.), and other herbaceous species such as *Impatiens capensis*. Flooding and scouring strongly influence this system and prevent the floodplain development found on larger rivers.

CES202.703 CONCEPTUAL MODEL

Environment: This system has little to no floodplain development and often contains cobble bars and steep banks. It is often characterized by a cobble bar with forest immediately adjacent with little to no marsh development. Because these habitats are moister than adjacent uplands, the streamside zones have much higher plant and animal diversity. Orchids and many other species of mesic habitats can be found here. At the larger end of the size continuum, these streams can have gravel and even sand bottoms that support a range of species, including *Salix* spp., *Justicia americana*, and others. Pools provide refugia for invertebrate and vertebrate species that can then rapidly recolonize the stream during high water.

Key Processes and Interactions: Flooding and scouring strongly influence this system and prevent the floodplain development found on larger rivers. It is traditionally higher gradient than larger floodplains and experiences periodic strong flooding. The distinctive dynamics of stream flooding are presumably the primary reason for the distinctive vegetation of this system, though not all of the factors are well known. Small rivers and streams, with small watersheds, have more variable flooding regimes that larger rivers. Floods tend to be of short duration and unpredictably variable as to season and depth. In addition to disturbance, floods bring nutrient input, deposit sediment, and disperse plant seeds. Fire does not appear to be a dominant factor, and most floodplain vegetation is not very flammable. Historical references to canebrakes dominated by *Arundinaria gigantea* suggest that fire may have once been more possible and more important in at least some portions.

Flooding is the major process affecting the vegetation, with the substrate more rapidly drained than in flat floodplain areas. The higher gradients of most of these streams and rivers limit floods to fairly short duration. Flooding is most common in the winter, but may occur in other seasons particularly in association with hurricanes, tornados, or microbursts from thunderstorms. Flood waters may have significant energy in higher gradient systems, but scouring and reworking of sediment are important in maintaining the small non-forested patches of the bar and bank communities. Flooding can act as a replacement disturbance in areas where beavers impounded a channel or in rare years with severe prolonged flood events. There are two general types of floods: occasional catastrophic, prolonged floods (due to beaver activity or other severe event); and more frequent repeated minor flooding (i.e., several minor floods within a 10-year period).

The wind disturbance associated with flooding is very significant along small streams because of wet and less dense soils and shallow-rooted trees. Canopy tree mortality from more common windstorms would have resulted in tree-by-tree or small group replacement. Windthrow is the primary cause of mortality in bottomlands. Major storms or hurricanes occurring at approximately 20 year intervals would have impacted whole stands.

In this system, the fire-return interval varies greatly. Except in canebrakes, most fires were very light surface fires, creeping in hardwood or pine litter with some thin, patchy cover of bottomland grasses. Flame lengths were mostly 15-30 cm (6-12 inches). Fire-scarred trees can be found in most small stream sites except in the wettest microsites. Stand-replacement fires are almost unknown in this type. Except where Native American burning was involved, fires likely occurred primarily during drought conditions and then often only when fire spread into bottomlands from more pyrophytic uplands. Trees may be partially girdled by fire in duff, followed by bark sloughing. While fire rarely killed the tree, this allowed entry of rot, which, in the moist environment, often resulted in hollow trees, providing nesting and denning habitat for many species of birds and animals. Surface fires occurred on a frequency ranging from about 3-8 years in streamside canebrake, streamside hardwood/canebrake, or pine, to 25 years or more in hardwood litter. Low areas having a long hydroperiod, islands, and areas protected from fire by back swamps and oxbows were virtually fire-free. Fire effects were largely limited to top-kill of shrubs and tree saplings less than 5 cm (2 inches) diameter, and formation of hollow trees.

Threats/Stressors: Undoubtedly, the greatest historic stressors have been the conversion to intensive agriculture in the 1850-1950 period (with subsequent abandonment and re-establishment of forest vegetation) and the construction of dams for mills, hydropower, and water supply during the same period. The threat of development is exacerbated by the current surge in population in northwestern and north-central Arkansas. Urban and exurban sprawl into previously forested lands outside the major communities is expected to continue to increase (Arkansas Forestry Commission 2010). This will lead to the conversion of sites to human-created land uses. In addition, invasive exotic species, including *Microstegium vimineum* and *Ailanthus altissima*, can become dominant in the ground and shrub layers following canopy disturbance. For hardwood forests containing *Fraxinus* species, emerald ash borer (which as of October 2013 has been reported from southeastern Missouri) may also be (or become) a significant stressor.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from removal of the canopy due to logging. It also results from fragmentation, in that smaller stands will not function ecologically, and will not provide habitat for characteristic animal species. Ecological collapse tends to result from repeated removal of the canopy and the failure of the characteristic hardwood tree species to regenerate. Ecosystem collapse has occurred where the native forest and herbaceous vegetation has been removed (as occurred throughout much of the region between about 1800 and 1950), and the land converted to agricultural uses (pasture and cropland). The construction of dams for mills, hydropower, and water supply during the recent historical period (ca. 1870 to 1950) has led to local ecological collapse due to impoundment of the areas behind the dams, as well as severe alteration of the flooding regime downstream.

CES303.654 Edwards Plateau Upland Depression

CES303.654 CLASSIFICATION

Concept Summary: This system includes shallow wetlands formed over limestone on the Edwards Plateau of Texas. Variable in size and duration of inundation, these wetlands are typically found on level uplands. Dominant vegetation includes both graminoids and forbs tolerant of wet periods but not necessarily wetland-dependent. Dominant species may include *Pleuraphis mutica, Bouteloua dactyloides, Sedum pulchellum, Sedum nuttallianum, Sporobolus vaginiflorus, Chaetopappa bellidifolia, Paronychia* spp., and the alga *Nostoc commune*. Some larger occurrences of this wetland system are found in Crocket, Reagan, Schleicher, Irion and Sterling counties in the northwest Edwards Plateau (the Eldorado Plateau). Formation of these occurrences is apparently from solution of the underlying limestone.

Related Concepts:

CES303.661 Great Plains Prairie Pothole

CES303.661 CLASSIFICATION

Concept Summary: The prairie pothole system is found primarily in the glaciated northern Great Plains of the United States and Canada, and is characterized by depressional wetlands formed by glaciers scraping the landscape during the Pleistocene era. This system is typified by several classes of wetlands distinguished by changes in topography, soils and hydrology. Many of the basins within this system are closed basins and receive irregular inputs of water from their surroundings (groundwater and precipitation), and some export water as groundwater. Hydrology of the potholes is complex. Precipitation and runoff from snowmelt are the principal water sources, with groundwater inflow secondary. Evapotranspiration is the major water loss, with seepage loss secondary. Most of the wetlands and lakes contain water that is alkaline (pH >7.4). The concentration of dissolved solids result in water that ranges from fresh to extremely saline. The flora and vegetation of this system are a function of the topography, water regime, and salinity. In addition, because of periodic droughts and wet periods, many wetlands within this system undergo vegetation cycles. This system includes elements of aquatic vegetation, emergent marshes, and wet meadows that develop into a pattern of concentric rings. This system is responsible for a significant percentage of the annual production of many economically important waterfowl in North America and houses more than 50% of North American's migratory waterfowl, with several species reliant on this system for breeding and feeding. Much of the original extent of this system has been converted to agriculture, and only approximately 40-50% of the system remains undrained.

Related Concepts:

Distribution: This system can be found throughout the northern Great Plains ranging from central Iowa northwest to southern Saskatchewan and Alberta, and extending west into north-central Montana. It encompasses approximately 870,000 square km with approximately 80% of its range in southern Canada. It is also prevalent in North Dakota, South Dakota, and northern Minnesota.

Concept Source: S. Menard

Description Author: S. Menard and J. Drake

CES303.661 CONCEPTUAL MODEL

Environment: This system is characterized by closed basins, potholes, that receive irregular inputs of water from the surroundings and may export water as groundwater. The climate for the range of this system is characterized by mid-continental temperature and precipitation extremes. Across the range of this system, precipitation triples from 30-90 cm (west to east) and average annual temperature increases from 1-10°C (north to south). Snowmelt and spring rains typically fill many of the potholes in examples of this system. The region in the range of this system is distinguished by a thin mantle of glacial drift overlying stratified sedimentary rocks of the Mesozoic and Cenozoic ages; these form a glacial landscape of end moraines, stagnation moraines, outwash plains and lakeplains. The glacial drift ranges 30-120 m thick and forms steep to slight local relief with fine-grained, silty to clayey soils. Soils in outwash plains are coarser. Limestone, sandstone, and shales predominate as bedrock, and highly mineralized water can discharge from these rocks. The hydrology of this system is complex with salinity ranging from fresh to saline, and chemical characteristics varying seasonally and annually. Sites with substantial surface or groundwater outlet are typically fresh while sites with little or no outlet tend to accumulate salts. Rain and snowmelt are the primary water sources with evapotranspiration being the source of major water loss. Some potholes are connected to groundwater sources and can serve as groundwater recharge sources, some receive groundwater outflow, and some have both. Water depth in most potholes is shallow. Many have a maximum depth of <2 m and most are <1 m deep (Sloan 1970). Seasonal water level fluctuations mean that the depth during much of the growing season is less than these maximums.

Key Processes and Interactions: A cycle of flooding and drying is the primary natural dynamic influencing this system. Snowmelt contributes substantially to the seasonal water input. In addition to runoff from snow melting within the watershed, snow tends to accumulate within the pothole due to the slightly more sheltered landscape position and the typically heavier and taller vegetation cover present in at least parts of the pothole. Spring rains contribute additional water, and potholes consistently have their yearly maximum water depth in late spring. Heavy rains in the summer can fill potholes, but the tendency is for water levels to fall as the growing season progresses. This fluctuation of water level during the year results in very different flooding regimes for different parts of the pothole. At the driest edge, the ground may be flooded or saturated for only a few weeks during the growing season, while the wettest parts of some potholes are flooded year-round. These different flooding regimes create environments favoring different types of plants and many potholes have strong zonation of vegetation (Johnson et al. 1987). From driest to wettest, these zones are wet meadow, shallow marsh, deep marsh, aquatic, and deep water. Many potholes do not have enough water to support the wetter vegetation zones so individual potholes may have shallow marsh at the center with a ring of wet meadow or deep marsh surrounded by shallow marsh which in turn is surrounded by wet meadow. The changes in water volume in a given pothole are also reflected in the salinity of the water. Prairie potholes are least saline in the spring when snowmelt and spring rains fill the wetland,

and possibly flush water out of the basin through seasonal overflow, but salinity increases as evapotranspiration reduces the volume of water in the basin throughout the growing season (Stewart and Kantrud 1972).

In addition to seasonal water level fluctuations, there are longer-term changes in water levels that affect prairie potholes (Kantrud et al. 1989a). Multi-year patterns of above or below average precipitation result in shifting vegetation zones within a single site. A multi-year dry period will cause a pothole to shrink, and the environments suitable for each vegetation zone will move towards the center, possibly eliminating the wettest zones altogether. A multi-year wet period will fill potholes, moving the environments conducive to each vegetation zone away from the center and possibly creating habitats for new, wetter zones in the middle. Changes in water depth of several feet are possible over a few to several years (Stewart and Kantrud 1972). These multi-year changes in the location of vegetation zones promote floristic diversity by creating shifting environments at any one place on the landscape. During the wetter seasonal or multi-year periods, temporary connections may be formed among otherwise discontinuous wetlands, allowing the spread of species and possibly affecting water chemistry through flushing of salts or other dissolved chemicals into or out of basins (Leibowitz and Vining 2003).

Fire and grazing can affect this system. Fire could spread from adjacent upland prairie, especially in the fall when water levels tended to be low and vegetation was driest. The wet prairie/wet meadow zone burned most frequently, but in the fall, dense, dry tall emergent vegetation in shallow or deep marshes could carry fire, as well. These fires could remove standing dead vegetation, allowing more light to reach the ground and returning nutrients to the soil, but they did not result in a conversion to a different system. In the eastern portion of this system's range, fire was more important in keeping woody species from invading. Native ungulates grazed the margins of potholes and used them as water sources. Muskrats live in larger, wetter potholes and, when populations get high, can have significant effects on the vegetation by eating *Typha* spp. and substantially reducing its cover (Kantrud et al. 1989b).

Threats/Stressors: The main threat to prairie potholes is changes to the hydrologic regime. Other important threats are overuse of sites for agricultural purposes, runoff from surrounding cropland, and introduction of exotic species. More than one of these may result from the same disturbance. Negative changes to the hydrologic regime often take the form of partial or complete drainage of potholes. This is typically done to allow the land to be used more consistently for crop production. Conversion to cropland completely destroys a prairie pothole, but even if the drainage is incomplete or done on nearby wetlands, it can harm the site. Partial drainage reduces the amount of water in a pothole, effectively shrinking it. Drainage of nearby wetlands can affect groundwater flow in a wider area, increasing or decreasing the amount of water flowing into nearby wetlands. Changes in landscape-level water drainage patterns can result in a more consistent water supply to a pothole and may reduce the multi-year water level and associated vegetation changes. Without these longer-term changes in water level, dense emergent vegetation dominated by a few species tends to take over the margins of these wetlands (Kantrud et al. 1989b).

The drier margins of prairie potholes are most susceptible to agricultural use. The wet meadow zone can be farmed in drier years and can be mowed for hay or used for grazing later in the growing season in most years. Moderate grazing or mowing is unlikely to have serious impacts, and may even increase diversity, but consistent heavy grazing or mowing usually reduces species diversity and vegetation cover and opens up sites for colonization by weedy species. Sites that are not directly used for any agricultural purpose can be negatively impacted by runoff from nearby fields. Row crops are more prone to erosion than pasture or small grains, but all can cause significant sedimentation of potholes, affecting water chemistry and turbidity and even filling them in over time (Preston et al. 2013). Runoff from agricultural fields can introduce pesticides, herbicides, and increased nutrient levels. Road construction through a pothole can affect water movement, effectively creating two new wetlands, and can cause increased sedimentation and chemical runoff from road maintenance.

The climate in the prairie pothole region became warmer and wetter during the 20th century but the effects were not uniform. The western edge became effectively drier while the eastern edge became effectively wetter (Millett et al. 2009). This is due to the greater increase in average temperature creating more evaporation compared to lesser increases in precipitation in the west and greater increases in the east. If this trend continues, it will shrink the potential range of this system on its western margins as those wetlands dry out, and convert some prairie potholes to permanent lakes or ponds on the eastern margin as increased precipitation eliminates the wet-dry cycle in some wetlands. This potential shift in the range of prairie potholes would also move more of the range out of the relatively less intensively farmed and drained landscape of the central and eastern Dakotas and southern Canadian Prairie Provinces and into the more intensively farmed areas of western Minnesota and northern Iowa where wetland draining and filling has been much more extensive (Johnson et al. 2005).

Prairie potholes are naturally dynamic and the native species in them respond quickly to changing environments so they have the potential to recover if the natural processes are returned and the seed bank is sufficiently intact.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the seasonal and multi-year hydrologic cycles characteristic of prairie potholes are greatly modified. Removal of water from the system transforms it to an upland and is often a precursor to increased use for crop or pastureland. Reduction in water input or an increase in drainage can shrink the size of these wetlands and possibly eliminate the deeper, wetter portions, transforming them to seasonally flooded shallow marshes or wet meadows. These shallow wetlands are quicker to disappear during the dry years of the climatic cycles. Use of the watershed for crop production increases the amount of sedimentation and runoff of pesticides and herbicides. Increased sedimentation and nutrient loads disproportionately affect submergent vegetation, where that is present (Adamus and Hairston 1996). These can change the composition of the plants and animal species, including the invertebrates that are so important to the waterfowl that use prairie potholes. Exotic species can dominate prairie potholes, particularly those that are consistently wet.

CES303.666 Western Great Plains Closed Depression Wetland

CES303.666 CLASSIFICATION

Concept Summary: Communities associated with the playa lakes in the southern areas of this province and the rainwater basins in Nebraska characterize this system. They are primarily upland depressional basins. This hydric system is typified by the presence of an impermeable layer such as a dense clay, hydric soil and is usually recharged by rainwater and nearby runoff. They are rarely linked to outside groundwater sources and do not have an extensive watershed. Ponds and lakes associated with this system can experience periodic drawdowns during drier seasons and years, and are often replenished by spring rains. *Eleocharis* spp., *Hordeum jubatum*, along with common forbs such as *Coreopsis tinctoria, Symphyotrichum subulatum*, and *Polygonum pensylvanicum* are common vegetation in the wetter and deeper depression, while *Pascopyrum smithii* and *Bouteloua dactyloides* are more common in drier playas such as shallow depressions in rangeland. Species richness can vary considerably among individual examples of this system and is especially influenced by adjacent land use, which is often agriculture, and may provide nutrient and herbicide runoff. Dynamic processes that affect these depressions are hydrological changes, grazing, and conversion to agricultural use. Additional species found in Texas examples include *Ambrosia grayi, Chenopodium leptophyllum, Helianthus ciliaris, Heteranthera limosa, Marsilea vestita, Oenothera canescens, Panicum obtusum, Phyla nodiflora, Sagittaria longiloba, Schoenoplectus* spp., and *Typha domingensis*.

Distribution: This system can be found throughout the eastern portion of the Western Great Plains Division, however, it is most prevalent in the central states of Nebraska, Kansas, Oklahoma, and Texas. In addition, it does occur farther to the west, in central and eastern Montana and eastern Wyoming.

Nations: US

Concept Source: S. Menard and K. Kindscher

Description Author: S. Menard, K. Kindscher, J. Drake

CES303.666 CONCEPTUAL MODEL

Environment: This system is typified by circular upland depressional basins with an impermeable layer such as dense clay which slows infiltration and promotes retention of water. Soils are hydric and fine-grained. Rainwater and runoff recharge this system and it is rarely linked to outside groundwater sources. Water is lost through both evapotranspiration and percolation to aquifers such as the Ogallala Aquifer in the Texas High Plains. It has been estimated that 20-80% of water in playas infiltrates into the aquifers, principally along the margins of the wetlands where subsurface clay content is less (Osterkamp and Wood 1987). Playas are shallow, generally less than 1 m deep, with very shallow sloping sides. This results in nearly equal water depths throughout the playa, and small changes in water depth have effects across a relatively large surface area. Playas in the Southern High Plains average 6.3 ha in area. These ephemeral wetlands have small watersheds. The average watershed size is 55.5 ha (Guthery and Bryant 1982). Playas are isolated, with no surface outflow except in unusually wet periods. In Texas, playas are typically lined by Vertisols included in Playa, Lakebed, or in some cases Clay Flat ecoclasses.

Key Processes and Interactions: Playas have a large change in hydrologic status over much of their areas. That is, most of the area of an individual playa is wet or flooded at one point in the growing season and also dry during another point in the growing season. Some do have deeper areas that are wet or flooded for nearly the entire growing season. More common is having multiple wet-dry cycles during one growing season in response to rain and dry periods. This rapid change in available moisture and in exposed soil limits the species that can grow. This often results in strong dominance by a few perennial species able to tolerate these conditions or by annuals that can go through their life cycle before conditions change (Haukos and Smith 1993). However, the unconnected nature of playas combined with the variable environmental conditions throughout the year favors the formation of differing assemblages of vegetation at any one time on playas across the landscape. This contributes to regional diversity of plant and animal habitats throughout the year (Haukos and Smith 1994). Fire can spread into this system from surrounding grasslands but it is uncommon. The surrounding grasslands are typically short and do not have sufficient fuel to carry fire well, and while playas usually have more dense vegetation cover than the adjacent uplands, they may be wet.

Threats/Stressors: Given their shallow nature, many playas can be cultivated during dry years, even without filling. This destroys existing vegetation, churns the upper soil profile, and increases the effects of wind erosion on the bare soil (Bolen et al. 1979). Playas are often ditched to increase their suitability for farming or dug out to create stock ponds or sources for irrigation water (Guthery and Bryant 1982). These activities decrease the amount of water over most or all of the playa. Deepening a portion of the playa creates a deeper, more permanent lake or pond habitat, as well as draining water from the remainder of the site. Sedimentation can be a serious problem, resulting from cultivation and increased erosion from the surrounding landscape (Luo et al. 1997). This causes filling of the shallow playas, reductions in hydroperiod, subsequent changes to vegetation, and makes the site more suitable for direct cultivation. Other physical disruptions to playas include island construction, road building, and filling (Haukos and Smith 1994). Islands have been built in larger, wetter playas as an attempt to create safer nesting habitat for waterfowl, while some smaller playas have been completely filled in to increase the area available for cultivation. Road building can split a playa in two, severing the hydrologic connection and serving as a point for the introduction of sediment and chemicals associated with road construction and maintenance. Playas are often favored for grazing, both by wildlife and livestock. Most large species of wildlife have been removed from or greatly reduced across the landscape, but livestock can greatly affect playas. Livestock often concentrate their grazing and associated trampling in playas in preference to the surrounding uplands. Vegetation in playas typically begins growth earlier in the year and has increased production in comparison to surrounding uplands, and the lower level of playas is a slightly more favorable microclimate during hard weather (Haukos and Smith 1993).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when playas are periodically used for production of crops or livestock or when the watershed is sufficiently altered so as to greatly change the input of water over the site. Alteration can come from conversion of the surrounding landscape to cropland, road construction, or the digging of irrigation ditches. These can result in increased or decreased water input, which alters the hydroperiod of the site. In addition to activities in the surrounding area, physical modifications to the site itself, ditching or digging out a portion of the playa, or intermittent use as cropland or grazing land, can also lead to ecological collapse.

Severe environmental degradation occurs when a site is used for the production of crops frequently; when the surrounding landscape is substantially converted to cropland, reducing the buffer of natural vegetation to <50 m (Faber-Langendoen et al. 2011); when >50% of a site is permanently converted to non-natural land use (crops, roads, ponds); or when the hydroperiod is changed such that the site is nearly always flooded or dry. Moderate environmental degradation occurs when a site is used for the production of crops occasionally; when the surrounding landscape is substantially converted to cropland, reducing the buffer of natural vegetation to 50-100 m (Faber-Langendoen et al. 2011); when 20-50% of a site is permanently converted to non-natural land use (crops, roads, ponds); or when the hydroperiod is changed such that the site is flooded or dry throughout much of the growing season. Severe disruption of biotic processes occurs when exotic species have >50% cover. Moderate disruption of biotic processes occurs when exotic species have 10-50% cover.

CES303.675 Western Great Plains Open Freshwater Depression Wetland

CES303.675 CLASSIFICATION

Concept Summary: This Great Plains emergent marsh ecological system is composed of lowland depressions; it also occurs along lake borders that have more open basins and a permanent water source through most of the year, except during exceptional drought years. These areas are distinct from ~Western Great Plains Closed Depression Wetland (CES303.666)$$ by having a large watershed and/or significant connection to the groundwater table. A variety of species are part of this system, including emergent species of *Typha, Carex, Eleocharis, Juncus, Spartina*, and *Schoenoplectus*, as well as floating genera such as *Potamogeton, Sagittaria, Stuckenia*, or *Ceratophyllum*. The system includes submergent and emergent marshes and associated wet meadows and wet prairies. These types can also drift into stream margins that are more permanently wet and linked directly to the basin via groundwater flow from/into the pond or lake. Some of the specific communities will also be found in the floodplain system and should not be considered a separate system in that case. These types should also not be considered a separate system if they are occurring in lowland areas of the prairie matrix only because of an exceptional wet year.

Related Concepts:

- Western Great Plains Open Freshwater Depression Wetland (Rolfsmeier and Steinauer 2010) **=**

Distribution: This system can occur throughout the Northwestern Great Plains Division but not in the arid shortgrass region.
Nations: US
Concept Source: S. Menard and K. Kindscher
Description Author: S. Menard, K. Kindscher, J. Drake

CES303.675 CONCEPTUAL MODEL

Environment: This system is found within lowland depressions and along lakes that have more permanent water sources throughout the year. These areas typically have a large watershed and are connected to the groundwater sources, resulting in a relatively consistent source of water for the semi-arid climate they occur in. Examples may also drift into stream margins that are more permanently wet and linked to a basin via groundwater flow from/into a pond or lake. Those areas that are found within larger prairie matrix that are only lowland or wet because of an exceptional wet year are not part of this system. This system occurs south of the limit of recent glaciation. Salinity ranges from fresh to brackish. Soils range from clay and silt to sandy loam. Marshes with coarser soils are usually connected more directly to the water table, which prevents rapid draining of the wetland.

Key Processes and Interactions: Hydrology is the primary process influencing this system. Examples of this system have a core area that is saturated or flooded much or all of the growing season. In some sites, water levels exceed 1 m throughout the growing season. Examples of this system receive water from groundwater flow, surface drainage from the watershed, and direct precipitation. In the northern half of the range of this system, snowmelt can cause a relatively large influx of water in the spring. Water levels are typically highest in the spring and generally fall throughout the growing season, with occasional refilling of the basin after very heavy summer rains. Changes in precipitation over a period of years or decades (wetter or drier periods) will increase or decrease the extent of individual examples of this system and can move the range of the entire system slightly.

Fires can occur in this system, often spreading from adjacent upland prairie. Fire is more common in the fall when water levels are lower and the vegetation has dried out. Fire is also more common in the eastern portion of the range of this system where surrounding uplands had more dense upland tallgrass prairie rather than the sparser mixedgrass uplands typical of the western range of this system.

Threats/Stressors: Grazing and other agricultural uses are the main threats to most sites and can significantly impact the hydrology and species composition of this system. A reduction in water input (through water diversion) or water retention (through drainage) is the most common threat to this system. Most wetlands in the Great Plains have had significant reductions in their hydrologic regime. This has resulted in many sites being destroyed by conversion for crop or livestock production (farmland, hayfields, or pastures) and has had a negative impact on others by shrinking the wetland, drying it out with loss of semipermanently or seasonally flooded portions and those species adapted to those conditions, and opening up the newly formed wet meadow and wet prairie zones to agricultural use and potential invasion by exotic species. Short of outright conversion to cropland, the drier edges of this system can be used for haying and grazing. Moderate use for those purposes does not usually have significant impacts but heavy and repeated use does. Repeated early- or mid-summer haying favors early-flowering sedges, forbs, and invasive grasses over warm-season native grasses and late-flowering forbs. Heavy, long-term grazing can reduce vegetation cover, create openings for weedy species and introduce weed seeds brought in by livestock. Some sites have been seeded to exotic forage species (Rolfsmeier and Steinauer 2010). Whether or not a site has been hydrologically altered, invasive species can degrade the site. Many species do well in the wet prairie and wet meadow zones, including some that can form near monocultures such as *Bromus inermis, Elymus repens (= Agropyron repens), Phalaris arundinacea, Phragmites australis*, and *Poa pratensis*. *Lythrum salicaria* and *Typha x glauca* can have similar impacts in wetter zones. Nearby crops fields lead to increased runoff into the wetlands, particularly row crops (Preston et al. 2013). This runoff includes sediments and pesticides and herbicides. Sediments increase turbidity and negatively affect germination and invertebrate populations (Gleason and Euliss 1998).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when sites in this system are drained or the water input is greatly reduced. Both result in a net reduction in water on the site which reduces the size of the wetland and shifts vegetation zones from wetter to drier, potentially eliminating some zones. Sites can recover if the seedbank is intact and water is returned. Farming of temporarily dried sites, whether dried through natural drought or drainage, can permanently convert a site by eliminating the native seed bed and allowing the introduction of weeds. Invasive species can transform a site when they become abundant and exclude most native species.

2.C.4.Ne. Atlantic & Gulf Coastal Marsh, Wet Meadow & Shrubland

M066. Atlantic & Gulf Coastal Fresh-Oligohaline Tidal Marsh

CES203.259 Atlantic Coastal Plain Embayed Region Tidal Freshwater Marsh

CES203.259 CLASSIFICATION

Concept Summary: Embayed region tidal freshwater marshes are characterized by fresh to oligohaline waters which are driven by irregular wind tides, with minimal lunar tidal influence. They are the predominant marsh system in the drowned creeks and inland estuary shores of the embayed region of northeastern North Carolina and adjacent Virginia. This system typically occurs as complexes of several associations dominated by large graminoids such as *Spartina cynosuroides, Cladium mariscus ssp. jamaicense, Schoenoplectus pungens, Typha angustifolia, Typha latifolia*, and *Juncus roemerianus*, sometimes with species-rich associations of shorter graminoids, forbs, and floating or submerged aquatic plants. While some association dominants are tolerant of brackish water, they are associated with plants restricted to oligohaline or freshwater. Irregular flooding and fire are both important forces in this system, and rising sea level is a particularly important driver of long-term trends.

Related Concepts:

Distribution: This system is restricted to the embayed region of North Carolina and Virginia, with the best development in coastal areas along the North Carolina-Virginia border. The transition to areas with more lunar tidal influence is fairly gradual to the south over a space of 50 miles.

Nations: US

Concept Source: R. Evans, M. Schafale, G. Fleming

Description Author: R. Evans, M. Schafale, G. Fleming, C. Nordman

CES203.259 CONCEPTUAL MODEL

Environment: The embayed region of the Mid-Atlantic Coastal Plain stretches along northeastern North Carolina and adjacent areas of Virginia. Estuaries in drowned river valleys are unusually extensive here. The barrier islands along the coast are unusually continuous and the ocean's tidal range modest. This produces estuaries where irregular wind tides are the dominant hydrological process. The water is oligohaline to fresh over most of the tidal areas, with brackish water near the coast and saltwater only on or near the barrier island inlets. Rainfall may be an important influence in marsh interiors for significant periods of time between high wind tides. Soils appear to be essentially always saturated, with shallow flooding for periods of several days at all times of year. Due to limited sediment transport, marsh soils are primarily organic. Marshes occur in small to large patches or bands along the drowned creeks and rivers. Most give way to tidal swamps inland and upstream, but some occur on islands. Those near the transition to brackish water may grade to wind tide-influenced brackish marshes downstream.

Key Processes and Interactions: Hydrology is the most important driving process, with the constant saturation determining the potential vegetation, and the variable flooding and variations in salinity in the fresh to brackish range a primary disturbance. Wind tides flood or expose the marshes at irregular intervals and transport nutrients and organic matter. Storm surges and unusually high tides associated with storms may bring saltier water into these systems, disturbing the less salt-tolerant plants. These disturbances may be an important factor determining the boundary between this system and adjacent tidal swamps, but this is not well documented. Rising sea level is an important driver of longer term vegetation trends, including expansion into adjacent swamp areas. Fire is also an important natural process in all but the smallest and most isolated patches. Frost (pers. comm.) estimates that many marshes burned as often as every three years in presettlement times and were an important source of ignition for adjacent communities. Marshes that have not burned recently have lower species richness, are more strongly dominated by the large graminoids, and are believed to be poorer habitat for waterfowl. Marshes often show evidence of transition to or from tree-dominated communities, in the form of young invading trees and shrubs or standing dead older trees. Lack of fire appears to be allowing sufficient tree invasion to eventually produce a swamp forest in some upstream examples, but the trend in most places is toward development of marshes in former swamp areas.

Threats/Stressors: Threats to this ecological system include hydrological alteration and saltwater intrusion, which may be worsened by channel dredging, subsidence and sea-level rise. Channel dredging is likely to be associated with oil and gas exploration and development of the tidewater area, and is a threat to these habitats. Filling these wetlands is a threat, such as is associated with development and road building projects. The construction of bulkheads and other coastal engineering structures threaten these dynamic wetlands (Bertness et al. 2004). Water pollution is a threat (including from urban stormwater runoff), which may lead to eutrophication and disrupt native species and lead to an increase in ruderal or invasive exotic species (Bertness et al. 2004). Lack of fire is a threat to some examples, which may have burned frequently in the past. Large dams such as on the Roanoke River have limited the transport of sediments into the tidewater marsh areas. Invasive plant species such as *Triadica sebifera*, introduced exotic *Phragmites australis*, and *Hydrilla verticillata* are threats. Some invasive exotic mammals are threats, such as nutria (*Myocastor coypus*) and feral hogs (*Sus scrofa*).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from hydrological alteration such as dredging, the intrusion of salt water, substrate erosion or accretion which can lead to the conversion to open water, or exotic species dominance, especially by introduced exotic *Phragmites australis*. Ecosystem collapse is characterized by conversion of the tidal herbaceous or shrub vegetation to open water, or native or exotic species dominated swamp forest. Invasive exotic plant species such as *Triadica sebifera*, introduced exotic *Phragmites australis*, or *Hydrilla verticillata* may be dominant in collapsed examples.

CES203.507 Florida Big Bend Fresh and Oligohaline Tidal Marsh

CES203.507 CLASSIFICATION

Concept Summary: This ecological system includes tidal freshwater and oligohaline marshes of the northern Gulf of Mexico along the Florida Big Bend area (roughly from Wakulla County to the Pasco/Hernando county line on Florida's west coast). The tidal range in this region is higher than in the western Panhandle, and wave energy is low; lunar, wind and seasonal tides make flooding irregular. In comparison to the matrix-forming salt and brackish marshes of the same region, this system is confined to small patches that are generally restricted to areas near the mouths of rivers where freshwater is abundant. This system is dominated by herbaceous graminoids tolerant of tidal flooding, but not tolerant of saltwater and with only a limited tolerance of true brackish conditions.

Related Concepts:

Distribution: Endemic to Florida from Wakulla County (Apalachicola Bay) to Pasco/Hernando county line, north of Tampa Bay.

Nations: US

Concept Source: R. Evans and C. Nordman

Description Author: R. Evans, C. Nordman, M. Pyne

CES203.507 CONCEPTUAL MODEL

Environment: The flooding regime is tidal (irregular) but influenced by the freshwater flows of rivers. This system occurs where there is adequate river flow and discharge to maintain fresh to oligohaline conditions, while still within tidal range. These marshes occur near the mouths and upstream, well inside the mouths of tidal creeks and rivers.

Key Processes and Interactions: The tidal range in this region is higher than in the western Panhandle, and wave energy is low; lunar, wind and seasonal tides make flooding irregular (Montague and Wiegert 1990). In times of drought and low freshwater flows, brackish water will reach upstream further, into areas which would normally be freshwater. This can be a disturbance which alters community structure, decreasing populations or fecundity of those species intolerant of brackish water.

Threats/Stressors: Threats to this ecological system include hydrological alteration and saltwater intrusion, which may be worsened by channel dredging, subsidence and sea-level rise. Filling these wetlands is a threat, such as is associated with development and road building projects. The construction of bulkheads and other coastal engineering structures threaten these dynamic wetlands (Bertness et al. 2004). While this marsh occurs along a relatively undeveloped part of Florida's coast, water pollution is an increasing threat (including from urban stormwater runoff), which may lead to eutrophication and disrupt native species and lead to an increase in ruderal or invasive exotic species (Bertness et al. 2004). Invasive plant species such as *Triadica sebifera*, introduced exotic *Phragmites australis*, and *Hydrilla verticillata* are threats. Some invasive exotic mammals are threats, such as nutria (*Myocastor coypus*) and feral hogs (*Sus scrofa*).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from hydrological alteration such as dredging, the intrusion of saltwater, erosion or accretion which can lead to the conversion to open water, or native- or exotic species-dominated swamp forest. Ecosystem collapse is characterized by conversion of the tidal herbaceous or shrub vegetation to open water, or native- or exotic species-dominated swamp forest.

CES203.467 Gulf Coast Chenier Plain Fresh and Oligohaline Tidal Marsh

CES203.467 CLASSIFICATION

Concept Summary: This system includes large expanses of tidal marshes, strongly influenced by freshwater, along the Chenier Plain of Louisiana and Texas. Fresh to oligohaline marsh is the most common marsh type of the Chenier Plain because of the unique geomorphology of the area. The Chenier Plain is characterized by a prograding coastline replenished by sediments carried to the Gulf of Mexico by the Atchafalaya and other rivers. It is void of barrier islands, and shoreline sediments are reworked by waves into beach ridges. This process has been continuing since the last glacial retreat, and as the coastline progrades, older beach ridges are left as interior ridges surrounded by marsh. Historically, there were very few natural connections between the marshes and the ocean, resulting in a predominance of fresh to oligohaline salinity. This is a highly threatened system in coastal Louisiana.

Related Concepts:
- Chenier Plain: Fresh and Intermediate Tidal Marsh (5807) [CES203.541.7] (Elliott 2011) **<**
- Chenier Plain: Fresh and Intermediate Tidal Shrub Wetland (5806) [CES203.541.6] (Elliott 2011) **<**

Distribution: This system extends from Vermillion Bay, Louisiana, through Jefferson County, Texas. It does not extend into Galveston Bay. Approximately 3000 square km of marshes were present in the Chenier Plain of Louisiana in 1997 and the majority of these were fresh to oligohaline marshes (Visser et al. 2000).
Nations: US
Concept Source: J. Teague and R. Evans
Description Author: J. Teague, R. Evans, M. Pyne and L. Elliott

CES203.467 CONCEPTUAL MODEL

Environment: This system occupies coastal sites with mucky soils and salinities generally less than 4 ppt. Soils are recent alluvial deposits. It occurs along bay margins and outlets of coastal rivers where freshwater inflow is sufficient to drive marsh composition. Sites may be interspersed with areas of open water. Soils are saturated, very deep, mineral soils, often with high organic content, at least at the surface. Ecoclasses (from Ecological Site Descriptions) include various fresh and intermediate marsh types (Elliott 2011). Coastal Louisiana contains about "37% of the estuarine herbaceous marshes in the conterminous U.S." (Glick et al. 2013).

Key Processes and Interactions: Historically, the deltaic processes of the Mississippi River helped to build and maintain this system. Sediments brought to the coast by the Mississippi River and its distributaries were carried west along the coast by longshore currents. The shifting over time of the location of the Mississippi River deltas resulted in variations in sediment availability which, along with other coastal processes, caused an alternating prograding and retreating chenier plain coastline. Sediments were reworked into beach ridges that trapped freshwater flowing coastward off the mainland resulting in a chenier plain of beach ridges (cheniers) alternating with large expanses of fresh to oligohaline marshes. Today, sediments from the Atchafalaya River are again forming mudflats in the chenier plain but not to the extent that was associated with Mississippi River deltaic processes (Gosselink et al. 1998). One of the few areas of coastal accretion in Louisiana is located in the eastern Chenier Plain, a process fed by sediments from the Atchafalaya. Given the predominance of coastal loss and subsidence in Louisiana, the accretion of the eastern Chenier Plain is unusual (Gosselink et al. 1998, Draut et al. 2005). In addition to local rainfall, freshwater entering the chenier plain marshes comes from rivers and streams, and is dependent on functioning hydrological processes in those systems. This marsh system is dependent upon freshwater input, sediment input and organic matter build-up. Species richness is typically higher in oligohaline marshes than in brackish marshes. In addition to these natural barriers limiting waterflow, many human-made impoundments exist in the Chenier Plain. These impoundments tend to support fresh marsh because water loss through evapotranspiration is less than local rainfall (Gosselink et al. 1979).

Threats/Stressors: Threats to this system include altered hydrology and increases in salinity. The coast of Louisiana, including the fresh to oligohaline marshes, is being impacted by saltwater intrusion and inundation because the lack of sediment supply by the Mississippi River, eustatic sea-level rise and enhanced relative sea-level rise caused by the natural compaction of coastal sediments and the increased subsidence resulting from groundwater and oil and gas removal. Dredging canals that increase the connection between the fresh and oligohaline marshes and the saline waters of the Gulf of Mexico also work to increase salinity of these marshes. While fresh to oligohaline marsh species have been shown to adapt to rising water levels, increased salinity has been shown to reduce the growth and survival of these species (Howard and Mendelssohn 1999, Willis and Hester 2004, Couvillon and Beck 2013, Neubauer 2013). As salinity increases fresh marsh composition shifts to species more tolerant of higher salinity causing a reduction in species richness. If the increase in salinity is accompanied by increased water levels (e.g., relative sea-level rise and dredged canals), this can ultimately result in conversion of marsh to open waters. These marshes are also threatened by reduced freshwater inflow caused by upstream dams and water diversion. Invasive plant species such as *Triadica sebifera* are threats. Some invasive exotic mammals are threats, such as nutria (*Myocastor coypus*) and feral hogs (*Sus scrofa*).

This is a highly threatened system in coastal Louisiana and conversion of marsh to open water has been high in Louisiana (Couvillion et al. 2011, Bernier 2013, Williams 2013). Coastal Louisiana has the highest rates of relative sea-level rise (>9 mm/year) in the nation (Williams 2013). A global eustatic sea-level rise of 0.5 to 2.0 m by A.D. 2100 when coupled with subsidence and barriers to the landward migration of marshes could result in devastating impacts on the coastal marshes of Louisiana (Neubauer 2013, Williams 2013). "Louisiana has sustained more coastal wetland loss than all other states in the continental United States combined" (Glick et al. 2013). SLAMM models predict 42 to 99% marsh and swamp loss in southeastern Louisiana by 2100 if eustatic sea-level rise exceeds 0.75 m (Glick et al. 2013).

Ecosystem Collapse Thresholds: Ecological collapse in the system tends to result from hydrological alteration, increase in salinity, subsidence and lack of sedimentation and organic matter to maintain marshes, and lack of sediments from Mississippi River to build barrier ridges, eustatic sea-level rise, and resulting rise in relative sea level. Ecosystem collapse is characterized by conversion of the tidal herbaceous or shrub vegetation to mesohaline marshes or open water resulting in a loss of species richness. Invasive exotic plant species such as *Triadica sebifera* may be dominant in collapsed examples.

CES203.470 Mississippi Delta Fresh and Oligohaline Tidal Marsh

CES203.470 CLASSIFICATION

Concept Summary: This system includes tidal marshes strongly influenced by freshwater producing a fresh to oligohaline chemistry. These areas can occupy small to large patches of the Mississippi Delta. A unique type of floating fresh marsh (flotant) is also included in this system. This system has a heterogeneous physiognomy including shrublands, grasslands, and aquatic herbs. Significant fresh marsh loss has occurred in the deltaic plain of the Mississippi River. These losses are related to natural and anthropogenic causes. Subsidence and loss of wetlands are a natural part of the deltaic process, but they have been exacerbated by the reduction in sediment load and freshwater input into coastal areas caused by the impoundment and channelization of streams and rivers. In addition dredged channels in the marsh facilitate saltwater intrusion, and spoil banks prevent marshes from draining. Increases in salinity cause shifts in composition to species more tolerant of salinity, ultimately resulting in loss of species diversity and open saline waters.

Related Concepts:

Distribution: This system occurs in the Mississippi River deltaic plain. Marshes in the Mississippi River deltaic plain encompass 22% of the marshes in the conterminous U.S. and about half of these are fresh to oligohaline marshes (Gosselink 1984, Visser et al. 1998).

Nations: US

Concept Source: J. Teague and R. Evans

Description Author: J. Teague, R. Evans, M. Pyne

CES203.470 CONCEPTUAL MODEL

Environment: This system occurs in the Mississippi River deltaic plain where freshwater inflow is greatest - near the mouths of distributary channels for the Mississippi River and near the mainland where freshwater flow from upland runoff and smaller creeks and rivers enters the marshes.

Key Processes and Interactions: Historically, the deltaic processes of the Mississippi River helped to build and maintain this system. Today, in addition to the large fresh to oligohaline marshes that hug the mainland, two active deltas, the Atchafalaya and the Mississippi Balize deltas, support fresh to oligohaline marshes areas. However, these areas of sediment accumulation and accretion are an anomaly compared to the predominance of coastal loss and subsidence in the Mississippi River deltaic plain (Gosselink et al. 1998, Draut et al. 2005). The natural sediment load and freshwater entering the deltaic marshes are dependent on functioning hydrological processes in the Mississippi River. This marsh system is dependent upon freshwater input, sediment input and organic matter build-up. Species richness is typically higher in oligohaline marshes than in brackish marshes. Much of this system is characterized by floating mats of vegetation (Visser et al. 1998). Some studies suggest that marshes may convert to floating mats as a result of rapid subsidence.

Threats/Stressors: Threats to this system include altered hydrology and increases in salinity. The coast of Louisiana, including the fresh to oligohaline marshes, are being impacted by saltwater intrusion and inundation because the lack of sediment supply by the Mississippi River, eustatic sea-level rise and enhanced relative sea-level rise caused by the natural compaction of coastal sediments and the increased subsidence resulting from groundwater and oil and gas removal (USGS 2013). Dredging canals that increase the connection between the fresh and oligohaline marshes and the saline waters of the Gulf of Mexico also work to increase salinity and loss of these marshes (Deegan et al. 1984). While fresh to oligohaline marsh species have been shown to adapt to rising water levels, increased salinity has been shown to reduce the growth and survival of these species (Howard and Mendelssohn 1999, Willis and Hester 2004, Couvillon and Beck 2013, Neubauer 2013). As salinity increases, fresh marsh composition shifts to species more tolerant of higher salinity causing a reduction in species richness. If the increase in salinity is accompanied by increased water levels, this can ultimately result in conversion of marsh to open saline waters. These marshes are also threatened by reduced freshwater inflow caused by upstream dams and water diversion. Invasive plant species such as *Triadica sebifera* are threats. Some invasive exotic mammals are threats, such as nutria (*Myocastor coypus*) and feral hogs (*Sus scrofa*). An increase in storm intensities and barriers to landward marsh migration could further exacerbate the impacts of subsidence and sea-level rise. Other threats include pollution entering the marsh from point and nonpoint sources.

This is a highly threatened system in coastal Louisiana and conversion of marsh to open water has been high in Louisiana (Couvillion et al. 2011, Bernier 2013, Williams 2013). Coastal Louisiana has the highest rates of relative sea-level rise (>9 mm/year) in the nation (Williams 2013). A global eustatic sea-level rise of 0.5 to 2.0 m by A.D. 2100 when coupled with subsidence and barriers to the landward migration of marshes could result in devastating impacts on the coastal marshes of Louisiana (Neubauer 2013, Williams 2013). "Louisiana has sustained more coastal wetland loss than all other states in the continental United States combined" (Glick et al. 2013). SLAMM models predict 42 to 99% marsh and swamp loss in southeastern Louisiana by 2100 if eustatic sea-level rise exceeds 0.75 m (Glick et al. 2013).

Ecosystem Collapse Thresholds: Ecological collapse in the system tends to result from hydrological alteration, increase in salinity, subsidence and lack of sediments from Mississippi River to maintain marshes, eustatic sea-level rise, and resulting rise in relative sea level. Ecosystem collapse is characterized by conversion of the tidal herbaceous or shrub vegetation to mesohaline marshes or open water resulting in a loss of species richness.

CES203.516 Northern Atlantic Coastal Plain Fresh and Oligohaline Tidal Marsh

CES203.516 CLASSIFICATION

Concept Summary: This system includes freshwater tidal vegetation occurring on the upper reaches of large rivers influenced by tidal flooding, but beyond the reach of the salt or brackish waters. The system is well-developed on the Chesapeake and Delaware Bay drainages, including the rivers of southern New Jersey, then extends northeast and includes inland portions of the Hudson, Connecticut, Merrimack, Kennebec, and Penobscot rivers and their tributaries. The vegetation includes tall marshes dominated by tall grasses such as *Zizania aquatica*, marshes of lower stature dominated by forbs such as *Amaranthus cannabinus, Hibiscus moscheutos* and others, and vegetation characterized by short-statured and rosette-forming forbs such as *Eriocaulon parkeri* and *Isoetes riparia*. Associations are distributed by proximity to tidal waters and thus duration and force of flooding. Sediments of more protected and isolated vegetation is composed of finer-grained materials that are poorly drained, or of well-consolidated peat deposits. Vegetation exposed to greater flooding force and scouring action is supported by mineral substrates such as sand and gravel.

Related Concepts:

Distribution: This system is best developed on the Chesapeake and Delaware Bay drainages, including the rivers of southern New Jersey, but extends northeast and includes inland portions of the Hudson, Connecticut, Merrimack, Kennebec, and Penobscot rivers and their tributaries.

Nations: US

Concept Source: R. Evans and L. Sneddon

Description Author: R. Evans, L.A. Sneddon, S.C. Gawler

CES203.516 CONCEPTUAL MODEL

Environment: This system forms on the upper reaches of large rivers regularly inundated by tidal flooding but beyond the effects of saline waters.

Key Processes and Interactions: This system is characterized by a mosaic of patches controlled by a combination of substrate particle size, amount of organic matter deposition, and the degree of stress (persistent natural processes) versus disturbance (episodic and disruptive processes) (Barrett 1994). Tidal amplitude in the Delaware Estuary supporting this system is approximately 2m.

Threats/Stressors: Major threats to this system are shoreline development, resulting in restricted tidal flow, introduction of invasive species (*Phragmites australis, Lobelia chinensis, Cyperus serotinus*); runoff, and deposition of dredge spoils (NYNHP 2013d). sea-level rise poses a threat to this system; loss of fine sediments through erosion caused by the wakes of commercial ships (Rhoads and Block 2011c).

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when the system has been heavily impacted by tidal disruption, erosion caused by commercial ships has removed algal crusts and fine sediments that sustain this system (Rhoads and Block 2011c); average buffer width <10 m and/or in poor condition; >10% cover by invasive species; absence or low cover of characteristic species; <50% native flora; riverbank deeply undercut with abundant slumps (Faber-Langendoen et al. 2011).

CES203.376 Southern Atlantic Coastal Plain Fresh and Oligohaline Tidal Marsh

CES203.376 CLASSIFICATION

Concept Summary: This ecological system represents tidally-influenced freshwater herbaceous marshes and tidal shrublands ranging from the vicinity of Morehead City, Carteret County, North Carolina (south of the Embayed Region), south to the vicinity of Marineland or Daytona Beach (Flagler/Volusia counties) in northern Florida. This system occurs where there is adequate riverflow and discharge to maintain fresh to oligohaline conditions, while still within tidal range. These marshes most often occur well inside the mouths of tidal creeks and rivers. Different vegetation types occupy areas of slightly different elevations within the marsh.

Related Concepts:

Distribution: This system ranges from the vicinity of Morehead City, Carteret County, North Carolina (south of the Embayed Region), south to the vicinity of Marineland or Daytona Beach (Flagler/Volusia counties) in northern Florida (Montague and Wiegert 1990).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and C. Nordman

CES203.376 CONCEPTUAL MODEL

Environment: This system occurs where there is adequate riverflow and discharge to maintain fresh to oligohaline conditions, while still within tidal range. These marshes most often occur upstream, well inside the mouths of tidal creeks and rivers. Most of the region where this system occurs consists of marshy shores and sea islands.

Key Processes and Interactions: Tidal flooding with freshwater is the ecological factor that distinguishes this system from others. Tides bring nutrients, making the regularly-flooded marshes fertile. Rising sea level associated with climate change will affect this system strongly, drowning some marsh areas, promoting shoreline erosion, and causing salt or brackish marshes to spread inland

upstream into areas that have been freshwater marsh areas. Some limited natural shifting between this system and tidal swamps may occur, as trees are killed by storm-driven salt water intrusion and later trees may gradually regenerate. Fire may also have affected this boundary in the past - flammable marsh vegetation and non-flammable swamp vegetation may both have affected fire regimes in ways that helped maintain them, for instance when dry, herbaceous marsh vegetation may promote the spread of fires, which kill trees. Tidal swamps which have a shaded understory rarely have adequate dry fine fuels to carry fire.
Threats/Stressors: Threats to this ecological system include hydrological alteration and saltwater intrusion, which may be worsened by channel dredging and sea-level rise. This includes channel dredging associated with coastal oil and gas drilling activities. Water pollution is an increasing threat (including from urban stormwater runoff, and oil and gas drilling and service activities). Reduced freshwater river flows from upstream dams can contribute to the intrusion of saltwater into these tidal marshes. Filling these wetlands is a threat, such as is associated with development and road building projects. Coastal development can be a driver of habitat degradation, including the invasion by introduced exotic *Phragmites australis* (Bertness et al. 2004). Invasive plant species such as *Triadica sebifera*, introduced exotic *Phragmites australis, Hydrilla verticillata* and *Panicum repens* are threats. Some invasive exotic mammals are threats, such as nutria (*Myocastor coypus*) and feral hogs (*Sus scrofa*).
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from hydrological alteration such as from dredging, ditching for mosquito control, the intrusion of saltwater, erosion or accretion which can lead to the conversion to open water, or native or exotic species-dominated swamp forest. Several decades ago, deposition of dredge spoil destroyed substantial areas. Many examples of this system were heavily altered for rice cultivation several centuries ago. With the abandonment of rice cultivation in the Atlantic Coastal Plain, sites have recovered substantial natural character. Coastal development can be a driver of habitat degradation, including the invasion by introduced exotic *Phragmites australis* (Bertness et al. 2004). Ecosystem collapse is characterized by conversion of the tidal herbaceous or shrub vegetation to open water, or native or exotic species-dominated swamp forest, or marsh dominated by introduced exotic *Phragmites australis*. Ecological collapse associated with saltwater intrusion can lead to salt marsh developing on these sites.

CES203.472 Texas Coast Fresh and Oligohaline Tidal Marsh

CES203.472 CLASSIFICATION

Concept Summary: This ecological system includes tidal marshes strongly influenced by freshwater producing a fresh to oligohaline chemistry, where salinity is maintained sufficiently low through freshwater inflows to produce fresh to oligohaline water chemistry. These marshes typically occur as small patches along bay margins and river or bayou mouths of inflowing rivers from Galveston Bay in Chambers County, Texas, south to approximately Corpus Christi Bay. Some characteristic plant species include *Paspalum vaginatum, Spartina patens, Schoenoplectus americanus, Phragmites australis, Sagittaria platyphylla, Vigna luteola*, and *Typha* spp.
Related Concepts:
- Coastal: Fresh and Intermediate Tidal Marsh (5907) [CES203.472] (Elliott 2011) =

Distribution: This fresh and oligohaline marsh system ranges along the Texas coast south of the Chenier Plain. It is best developed along the central and upper coast of Texas from Galveston Bay in Chambers County, Texas, south to approximately Corpus Christi Bay.
Nations: US
Concept Source: J. Teague
Description Author: J. Teague, M. Pyne and L. Elliott

CES203.472 CONCEPTUAL MODEL

Environment: The typical geology is young Quaternary alluvium. Characteristic landforms include the mouths of rivers and bayous emptying into bays of the Galveston Bay system. The soils on which this system is found are the typical soils of the Tidal Flats and Salt Marsh Ecological Sites where they occur in areas of sufficient freshwater inflow (Elliott 2011).

Key Processes and Interactions: This marsh system is dependent upon freshwater input, sediment input and organic matter build-up. Species richness is higher in oligohaline marshes than in mesohaline and polyhaline marshes.

Threats/Stressors: Threats to this system include altered hydrology, increases in salinity, sea-level rise, and point and nonpoint source pollutants. While fresh to oligohaline marsh species have been shown to adapt to rising water levels, increased salinity has been shown to reduce the growth and survival of these species (Howard and Mendelssohn 1999, Couvillon and Beck 2013, Neubauer 2013). As salinity increases, fresh marsh composition shifts to species more tolerant of higher salinity causing a reduction in species richness. If the increase in salinity is accompanied by increased water levels, this can ultimately result in conversion of marsh to open saline waters. These marshes are also threatened by reduced freshwater inflow caused by upstream dams and water diversion. Invasive plant species such as *Triadica sebifera* are threats. Some invasive exotic mammals are threats, such as nutria (*Myocastor coypus*) and feral hogs (*Sus scrofa*). An increase in storm intensities and barriers to landward marsh migration could further exacerbate the impacts of sea-level rise. Other threats include pollution entering the marsh from point and nonpoint sources.

Ecosystem Collapse Thresholds: Ecological collapse in the system tends to result from hydrological alteration, increase in salinity, subsidence and lack of sediments to maintain marshes, eustatic sea-level rise, and resulting rise in relative sea level. Ecosystem collapse is characterized by conversion of the tidal herbaceous or shrub vegetation to mesohaline or polyhaline marshes or open water resulting in a loss of species richness.

M067. Atlantic & Gulf Coastal Plain Wet Prairie & Marsh

CES203.890 Central Florida Herbaceous Pondshore

CES203.890 CLASSIFICATION

Concept Summary: This system includes a variety of seasonal depression ponds in central Florida, especially along the Lake Wales Ridge. Examples are rounded or irregularly shaped, shallow depressions from tens to hundreds of meters in diameter. Extensive variation is present based on the variety of soils and hydroperiods. Most examples have vegetation in zones, and nearly all are ringed by *Serenoa repens*. Characteristic or dominant species associated with the interior of the ponds include *Panicum hemitomon, Panicum abscissum, Hypericum edisonianum*, and *Andropogon brachystachyus*.

Related Concepts:

Distribution: Endemic to central Florida.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans and C. Nordman

CES203.890 CONCEPTUAL MODEL

Environment: Most examples are known from the Lake Wales Ridge area of central Florida. These are shallow depressions from tens to hundreds of meters in diameter, found on a variety of different soils with different hydroperiods (Abrahamson et al. 1984).
Key Processes and Interactions: Variation in the duration and depth of flooding is part of the natural dynamics of the ponds in central Florida. The herbaceous pondshore or rim can burn with fires that burn the surrounding uplands or flatwoods. These fires help maintain the diversity of plants which can occur along the herbaceous pondshore or rim which circles the pond.
Threats/Stressors: Threats include lack of fire, alteration to the hydrology and damage to the herbaceous ground cover from vehicles, hog rooting, plowlines, and ditching. Lack of fire has been a widespread threat, and generally only sites which are within an area managed for conservation have prescribed fires frequently enough to conserve the biological diversity of this open wetland habitat, especially the ecotone or pondshore rim area. The lack of fire can lead to shrub and tree encroachment, increased shading and evapotranspiration, accumulation of leaf litter, and a drying out of the depression wetland during drier times of year. Since many of the herbaceous plants which grow in these predominantly herbaceous wetlands have corms, or starchy root structures, feral hogs (*Sus scrofa*) are a real threat. Feral hogs will turn up the soil and eat the below-ground plant parts and amphibians and invertebrates that live in the wet soil. In doing this they disturb the soil and degrade the habitat. The disturbed soil areas where feral hogs have rooted (or vehicles have rutted the wet soil) can provide habitat for weedy or invasive exotic plants. On lands managed as pine plantations, sometimes shallow depression pond habitat is bedded and planted in *Pinus elliottii*.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur from long-term lack of fire (more than 15 years), increase of shading of the herbaceous vegetation, feral hog (*Sus scrofa*) rooting, invasive exotic plants, vehicle use in the wetland, or alteration of the hydrology, such as from drainage, from groundwater extraction or long-term drought lowering the water table. Prescribed fires even after 15 years can improve the ecotone or pondshore rim area habitat, but a schedule of at least one fire per decade is needed to maintain the high native species diversity of the pondshore rim transition or ecotone edges of these habitats. Many of these habitats that were forested with *Taxodium ascendens* have been cleared of trees which are used for cypress mulch.

Ecosystem collapse is characterized by a midstory tall-shrub or tree canopy, especially *Acer rubrum, Liquidambar styraciflua, Pinus taeda, Liriodendron tulipifera*, or invasive exotic species such as *Triadica sebifera*. The trees and tall shrubs shade the herbaceous ground cover plants. Contributors to ecological collapse are disturbance to the herbaceous plants from ditching, vehicle use in the wetland, feral hog rooting, plowlines, or a combination of these factors. Altered hydrology from ditching or from groundwater extraction or long-term drought lowering the water table can also be a characteristic of ecosystem collapse of this ecological system.

CES203.491 Central Florida Wet Prairie and Herbaceous Seep

CES203.491 CLASSIFICATION

Concept Summary: This system includes herbaceous seepage wetlands and nearly treeless plains over poorly drained soils in central Florida. Although examples of this system are similar to other wetland ecological systems, these are characterized by the presence of subtropical plant species not occurring in herbaceous-dominated wetlands farther north, especially *Panicum abscissum*. At least some examples have dense cover of grasses and low shrubs, with fairly high species diversity. Examples may be most common along the southern part of the Lake Wales Ridge area.
Related Concepts:
Distribution: Endemic to central Florida, mainly found in the southern Lake Wales Ridge.
Nations: US
Concept Source: R. Evans and C. Nordman
Description Author: R. Evans and C. Nordman

CES203.491 CONCEPTUAL MODEL

Environment: Associated with saturated soils caused by seepage or high water tables; some examples may be saturated for 50-100 days/year. Seepage-influenced examples tend to occur in areas of greater topographic relief than wet prairies.
Key Processes and Interactions: Frequent fires were an important natural process in this system, with an estimated frequency of 1-4 years (FNAI 1990, FNAI 2010a).
Threats/Stressors: Threats include lack of fire, alteration to the hydrology and damage to the herbaceous ground cover from vehicles, feral hog (*Sus scrofa*) rooting, plowlines, and ditching. Lack of fire has been a widespread threat, and generally only sites which are within an area managed for conservation have prescribed fires frequently enough to conserve the biological diversity of

this open wetland habitat. The lack of fire can lead to shrub and tree encroachment, increased shading and evapotranspiration, accumulation of leaf litter, and a drying out of the normally saturated soil. Since many of the herbaceous plants which grow in these predominantly herbaceous wetlands have corms, or starchy root structures, feral hogs are a real threat. Feral hogs will turn up the soil and eat the below-ground plant parts and amphibians and invertebrates that live in the wet soil. In doing this they disturb the soil and degrade the habitat. The disturbed soil areas where feral hogs have rooted (or vehicles have rutted the wet soil) can provide habitat for weedy or invasive exotic plants. On lands managed as pine plantations, sometimes the herbaceous seep habitat is bedded and planted in *Pinus elliottii*.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur from long-term lack of fire (more than 15 years), increase of shading of the herbaceous vegetation, feral hog (*Sus scrofa*) rooting, invasive exotic plants, vehicle use in the wetland, or alteration of the hydrology (such as drainage or impoundment). Prescribed fires even after 15 years can improve the habitat, but a schedule of several fires per decade is needed to maintain the high native species diversity of these habitats. Ecosystem collapse is characterized by a midstory tall-shrub or tree canopy that shades the herbaceous ground cover plants, disturbance to the herbaceous plants from ditching, vehicle use in the wetland, feral hog rooting, plowlines, or a combination of these factors. Altered hydrology from ditching or impoundment can also be a characteristic of ecosystem collapse of this ecological system.

CES203.558 East Gulf Coastal Plain Depression Pondshore

CES203.558 CLASSIFICATION

Concept Summary: This small-patch herbaceous or shrub dominated wetland ecological system occupies upland depressions (ponds and pondshores) in the East Gulf Coastal Plain. Included here are shallow ponds of various geomorphic origins in a variety of substrates (e.g., limesinks, Grady Ponds, Citronelle Ponds, flatwoods depression marshes) which are not separately distinguished as ecological systems. This ecological system only includes herbaceous or shrub ponds and pondshores in more-or-less isolated upland settings, not those in riparian or floodplain environments. They may serve as the origin of a stream system in a general way, releasing water gradually into the stream drainage system during periods of very wet weather. These tend to occupy basins that were formed by subsidence of surface sediments caused by solution in underlying limestone or as swales in eolian sand deposits. In some examples, a distinct zonation of vegetation is present, in others the zones are not distinct or the differing associations are present in a complex mosaic. Most seasonal depression ponds are composed of mosaics of several plant associations. The vegetation includes various zones which become exposed as water levels decline, as well as emergent (rising out of the water) or submergent/floating plants. Some typical species are *Dichanthelium wrightianum, Dichanthelium erectifolium, Eleocharis equisetoides, Eleocharis microcarpa, Juncus effusus, Juncus repens, Leersia* spp., *Ludwigia* spp., *Rhynchospora corniculata, Rhynchospora inundata, Panicum hemitomon, Panicum verrucosum, Proserpinaca* spp., *Pluchea* spp., *Saccharum* spp., *Rhexia* spp., and *Sabatia angularis*. Coastal dune lakes and related wetlands of barrier islands are covered by another system, ~Southeastern Coastal Plain Interdunal Wetland (CES203.258)$$.

Distribution: This ecological system is found in the East Gulf Coastal Plain, including the Gulf Coast Flatwoods (i.e., EPA Level IV Ecoregion 75a (EPA 2004)), as well as more inland portions (EPA Level III Ecoregion 65). In particular, there are clusters of large ponds in parts of the Southern Pine Plains and Hills (EPA 65f), the Dougherty Plain (EPA 65g), and Tallahassee Hills/Valdosta Limesink (EPA 65o), and the Okefenokee Plain (EPA 75e).

Nations: US

Concept Source: M. Pyne

Description Author: M. Pyne and C.W. Nordman

CES203.558 CONCEPTUAL MODEL

Environment: Examples of this ecological system occur in relatively shallow depressions or basins that were formed by subsidence of surface sediments caused by solution in underlying limestone or were formed as swales in eolian sand deposits. However, sinkholes with steep, vertical, exposed limestone walls are accommodated by another ecological system, as are sandhill ponds that develop on extreme sandy sites in the East Gulf Coastal Plain of Florida and adjacent Alabama. Hydroperiod can vary substantially from year to year, and vegetation can similarly vary significantly in aspect and dominants. Highly variable hydroperiods help maintain herbaceous vegetation, and prevent the succession to forest.

Key Processes and Interactions: The seasonal fluctuation in the water levels in these ponds controls both the overall vegetation composition as well as the composition of the zones of the vegetation, which may be quite distinct from one another. Hydroperiod can vary substantially from year to year, and vegetation can similarly vary significantly in aspect and dominants. Highly variable hydroperiods help maintain herbaceous vegetation and prevent the succession to forest. Fire is an important natural disturbance, and the outer, drier portions of the depressions burn most frequently. Fires may sweep through the interior of many examples during dry periods. Today, prescribed fire is important for the management of the pineland landscapes which include these herbaceous or shrub wetland ecological systems.

Threats/Stressors: Threats include lack of fire, alteration to the hydrology, and damage to the herbaceous ground cover from vehicles, feral hog (*Sus scrofa*) rooting, firebreak plowlines, and ditching. Lack of fire has become a widespread threat. Mainly sites which are within an area managed for conservation (in conjunction with other resource management goals) have prescribed fires frequently enough to conserve the biological diversity of this open wetland habitat. The lack of fire can lead to shrub and tree encroachment, increased shading and evapotranspiration, accumulation of leaf litter, and a drying out of the depression wetland during drier times of year. Since many of the herbaceous plants which grow in these predominantly herbaceous wetlands have corms, or starchy root structures, feral hogs are a real threat. Feral hogs will turn up the soil and eat the below-ground plant parts and amphibians and invertebrates that live in the wet soil. In doing this they disturb the soil and degrade the habitat. The disturbed soil areas where feral hogs have rooted (or vehicles have rutted the wet soil) can provide habitat for weedy or invasive exotic plants. Collecting amphibians for bait is a threat. On lands managed as pine plantations, sometimes the depression pond habitat is bedded and planted in *Pinus elliottii* or *Pinus taeda*.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur from long-term lack of fire (more than 15 years), increase of shading of the herbaceous vegetation, feral hog (*Sus scrofa*) rooting, invasive exotic plants, off-road vehicle use in the wetland, or alteration of the hydrology, such as from drainage. Prescribed fires even after 15 years can improve the habitat, but a schedule of at least one fire per decade is needed to maintain the high native species diversity of the pondshore rim transition or ecotone edges of these habitats. Many of these habitats that were forested with *Taxodium ascendens* have been cleared of trees which are used for cypress mulch.

Ecosystem collapse is characterized by a midstory tall-shrub or tree canopy, especially *Acer rubrum, Liquidambar styraciflua, Pinus taeda, Liriodendron tulipifera*, or invasive exotic species such as *Ligustrum sinense* or *Triadica sebifera*. The trees and tall shrubs shade the herbaceous ground cover plants. Contributors to ecological collapse are disturbance to the herbaceous plants from ditching, off-road vehicle use in the wetland, feral hog rooting, plowlines, or a combination of these factors. Altered hydrology from ditching can also be a characteristic of ecosystem collapse of this ecological system.

CES203.192 East Gulf Coastal Plain Savanna and Wet Prairie

CES203.192 CLASSIFICATION

Concept Summary: This ecological system of western Florida and adjacent Alabama and Mississippi has been called "lush grassland," "grass-sedge savannah," wet prairie, or wet savanna. As implied by these names, this system consists of primarily herbaceous vegetation with relatively thick cover of grasses and sedge species. Examples occupy low, flat plains on poorly drained soils, often saturated for 50-100 days per year. Frequent fires, including growing-season burns, are essential for maintenance of this system. Some examples have a sparse tree component of *Pinus elliottii* or *Pinus palustris* and scattered shrubs, such as *Morella caroliniensis*.

Related Concepts:

- Pondcypress: 100 (Eyre 1980) **<**

Distribution: Western Florida and adjacent Alabama and Mississippi.

Nations: US

Concept Source: R. Evans and C. Nordman

Description Author: R. Evans and C. Nordman

CES203.192 CONCEPTUAL MODEL

Environment: This system occupies low, flat plains on poorly drained Ultisols. Sites are saturated for 50-100 days per year (FNAI 2010a). Other soil orders may include Ultisols, Spodosols, Inceptisols, and Entisols (Collins et al. 2001); some of these soils have an argillic horizon which impedes drainage and contributes to high water tables. On Eglin Air Force Base, this system is found on the Rutledge series (Kindell et al. 1997).

Key Processes and Interactions: Wet prairies are seasonally inundated or saturated for 50 to 100 days a year (FNAI 2010a). Fire-return intervals have been estimated to be 2-3 years (FNAI 2010a). Wet prairies can be large areas which would have been naturally prone to frequent fire. Today prescribed fire is needed to maintain high-quality examples of wet prairies. Without frequent fire, shrubs and trees can dominate the site, and this leads to a decline in the herbaceous plant diversity.

Threats/Stressors: Prescribed fires, including some growing-season fires, are essential for the maintenance of wet prairies. In the absence of fire, woody plants, including evergreen shrubs and pines, will invade the prairie and competition will reduce the layer of herbaceous vegetation. Wet prairies are also vulnerable to hydrologic changes and soil disturbance. The alteration of hydrology (such as drainage) is a threat because these wetlands depend on natural hydrology. Many wet prairies have been degraded due to disturbances from silviculture, ditching, ORV use, and feral hog (*Sus scrofa*) foraging activities (Kindell et al. 1997). Roads with significant traffic and, to a lesser extent, powerlines and gaslines reduce the ability to manage savannas and wet prairies with prescribed fire, due to smoke safety concerns. Conversion of nearby areas to suburban development makes the use of prescribed fire in remaining wet prairies and savannas more difficult. Areas drained in the past have been converted to pine plantations, then converted to suburban development such as housing and commercial. Overgrazing by livestock of natural savannas can be a threat. Hogs are especially destructive to these habitats, due to their rooting activities. Conversion to improved pasture with exotic forage grasses is a threat. Prior to the 1900s, cattle breeds such as Florida Cracker and Pineywoods grazed on the native grasses and shrubs in the frequently burned open range, including these savanna and wet prairie habitats. These now rare cattle breeds were descended from cattle brought by the Spanish in the 1500s. The past grazing by these breeds may have been more compatible with the natural wet prairies and savannas than modern cattle grazing. Invasive exotic plants are a threat, including *Imperata cylindrica* and *Triadica sebifera*. Poaching of orchids and carnivorous plants is a threat.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur from long-term lack of fire (more than 15 years), increase of shading of the herbaceous vegetation, feral hog (*Sus scrofa*) rooting, invasive exotic plants, vehicle use in the wetland, or alteration of the hydrology (such as drainage). Prescribed fires even after 15 years can improve the habitat, but a schedule of several fires per decade is needed to maintain the high native species diversity of these habitats. Ecosystem collapse is characterized by a midstory tall-shrub or tree canopy that shades the herbaceous ground cover plants, disturbance to the herbaceous plants from ditching, vehicle use in the wetland, feral hog rooting, plowlines, or a combination of these factors. Altered hydrology from ditching can also be a characteristic of ecosystem collapse of this ecological system.

CES203.077 Floridian Highlands Freshwater Marsh

CES203.077 CLASSIFICATION

Concept Summary: This system represents non-tidal marsh vegetation in the peninsula of Florida and in the Tallahassee area. These highland marshes occupy different types of depressions such as former lake basins, shallow peat-filled valleys, and zones around existing natural lakes. The marshes and the basins they occur within are unstable over time due to subsurface subsidence and drainage pattern changes. In some examples, surface waterflow is generally lacking due to the presence of limestone near the surface, but water levels have fluctuated greatly over time. Soils range from mucky surfaces to sandy loams or sands, but slowly permeable subsoils contribute to the presence of standing water for much of the year. The vegetation mosaic includes a range of mostly herbaceous plant communities that may be referred to as marshes, meadows, and prairies, collectively comprising a relatively diverse number of associations. Permanent water bodies support a range of submerged and floating aquatic species. Areas with approximately a meter of standing water tend to support dense stands of emergent herbaceous perennials, often in monospecific stands; species include *Typha latifolia, Pontederia cordata, Nelumbo lutea*, and others. Where there is less water (usually present only during wet season), more graminoid vegetation is present, with species such as *Panicum hemitomon, Leersia hexandra*, and others. With historic water level fluctuations, the vegetation mosaic has also changed, sometimes quite rapidly.

Related Concepts:

Distribution: This system is found in the Florida Peninsula and in the Tallahassee Hills/Valdosta Limesink area, possibly ranging into adjacent Georgia. See map in Kushlan (1990, p. 327).

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, C.W. Nordman and M. Pyne

CES203.077 CONCEPTUAL MODEL

Environment: These highland marshes occupy different types of depressions such as former lake basins, shallow peat-filled valleys, and zones around existing natural lakes (Kushlan 1990). The marshes and the basins they occur within are unstable over time due to subsurface subsidence and drainage pattern changes. Soils range from mucky surfaces to sandy loams or sands, but slowly permeable subsoils contribute to the presence of standing water for much of the year.

Key Processes and Interactions: In some examples, surface waterflow is generally lacking due to the presence of limestone near the surface, but water levels have fluctuated greatly over time (Patton and Judd 1986). In the absence of fire, portions of stands will become dominated by *Salix caroliniana*. If fire continues to be absent, these areas may succeed to *Acer rubrum* until a replacement fire or mechanical activity restores the marsh. Paynes Prairie is a large permanently protected example of highland marsh. Water-control structures allow the manipulation of water levels in Paynes Prairie to achieve ecosystem management goals (Kushlan 1990).

Threats/Stressors: Drainage is the biggest threat to highland marshes, but many have been grazed by cattle and some have been mined for peat (Kushlan 1990). Nutrient-laden runoff from adjacent developed or agricultural land is a threat to many highland marshes (Kushlan 1990). Invasive exotic plants are also a threat.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from drainage, cattle grazing or mining peat from the marsh. Invasive exotic plants can contribute to ecosystem collapse. Ecosystem collapse is characterized by altered hydrology, drying out of the herbaceous wetland, dominance by woody plants, or invasive exotic plants.

CES203.258 Southeastern Coastal Plain Interdunal Wetland

CES203.258 CLASSIFICATION

Concept Summary: This system encompasses the wettest dune swales and basins on barrier islands and coastal areas, supporting pond or marsh-like vegetation, from the Coastal Plain of Texas to southern Virginia. Most examples are permanently or semipermanently flooded with freshwater but are affected by salt spray or overwash during periodic storm events. It is broadly defined in terms of floristic composition and is wide-ranging along the Atlantic and Gulf coasts of the United States. These are graminoid-dominated sites, with species such as *Andropogon glomeratus, Cladium mariscus ssp. jamaicense, Distichlis spicata, Eleocharis* spp., *Fimbristylis castanea, Panicum virgatum, Paspalum monostachyum, Rhynchospora colorata, Rhynchospora* spp., *Schoenoplectus pungens*, and *Typha domingensis*.

Related Concepts:

- Coastal and Sandsheet: Deep Sand Grasslands Swale Marsh (6507) [CES203.258] (Elliott 2011) =

Distribution: Ranges along the Atlantic and Gulf coasts, from southern Texas to Florida and southeastern Virginia.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, M. Pyne, L. Elliott and C. Nordman

CES203.258 CONCEPTUAL MODEL

Environment: These wetlands occur on topographic lows, including dune swales or other basins, in nearly level to steeply rolling landscapes on sands and deep sands on barrier islands along the coast and inland on the South Texas Sand Sheet. These ponds have standing water well into the growing season, and most are permanently flooded. The water is from rainfall or the local water table and is fresh, except perhaps during storm events that produce overwash. Soils are sand, sometimes with a thin layer of muck accumulated in the pond. The geology includes coastal eolian sands, extending inland on the South Texas Sand Sheet, as well as Pleistocene barrier island and beach deposits of the Beaumont Formation, such as on the Ingleside Barrier. Examples occupy topographic lows of interdunal swales and potholes. Soils are deep sands and coastal sands (Elliott 2011).

Key Processes and Interactions: This system occurs in a geologically dynamic environment, where wind and waves may change landforms and hydrology quickly (Feagin et al. 2010). However, ponds usually occur in stable portions of islands, where they may last for decades. Salt spray, salt overwash, and heavy rainfall from storms may affect component communities, sometimes limiting vegetation to species that are somewhat salt-tolerant. Severe storms may bring about major changes in the landforms and hydrology (Feagin et al. 2010).

Threats/Stressors: The native vegetation and geological stability of these ecosystems are coupled and vulnerable to erosion events, especially when there has been a lot of development (Feagin et al. 2010). Threats to these coastal wetlands include filling for development, excavation to make open-water ponds, dropping of water tables caused by pumping of shallow groundwater, water pollution from surrounding developed areas, and potentially saltwater intrusion into water tables. Development of surrounding uplands allows these wetlands to become eutrophic from urban stormwater runoff. Within coastal developed areas, these wetlands have lost much of the upland natural vegetation which used to surround them. Those natural upland vegetation buffers allowed the wetlands ecological resiliency after large disturbances from hurricanes and nor'easters. Invasive plant species such as *Triadica sebifera*, introduced exotic *Phragmites australis* and *Panicum repens* are threats, as are feral hogs (*Sus scrofa*) and nutria (*Myocastor coypus*).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from losses of freshwater wetland habitat to development, from filling or excavation of wetlands or from the degradation of the water quality caused by eutrophication resulting from increased urban stormwater runoff or from increased saltwater intrusion. These are dynamic systems, and major changes from severe storms can include the loss of freshwater wetlands, from the movement of sand, which could transform the site to a sandy upland, or from the creation of a connection to tidal wetlands, allowing the daily tides to bring seawater into these wetlands. Ecosystem collapse is characterized by reduced wetland area, the loss of characteristic grasses and sedges of coastal freshwater wetlands, and lowered water quality due to higher salinity or eutrophication. This may include changes associated with development, reduced groundwater availability and the impacts from invasive exotic species.

CES203.044 Southeastern Coastal Plain Natural Lakeshore

CES203.044 CLASSIFICATION

Concept Summary: This system consists of wetland vegetation along large natural lakeshores in the Outer Coastal Plain of the southeastern United States. Natural lakes are generally rare features throughout most of this region. However, examples range northward to the Atlantic Coastal Plain in southeastern Virginia and North Carolina, but no examples are known from South Carolina and Georgia. However examples are present in Florida, where they are apparently found on smaller lakes than those to the north. Hydroperiod remains relatively constant from year to year, especially when compared to smaller limesink depressions of the region. Vegetation may appear to be zonal in relationship to distance from the lakeshore and may range from open water or floating-leaved aquatics in the deeper waters of the lakes, to emergent marsh zones along the edges. In some cases there are wet hardwood swamps present.

Related Concepts:
- Baldcypress: 101 (Eyre 1980) **<**
- Open Water Lake (Bennett and Nelson 1991) **<**

Distribution: This system is found in the Outer Coastal Plain of Virginia (apparently from a single site, Lake Drummond) and North Carolina, apparently absent from South Carolina and Georgia, but examples are present in Florida (i.e., Ocean Pond on Osceola National Forest).

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale and R. Evans

CES203.044 CONCEPTUAL MODEL

Environment: Occurs along the edges of lakes, where the water is flooded for long durations, but may dry out during dry summer months, or during drought.

Key Processes and Interactions: Long hydroperiod flooding is characteristic of these wetlands which occur along the shore of coastal plain natural lakes. Most of these habitats are naturally nutrient-poor.

Threats/Stressors: Drainage is the primary threat. Invasive exotic plant species are also threats. Logging of commercially valuable trees has degraded the quality of many of these wetlands. Eutrophication from nutrient-laden runoff from developed or agricultural lands is a threat.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from drainage or eutrophication. Invasive exotic plants can contribute to ecosystem collapse. Ecosystem collapse is characterized by altered hydrology, drying out of the wetland, or dominance by invasive exotic plants.

CES203.262 Southern Atlantic Coastal Plain Depression Pondshore

CES203.262 CLASSIFICATION

Concept Summary: This ecological system consists of wetlands in small basins formed in unconsolidated sediments of the Atlantic Coastal Plain, from southeastern Virginia to Florida. Many basins are formed by subsidence of surface sediments caused by solution in underlying limestone. Others may be formed as swales in mainland eolian sands, natural blockage of small drainages by sediment movement, and more obscure causes. Soils are generally sandy, with mucky surfaces in the wettest areas. Vegetation is often zonal in response to variation in duration of flooding in different parts of the depression pond. Vegetation usually ranges from open water or floating-leaved aquatic plants in the center of the deepest basins, to emergent marsh zones in semipermanent water, to drawdown zones with diverse small graminoid and forb vegetation, to dense shrub or woodland edges. A smaller number of basins may have emergent trees throughout their extent. Hydroperiod can vary substantially from year to year, and vegetation can similarly vary significantly in aspect and dominants. In addition to flooding, fire is an important natural disturbance to vegetation in the outer, drier portions of the pond.

Distribution: This system is found from southeastern Virginia to Florida, primarily in the Outer Coastal Plain, but occasional depressions in the Inner Coastal Plain and Sandhills could be included.
Nations: US
Concept Source: M. Schafale and R. Evans
Description Author: M. Schafale, R. Evans, C. Nordman

CES203.262 CONCEPTUAL MODEL

Environment: This system occurs in small basins, primarily in sandy terrain of the Atlantic Coastal Plain, from southeastern Virginia to Florida. Most basins are formed by subsidence of surface sediments caused by solution in underlying limestone. Others may be formed as dune swales in mainland eolian sands, natural blockage of small drainages by sediment movement, and more obscure causes. Basins often occur in complexes of a few to dozens, which vary in size, depth, and steepness of sides. Most of these basins are considered groundwater windows, with water levels matching the level of the local water table. Rainfall is probably also a substantial contributor. The water is acidic and is apparently not influenced by the underlying limestone or deeper groundwater. Hydroperiods vary substantially, with the deepest ponds having permanent water in the center, and the shallowest normally holding water only in the winter and spring. However, water levels can fluctuate substantially over the course of a year and from year to year in response to rainfall and longer term droughts. Soils have a mucky surface layer in the centers of basins that hold water most or all of the year and are generally sandy in smaller basins and in the outer drawdown zones that are more frequently exposed. Fire is potentially an important, if infrequent, influence in the system, penetrating the portions of the basin that are dry when adjacent communities burn. The northern range limit of this system is generally consistent with the northern limit of *Pinus palustris*, although this species is not a component.

Key Processes and Interactions: Flooding hydrology is the most important dynamic process. Standing water excludes plants not characteristic of the system. Variation in hydroperiod and amount of drawdown drive vegetation changes from year to year. Because ponds are connected to the local water table, hydroperiods respond to seasonal and long-term cycles in rainfall as much as, perhaps more than, single rainfall events. They may also be affected by regional drainage and groundwater extraction which lowers the water table. Fire is also an important dynamic process in the drier portions of this system. Fire may be important for preventing invasion of trees such as *Pinus taeda* during long-running droughts, as well as for driving variation in herbaceous species.

Threats/Stressors: Threats include lack of fire, alteration to the hydrology and damage to the herbaceous ground cover from vehicles, feral hog (*Sus scrofa*) rooting, firebreak plowlines, and ditching. Lack of fire has become a widespread threat. Depression ponds that are located within properties managed for conservation (in conjunction with other resource management goals) may be burned with prescribed fire frequently enough to conserve the biological diversity of this open wetland habitat. Lack of fire can lead to shrub and tree encroachment, increased shading and evapotranspiration, accumulation of leaf litter, and a drying out of the depression wetland during drier times of year. Since many of the herbaceous plants which grow in these predominantly herbaceous wetlands have corms, or starchy root structures, feral hogs are a real threat. Feral hogs will turn up the soil and eat the below-ground plant parts, as well as amphibians and invertebrates that live in the wet soil. In doing this they disturb the soil and degrade the habitat. The disturbed soil areas where feral hogs have rooted (or vehicles have rutted the wet soil) can provide habitat for weedy or invasive exotic plants. On lands managed as pine plantations, shallow depression ponds may be bedded and planted in *Pinus elliottii* or *Pinus taeda*. Other depression ponds have been ditched and drained for agricultural use or dewatered by groundwater withdrawal. These depression wetlands can receive stormwater runoff which is high in nutrients, such as from urbanized or agricultural lands surrounding the wetland. In some agricultural landscapes, depression ponds serve as receiving basins for adjacent wetland sites that have been ditched and may be managed as fishing ponds. Stocking these ponds with predatory fish makes them unsuitable as breeding sites for many amphibians.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur from long-term lack of fire, increase of shading of the herbaceous vegetation, feral hog (*Sus scrofa*) rooting, invasive exotic plants, vehicle use in the wetland, or alteration of the hydrology, such as from drainage or from groundwater extraction lowering the water table. Prescribed fires even after 15 years can improve the habitat, but a schedule of at least one fire per decade is needed to maintain the high native species diversity of the pondshore rim transition or ecotone edges of these habitats. Many of these habitats that were forested with *Taxodium ascendens* have been cleared of trees which are used for cypress mulch.

Ecosystem collapse is characterized by a midstory tall-shrub or tree canopy, especially *Acer rubrum, Liquidambar styraciflua, Pinus taeda, Liriodendron tulipifera*, or invasive exotic species such as *Ligustrum sinense, Melia azedarach* or *Triadica sebifera*. The trees and tall shrubs shade the herbaceous ground cover plants. Contributors to ecological collapse are disturbance to the herbaceous plants from ditching, vehicle use in the wetland, feral hog rooting, plowlines, or a combination of these factors. Altered hydrology from ditching or from groundwater extraction lowering the water table can also be a characteristic of ecosystem collapse of this ecological system.

CES203.078 Southern Coastal Plain Herbaceous Seep and Bog

CES203.078 CLASSIFICATION

Concept Summary: This small-patch ecological system includes wet, fire-maintained, seepage communities in the outermost portions of the East Gulf Coastal Plain, east of the Mississippi River in Louisiana, Mississippi, Alabama, and extending across northern Florida. These wetlands are generally found on gentle, almost imperceptible slopes maintained by constant seepage zones and/or perched water tables. Examples are typically grass and sedge dominated, and are often species-rich. *Sarracenia* spp. are notable indicators of many community types in this system. Shrubs frequently encroach in the absence of fire; due to greater topographic isolation, the most interior examples are often naturally shrubbier.

Distribution: This systems is found in the northern Gulf of Mexico region, east of the Mississippi River in Louisiana, Mississippi, Alabama, and extending across northern Florida.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and C. Nordman

CES203.078 CONCEPTUAL MODEL

Environment: Kindell et al. (1997) document examples in the western Panhandle of Florida on the Leefield, Albany, Pactolus, Pamlico, Rutledge, and Pansey soil series. Albany loamy sand is a common soil type in Florida (FNAI 2010a). Clewell (1981) describes these bogs as commonly occurring between bay swamps and pine flatwoods. These habitats occur on gentle slopes, where seepage water maintains saturated conditions most of the time.

Key Processes and Interactions: These habitats are kept continuously moist by groundwater seepage (FNAI 2010a). Plants found here tolerate saturated wetland conditions. Frequent fires are necessary to maintain this system. In the absence of fire, shrubs encroach, eventually shading out understory plants. Fires may have occurred every 1-4 years (FNAI 2010a).

Threats/Stressors: Threats include lack of fire, alteration to the hydrology, and damage to the herbaceous ground cover from vehicles, feral hog (*Sus scrofa*) rooting (Engeman et al. 2007), plowlines, and ditching. Lack of fire has been a widespread threat, and generally only sites which are within an area managed for conservation have prescribed fires frequently enough to conserve the biological diversity of this open wetland habitat. The lack of fire can lead to shrub and tree encroachment, increased shading and evapotranspiration, accumulation of leaf litter, and a drying out of the normally saturated soil. Since many of the herbaceous plants which grow in these predominantly herbaceous wetlands have corms, or starchy root structures, feral hogs are a real threat. Feral hogs will turn up the soil and eat the below-ground plant parts (Engeman et al. 2007) and amphibians and invertebrates that live in the wet soil. In doing this they disturb the soil and degrade the habitat. The disturbed soil areas where feral hogs have rooted (or vehicles have rutted the wet soil), can provide habitat for weedy or invasive exotic plants. On lands managed as pine plantations, sometimes the herbaceous seep habitat is bedded and planted in *Pinus elliottii var. elliottii* or *Pinus taeda*.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur from long-term lack of fire (more than 15 years), increase of shading of the herbaceous vegetation, feral hog (*Sus scrofa*) rooting, invasive exotic plants, vehicle use in the wetland, or alteration of the hydrology (such as drainage or impoundment). Prescribed fires even after 15 years can improve the habitat, but a schedule of several fires per decade is needed to maintain the high native species diversity of these habitats. Ecosystem collapse is characterized by a midstory tall-shrub or tree canopy that shades the herbaceous ground cover plants, disturbance to the herbaceous plants from ditching, vehicle use in the wetland, feral hog rooting, plowlines, or a combination of these factors. Altered hydrology from ditching or impoundment can also be a characteristic of ecosystem collapse of this ecological system.

CES203.541 Texas-Louisiana Coastal Prairie Pondshore

CES203.541 CLASSIFICATION

Concept Summary: This ecological system includes small to moderately large ponds and swales in the coastal prairie of southeastern Texas and adjacent Louisiana. These wetlands contain surface water during much of the year, desiccating only in the driest summer months. They are often fed by water runoff but may result from percolation from adjacent sandy areas. Soils in the basins are finer-textured than surrounding areas and may be underlain by pans that enhance perched water tables in the winter. These wetlands occur within the coastal prairie matrix of southeastern Texas and Louisiana and are wetter than wet prairie dominated by *Tripsacum dactyloides* and *Panicum virgatum*. These wetlands may be dominated by *Eleocharis quadrangulata*. Other species that may be present include *Sagittaria papillosa, Sagittaria longiloba, Steinchisma hians, Panicum virgatum, Cyperus haspan, Cyperus virens, Ludwigia glandulosa, Ludwigia linearis, Fuirena squarrosa, Xyris jupicai, Leersia hexandra, Centella erecta, Symphyotrichum subulatum, Sesbania* spp., and *Rhynchospora* spp. Open areas in the ponds may contain floating and submersed aquatic vegetation, including *Utricularia gibba, Stuckenia pectinata, Ceratophyllum demersum, Brasenia schreberi, Nymphoides aquatica, Nuphar advena*, and *Nelumbo lutea*.
Related Concepts:
- Gulf Coast: Coastal Prairie Pondshore (5307) [CES203.541] (Elliott 2011) =

Distribution: This system is restricted to the coastal prairie of southeastern Texas and Louisiana.
Nations: US
Concept Source: J. Teague
Description Author: J. Teague, M. Pyne and L. Elliott

CES203.541 CONCEPTUAL MODEL

Environment: This small-patch system occurs in shallow depressions (microtopographic lows) on coastal Pleistocene terraces, including the Beaumont and Lissie formations, within the matrix of the generally level landscape of the ~Texas-Louisiana Coastal

Prairie (CES203.550)$$. Soils tend to be fine-textured, or are characterized by a relatively impermeable subsurface horizon (Elliott 2011). Examples of this system are often fed by water runoff but may result from groundwater percolation from adjacent sandy areas. Studies have shown that coastal prairie ponds may collectively occupy a large percentage of the land area within the coastal prairie (Enwright et al. 2011).
Key Processes and Interactions: These wetlands are part of the larger hydrologic cycle of the coastal prairie ecosystem. They store surface water and in some cases groundwater during much of the year, desiccating only in the driest summer months. Soils in the basins are finer-textured than surrounding areas and may be underlain by pans that enhance perched water tables in the winter. They have been shown to play a role in landscape-level water quality regulation (Forbes et al. 2012). The herbaceous wetlands are maintained by fire.
Threats/Stressors: A major threat to this system is conversion of the matrix ecological system within which this system occurs to other land uses (agriculture, pasture, and residential and commercial development). Historic loss of this matrix is estimated to be greater than 99% (USFWS and USGS 1999, LDWF 2005). A 29% loss of this wetland system occurred between 1955 and 1992 (Moulton et al. 1997). Other threats include alteration of the natural fire and hydrologic regimes, damage to the herbaceous ground cover, and invasion by the exotic tree *Triadica sebifera*. Other impacts include grading and filling, contamination by chemical runoff, disturbance by off-road vehicles, rooting by feral hogs (*Sus scrofa*), road maintenance, and development and maintenance of utility corridors. Lack of fire has been a widespread threat, and generally only sites which are managed with prescribed fires conserve the biological diversity of this herbaceous wetland habitat. The lack of fire can lead to shrub and tree encroachment, increased shading and evapotranspiration, accumulation of leaf litter, and a drying out of the depression wetland during drier times of year.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to occur from alteration of the hydrologic regime, long-term lack of fire, increase of shading of the herbaceous vegetation by encroachment of woody plants, including the invasive exotic tree *Triadica sebifera*, damage to the herbaceous ground cover through feral hog (*Sus scrofa*) rooting, and off-road vehicle use in the wetland. Ecosystem collapse is characterized by conversion of the habitat to other land uses (agriculture, residential and commercial development), encroachment of woody plants, including the invasive exotic species *Triadica sebifera*; trees and tall shrubs block sunlight needed by the herbaceous ground cover plants. Depressions are disturbed from filling, off-road vehicle use in the wetland, feral hog (*Sus scrofa*) rooting, plowlines, or a combination of these factors.

CES402.592 Meso-American Salt Tidal Flat

CES402.592 CLASSIFICATION

Concept Summary: Este sistema agrupa las asociaciones vegetales dispersas que se desarrollan en las depresiones que se forman por detrás de las dunas costeras o entre bancos arcillosos que por la acción de la marea varían en posición y forma. El primer caso ocurre en ambientes de litoral marino y el segundo en zonas esturinas. Estas lagunas salobres reciben agua de lluvias, aguas dulces de los ríos o de vertientes y agua salada de filtración o por la marea. Esto hace que la salinidad sea variable y estacional. Los suelos son generalmente arcillosos, a veces con una capa de limo y arena en la superficie, en la época seca se forma una capa de sal cristalina en la superficie. La siguiente lista de las especies es de diagnóstica para este sistema: *Avicennia germinans, Conocarpus erectus, Bromelia pinguin, Tillandsia flexuosa, Chloris barbata (= Chloris inflata), Urochloa fusca (= Brachiaria fasciculata), Cordia curassavica, Marsdenia rotheana, Opuntia eliator, Acanthocereus tetragonus (= Acanthocereus pentagonus), Acacia costaricensis, Parkinsonia aculeata, Pavonia sessiliflora, Waltheria indica, Jacquinia macrocarpa, Sesuvium portulacastrum, Salicornia* spp.

2.C.5.Na. North American Great Plains Saline Marsh

M077. Great Plains Saline Wet Meadow & Marsh

CES303.669 Western Great Plains Saline Depression Wetland

CES303.669 CLASSIFICATION

Concept Summary: This ecological system is very similar to ~Western Great Plains Open Freshwater Depression Wetland (CES303.675)$$ and ~Western Great Plains Closed Depression Wetland (CES303.666)$$. However, strongly saline soils cause both the shallow lakes and depressions and the surrounding areas to be more brackish. Salt encrustations can occur on the surface in some examples of this system, and the soils are severely affected and have poor structure. Species that typify this system are salt-tolerant and halophytic species such as *Distichlis spicata, Sporobolus airoides*, and *Hordeum jubatum*. Other commonly occurring taxa include *Puccinellia nuttalliana, Salicornia rubra, Bolboschoenus maritimus, Schoenoplectus americanus, Suaeda calceoliformis, Spartina* spp., *Triglochin maritima*, and shrubs such as *Sarcobatus vermiculatus* and *Krascheninnikovia lanata*. During exceptionally wet years, an increase in precipitation can dilute the salt concentration in the soils of some examples of this system which may allow for less salt-tolerant species to occur. Communities found within this system may also occur in floodplains (i.e., more open depressions) but probably should not be considered a separate system unless they transition to areas outside the immediate floodplain. In Texas, these less saline *Sporobolus cryptandrus, Aristida purpurea*, and *Ziziphus obtusifolia* communities found within this system may also occur in floodplains (i.e., more open depressions) but probably should not be considered a separate system unless they transition to areas outside the immediate floodplain.

CES303.669 CONCEPTUAL MODEL

Environment: This system is found in basins and low parts of floodplains where water collects. The soils and water are moderately to strongly saline (>0.5-1%) (Ungar 1967, 1970). The salts are leached from saline soils in the watershed or, rarely, come from saline groundwater discharge. Salts accumulate as the water in which they were dissolved evaporates. Salt crusts are present on the soil surface of some stands. Soils are fine-grained, typically with a silt or clay component, and poorly drained. The wettest examples of this system are flooded through most or all of the growing season and can support aquatic species. Other aspects of the system can be flooded or saturated for short periods (Dodd and Coupland 1966, Stewart and Kantrud 1971). In Texas, this system may occur on High Lime, Salty Bottomland, and Wet Saline Ecological Sites, and some of these lakes were thought to form from wind deflation and/or dissolution of subsurface strata.

Key Processes and Interactions: Unusually wet periods or high spring snowmelt may flush some salt away, shifting the boundaries of this system temporarily until more salt accumulates. Salinity varies during the growing season, decreasing in the spring or after heavy rains and increasing during dry periods. The increased salinity due to concentration of the salt as the water evaporates - common in the late summer and early fall - creates a seasonally shifting environment. Species composition is strongly linked to salinity and soil moisture, so there is usually notable zonation within this system with the species tolerant of the wettest and most saline conditions in the center, grading towards midgrass prairie at the edges (Ungar 1967, 1970). Fire may spread into this system from adjacent upland prairies and can burn areas with higher vegetation cover, but the low vegetation cover and wet soils typical of many stands do not carry fire well.

Threats/Stressors: Some stands have been irrigated and converted to crop fields (Rolfsmeier 1993a), but even with the flushing of the soil by irrigation, most sites in this system are not well-suited to growing crops. Drainage of this system, with or without subsequent irrigation, also damages stands and results in reduced water-holding capacity and often reduced salinity as water is able to flow off the site and remove some of the salts. Many stands have been used for pasture and haying. Low-intensity uses of this nature do not pose a serious threat, but livestock can quickly cause damage by churning up the wet soils, overgrazing the palatable species on the less saline parts of the site, and introducing seeds of exotic species. Many invasives common to the mixedgrass prairies cannot tolerate the saline conditions, but there are several aggressive species that can, including *Thinopyrum ponticum (= Agropyron elongatum), Tamarix ramosissima*, and *Trifolium fragiferum* (Ungar 1967, Rolfsmeier 1993a). Disruptions in the watershed can cause increased or, more typically, decreased water inflow.

Ecosystem Collapse Thresholds: Ecological collapse tends to occur when sites have moderate to high stocking levels of livestock, the hydrologic regime is changed such that increased water creates a freshwater marsh or decreased water converts sites to dry salt flats, or when invasive species become abundant on sites. Severe environmental degradation occurs when hydrologic changes result in dilution of the salts such that species typical of less saline systems (e.g., ~Western Great Plains Open Freshwater Depression Wetland (CES303.675)$$ or ~Central Mixedgrass Prairie (CES205.683)$$) dominate or water input or retention is reduced to the point that wetland species can no longer grow. Moderate environmental degradation occurs when hydrologic changes result in dilution of the salts such that species typical of less saline systems (e.g., ~Western Great Plains Open Freshwater Depression Wetland (CES303.675)$$ or ~Central Mixedgrass Prairie (CES205.683)$$) become abundant in the core of the site or water input or retention is reduced to the point that wetland species can no longer dominate stands. Severe disruption of biotic processes occurs when sites are used for livestock grazing and watering or haying and native species are significantly reduced; or when invasive exotic species are >25% cover. Moderate disruption of biotic processes occurs when sites are used for livestock grazing and watering or haying and native species are moderately reduced; or when invasive exotic species are 10-25% cover.

2.C.5.Nb. North American Atlantic & Gulf Coastal Salt Marsh

M079. North American Atlantic & Gulf Coastal Salt Marsh

CES201.578 Acadian Coastal Salt Marsh

CES201.578 CLASSIFICATION

Concept Summary: This system ranges from northern Massachusetts on the Gulf of Maine north to Newfoundland, along the immediate ocean shore and near estuary mouths, where salinity regime is polyhaline. Sometimes called "salt meadows," these marshes display strong graminoid dominance, with patchy forbs. *Spartina patens* and *Spartina alterniflora* are the major dominants. Characteristic associates include *Puccinellia maritima, Juncus arcticus ssp. littoralis (= Juncus balticus), Plantago maritima var. juncoides (= Plantago juncoides)*, and *Juncus gerardii*. These marshes may be extensive where the local topography allows their development; they are generally not associated with sand beach and dune systems, being more characteristic of the primarily rocky portions of the Gulf of Maine coast. Where the coastal topography becomes more dissected, they are more commonly seen as a fairly narrow fringe along tidal shorelines. These marshes are typically less extensive and with some different floristic elements than the marshes southward along the Atlantic Coast from Cape Cod to Chesapeake Bay.

Related Concepts:

Distribution: This system occurs along the coastline of the Gulf of Maine, from northern Massachusetts north and east to Newfoundland, with the northern border at the Strait of Belle Isle between Labrador and Newfoundland.

Nations: CA, US

Concept Source: S.C. Gawler

Description Author: S.C. Gawler and L.A. Sneddon

CES201.578 CONCEPTUAL MODEL

Environment: Forms behind barrier beaches or at the outer mouths of tidal rivers where freshwater input is minimal and where vegetation is protected from high-energy wave action. Substrate is organic peat, which can reach 1-2 m in depth in low marsh.

Key Processes and Interactions: Tidal flooding is regulated by elevation; flooding is diurnal in low marshes, decreasing to more irregular flooding in high marsh and fringing salt shrublands. Ponded water remains in depressions, causing hypersaline conditions and panne formation. In the northern portion of the range, ice-rafting of large boulders creates a barrier, behind which salt marshes form. Ice-scour causes substantial impacts on the structure of salt marshes, causing patches of marsh to be removed. Furrows and ridges are physical features formed by ice movement. Strong onshore wind causes berm development in winter, with a transition to offshore winds in summer that level the berms. Such processes result in a substantial amount of sediment transport. Large amounts of wrack are deposited annually. Geese also impact the marshes (Roberts and Robertson 1986).

Threats/Stressors: Major stressors include oil spills, grazing by waterfowl, and restricted tidal flow by diking (Roberts and Robertson 1986). Kennish (2001) notes additional stressors including ditching, upland influx of water pollutants; dredging, spoil dumping, indirect effects caused by restricted tidal flow; and invasive species. sea-level rise is expected to impact marshes with insufficient buffer to allow migration landward; high-emission scenarios predict sea level increase of 1-1.5 m by the end of the century (Vermeer and Rahmstorf 2009, Jevrejeva et al. 2010) which may overtake the rate of salt marsh migration landward. sea-level rise, as well as storm intensity, is expected to affect coastal areas everywhere, but especially so in the northeastern U.S.

Ecosystem Collapse Thresholds: Extensive bare soils caused by erosion of marsh and channel banks; <50% relative cover of native plant species (usually *Phragmites australis*). Tidal channel sinuosity extensively altered; tidal channels are extensively blocked by dikes and tide gates; evidence of extensive human channelization. Tidal flooding is totally or almost totally impeded by tidal gates or obstructed culverts. Area is subject to inadequate drainage, such that the marsh plain tends to remain flooded during low tide; encroachment by terrestrial vegetation. Most or all diagnostic species absent, a few may remain in very low abundance (*Spartina alterniflora, Spartina patens, Iva frutescens*). Most examples are heavily reduced from original, natural extent (>50%) (Faber-Langendoen et al. 2011).

CES201.579 Acadian Estuary Marsh

CES201.579 CLASSIFICATION

Concept Summary: This brackish marsh system is found along mesohaline reaches of estuaries of the Gulf of Maine north to southern Newfoundland. Emergent and submergent vegetation characterizes this system. Dominance ranges from extensive grasslands to sparsely vegetated mudflats, all tidally influenced. Characteristic species include *Carex paleacea, Crassula aquatica, Juncus arcticus, Lilaeopsis chinensis, Limosella australis, Samolus valerandi ssp. parviflorus (= Samolus parviflorus), Bolboschoenus robustus (= Schoenoplectus robustus), Schoenoplectus tabernaemontani, Spartina pectinata*, and *Triglochin maritima*. These marshes grade into the salt marsh system at the mouth of estuaries. They are typically less extensive and more floristically depauperate than the marshes southward along the Atlantic Coast to Chesapeake Bay.

Related Concepts:

Distribution: This system is found along the coastline of the Gulf of Maine, from Cape Cod north and east to southern Newfoundland, extending upstream in estuaries to the brackish water limit.

Nations: CA, US

Concept Source: S.C. Gawler

Description Author: S.C. Gawler and L.A. Sneddon

CES201.579 CONCEPTUAL MODEL

Environment: This vegetation develops on tidal reaches of large rivers where freshwater from inland alluvial inputs mixes with marine saltwater incursion. Salinity levels are variable but generally range from 0.5 to 18 ppt. These marshes most commonly form on freely drained river levees. The substrate is moderately consolidated peat (Barrett 1989).

Key Processes and Interactions: Tidal flooding by mesohaline waters; alluvial deposition of sediments forms levees where this vegetation develops.

Threats/Stressors: Tidal restriction and mechanical disturbance of soils fosters growth of *Phragmites australis*, which overwhelms native species composition, including macroinvertebrates (Angradi et al. 2001); pollution. sea-level rise is expected to impact marshes with insufficient buffer to allow migration landward; high-emission scenarios predict up to 1 m to as high as 2 m sea level increase by the end of the century, which may overtake the rate of brackish marsh migration landward. sea-level rise, as well as storm intensity, is expected to affect coastal areas everywhere, but especially so in the northeastern U.S.

Ecosystem Collapse Thresholds: Marshes are poorly buffered by natural vegetation; tidal flow is impeded or obstructed; remaining patch sizes are in total less than one-third of historical size; characteristic species absent or overwhelmed by invasive species; levees supporting plant communities are eroded or deeply undercut; water sources other than tidal are evident; low diversity in natural community patchiness (Faber-Langendoen et al. 2011).

CES203.260 Atlantic Coastal Plain Embayed Region Tidal Salt and Brackish Marsh

CES203.260 CLASSIFICATION

Concept Summary: This ecological system encompasses the brackish to salt intertidal marshes of the Embayed Region of southeastern Virginia and adjacent North Carolina. It is distinguished by the extensive brackish water and tidal flooding driven by winds which are characteristic of that region. Low in plant diversity, these marshes are found on intertidal flats generally cut off from direct oceanic influence by a series of protective barrier islands. Embedded within the matrix of marshes are smaller hypersaline areas or salt pannes. Vegetation is primarily herbaceous marsh, most of it dominated by *Juncus roemerianus*. Areas near tidal inlets have salt marsh dominated by *Spartina alterniflora*. The marshes are low in plant species richness and are strongly dominated by a single plant species. Also part of the system are more limited communities such as hypersaline flats dominated by *Distichlis spicata* and *Sarcocornia*, as well as salt-tolerant shrublands and a few tree-dominated hammocks that occur on small elevated areas closely associated with the marshes.

Related Concepts:

Description Author: R. Evans, M. Schafale, G. Fleming

CES203.260 CONCEPTUAL MODEL

Environment: Occurs on intertidal flats that are tidally flooded with salt to brackish water in the Embayed Region of the Mid-Atlantic Coastal Plain in North Carolina and Virginia. The Embayed Region is characterized by very extensive sounds cut off from the ocean by long barrier islands with few tidal inlets. A low tidal range in the ocean in this region limits tidal exchange at the inlets. Saltwater is present only in limited areas near the inlets. Brackish water prevails in most of the southern part of the region and some of the seaward side of the northern part of the region, grading to oligohaline and freshwater inland and northward, as well as upstream in tidal creeks. Lunar tidal fluctuation is negligible in most of the Embayed Region, and the irregular flooding of wind tides dominates. Soils are generally organic, but mineral soils are present in the more regularly flooded areas.

Key Processes and Interactions: Tidal flooding is an environmental process which distinguishes this system from others. Because the wind tides are irregular and shifts not as frequent or as strong as in lunar tide-dominated areas, sediment transport and probably productivity are lower in these marshes. Storms may drive increased amounts of salt into the sounds, stressing or killing plants in the brackish marshes. For marshes on the back of barrier islands, overwash in storms may deposit sand in the marsh. Marshes usually recover from this, but if sufficient sand is deposited, a different system may develop on the site, such as ~Northern Atlantic Coastal Plain Dune and Swale (CES203.264)$$. Fire is a natural force in the larger and less isolated patches of marsh, removing dead material, stimulating growth, and increasing species richness slightly but not altering overall composition. Rising sea level will affect this system, drowning some marsh areas, promoting shoreline erosion, and causing salt or brackish marshes to spread into freshwater marsh areas. However, elevated atmospheric CO2 increases the productivity of marsh grasses, which can lead to marsh elevation gain (Langley et al. 2009). The marsh snail (*Littoraria irrorata*) is a native and characteristic part of the marsh ecosystem,

and is eaten by blue crabs. The disruption of marsh snail predation by blue crabs can lead to a trophic cascade (Silliman and Bertness 2002, Bertness et al. 2004).
Threats/Stressors: Channelization and dredging are threats (Hackney and Cleary 1987). Tidal marshes depend on sources of sediments to maintain and increase their elevation with sea-level rise. This includes sediments transported down rivers and sand transported during storms from the ocean through inlets to marshes. Reduced natural sediment input to marshes is a threat. This includes reductions caused by dams upstream on major rivers (such as the Neuse and Roanoke rivers), and from sand removal from certain subtidal areas for beach renourishment (Hackney and Cleary 1987). Filling of marsh is a threat, but is restricted by laws and regulations. Invasive species of plants such as exotic invasive *Phragmites australis, Triadica sebifera*, and invasive animals such as nutria (*Myocastor coypus*) and feral hogs (*Sus scrofa*) are threats. Shoreline development and the removal of woody vegetation between developed areas and marsh lead to increased high nitrogen runoff entering the marsh. This promotes the growth of exotic invasive *Phragmites australis*, which is strongly associated with developed shorelines (Bertness et al. 2004). Very high populations of the marsh snail (*Littoraria irrorata*) are associated with marsh dieback (Bertness et al. 2004). The marsh snail is a native and characteristic part of the marsh ecosystem, and is eaten by blue crabs. When blue crab populations decrease, the numbers of marsh snail can increase to levels which are detrimental to the salt marsh, known as a trophic cascade. Blue crab populations have been stressed by drought-caused increases in salinity, disease and overfishing (Bertness et al. 2004). The predation of marsh snail by healthy populations of blue crabs is needed to prevent very high numbers of marsh snail from contributing to marsh dieback.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from hydrological alteration such as channelization, dredging, and associated erosion, or the impacts of invasive exotic plants or animals. Coastal development contributed to ecological collapse, due to increased high nitrogen runoff entering the coastal marsh. Disruption of the natural marsh predator - prey dynamics can contribute to ecological collapse; populations of the marsh snail (*Littoraria irrorata)* are an example. Ecosystem collapse is characterized by conversion of the tidal herbaceous marsh to open water, or exotic species-dominated marsh, such as marsh dominated by exotic invasive *Phragmites australis* or *Triadica sebifera*. Conversion of the salt marsh to hypersaline flats, or loss of marsh due to coastal development also represents ecosystem collapse.

CES203.257 Atlantic Coastal Plain Indian River Lagoon Tidal Marsh

CES203.257 CLASSIFICATION

Concept Summary: This tidally influenced marsh system of the Indian River Lagoon along Florida's Atlantic Coast supports approximately 10% of the salt marshes in Florida. It is endemic to the Atlantic Coast of Florida where it ranges from central Volusia County, southward through Brevard, Indian River, St. Lucie, and northern Martin counties, beginning in the vicinity of Daytona Beach and extending south from there. The bulk of these are "high marshes" wholly above mean high water levels. They are protected from direct exposure to the Atlantic Ocean by perched barrier islands, and consequently receive natural inundation only from wind tides and seasonal sea level changes. A berm or levee generally separates these high marshes from lower fringing marshes of *Spartina alterniflora* (to the north) and *Rhizophora mangle* (to the south). Landward of this berm, salt flats or hypersaline zones often develop with *Salicornia, Distichlis spicata, Borrichia frutescens, Batis maritima*, and *Paspalum vaginatum*. In some areas these species occur in monospecific zones, while in others they co-occur, grading into occasional *Avicennia germinans*. These zones are followed by a typical *Juncus roemerianus* zone, and the most inland fringes may be dominated by *Spartina bakeri*. Marshes of this region have been heavily altered by mosquito control impoundments of the 1950s and 1960s.
Related Concepts:

Distribution: This system is endemic to the Atlantic Coast of Florida where it ranges from central Volusia County, southward through Brevard, Indian River, St. Lucie, and northern Martin counties. This area begins in the vicinity of Daytona Beach and extends south from there.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, M. Pyne and C. Nordman

CES203.257 CONCEPTUAL MODEL

Environment: Tidal amplitudes in this region range from 0.6-1.5 m. Tides have a minute range in the north contributing to a very narrow intertidal zone, which is sometimes occupied by *Spartina alterniflora*. In the south where tidal range is greater, mangroves occupy the intertidal zone, replacing *Spartina alterniflora*.
Key Processes and Interactions: Tidal flooding is the ecological factor that distinguishes this system, but tidal amplitudes along the east coast of Florida are low. Due to evaporation in the Indian River Lagoon, salt flats with *Batis maritima, Salicornia depressa*, and *Salicornia bigelovii* were a common feature (Rey and Connelly 2012). Some of these salt flats were lost to mosquito-control impoundments (Rey and Connelly 2012). Tides bring nutrients, making the regularly flooded marshes fertile. Storms may push saltwater into brackish areas and higher zones, acting as a disturbance to vegetation. For marshes on the back of barrier islands, storm overwash may deposit sand in the marsh. Marshes usually recover from this, but if sufficient sand is deposited, a different system may develop on the site. Fire may be a natural force in some patches that are connected to the mainland. Prescribed fire has been used to manage tidal marshes for wildlife. Rising sea level will affect this system, drowning some marsh areas, promoting shoreline erosion, and causing salt or brackish marshes to spread inland into freshwater marsh areas. However, elevated atmospheric CO_2 increases the productivity of marsh grasses, which can lead to marsh elevation gain (Langley et al. 2009). The marsh snail (*Littoraria irrorata*) is a native and characteristic part of the marsh ecosystem, and is eaten by blue crabs. The disruption of marsh snail predation by blue crabs can lead to a trophic cascade (Silliman and Bertness 2002, Bertness et al. 2004).
Threats/Stressors: Mosquito-control impoundments have been threats (Rey and Connelly 2012). About 16,000 ha (40,000 acres) of Indian River Lagoon tidal marsh was impounded for mosquito control before the mid 1970s. Restoration work has been conducted on most of these areas (Rey and Connelly 2012), so that mosquito control can take place while maintaining other ecological functions. Tidal marshes depend on sources of sediments to maintain and increase their elevation with sea-level rise. This includes sediments transported during storms from the ocean through inlets to marshes. Reduced natural sediment input to marshes is a threat. This includes reduction sand removal from certain subtidal areas for beach renourishment. Filling of marsh is a threat, but is restricted by laws and regulations. Invasive species of plants such as exotic *Phragmites australis, Triadica sebifera*, and invasive animals, such as feral hogs (*Sus scrofa)* are threats. Shoreline development and the removal of woody vegetation between developed areas and marsh lead to increased high nitrogen runoff entering the marsh. This promotes the growth of exotic invasive *Phragmites australis*, which is strongly associated with developed shorelines (Bertness et al. 2004). Very high populations of the marsh snail (*Littoraria irrorata*) are associated with marsh dieback (Bertness et al. 2004). The marsh snail is a native and characteristic part of the marsh ecosystem, and is eaten by blue crabs. When blue crab populations decrease, the numbers of marsh snail can increase to levels which are detrimental to the salt marsh, known as a trophic cascade. Blue crab populations have been stressed by drought-caused increases in salinity, disease and overfishing (Bertness et al. 2004). The predation of marsh snail by healthy populations of blue crabs is needed to prevent very high numbers of marsh snail from contributing to marsh dieback. If killing frosts are reduced due to climate change, *Avicennia germinans* and *Rhizophora mangle* are likely to spread from the southern part of the Indian River Lagoon and become more abundant in historically colder areas. This could lead to conversion of tidal salt marsh area to mangrove.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from hydrological alteration, such as impoundment, channelization, dredging, and associated erosion, or the impacts of invasive exotic plants or animals. Coastal development contributes to ecological collapse, due to increased high nitrogen runoff entering the coastal marsh. Disruption of the natural marsh predator - prey dynamics can contribute to ecological collapse; populations of the marsh snail (*Littoraria irrorata)* are an example. Ecosystem collapse is characterized by conversion of the tidal herbaceous marsh to open water, or exotic species-dominated marsh, such as marsh dominated by exotic invasive *Phragmites australis* or *Triadica sebifera*. Conversion of the salt marsh to mangrove, or loss of marsh due to coastal development also represents ecosystem collapse.

CES203.508 Florida Big Bend Salt and Brackish Tidal Marsh

CES203.508 CLASSIFICATION

Concept Summary: This ecological system represents salt and brackish marshes of the northern Gulf of Mexico along the Florida Big Bend (roughly from Wakulla County [Apalachicola Bay] to the Pasco/Hernando county line [more or less to Tampa Bay] on Florida's west coast). The tidal range here is higher than in the western Panhandle, and wave energy is low; lunar, wind and seasonal tides make flooding irregular. The bulk of these marshes are composed of monospecific stands of *Juncus roemerianus* that often exhibit tall- and short-growth zones. Patches of *Spartina alterniflora* are less common, and may be confined to the edges of creeks or in other pockets of low elevation. Small patches of *Distichlis spicata* may also be present near berms or levees.

Related Concepts:

Distribution: This system is endemic to Florida from Wakulla County (Apalachicola Bay) to the Pasco/Hernando county line, north of Tampa Bay. (To the west of Apalachicola Bay, where the tides are diurnal instead of semi-diurnal, ~Mississippi Sound Salt and Brackish Tidal Marsh (CES203.471)$$ replaces this system.)

Nations: US

Concept Source: R. Evans and C. Nordman

Description Author: R. Evans, C. Nordman, M. Pyne

CES203.508 CONCEPTUAL MODEL

Environment: Irregularly tidal; wind, lunar, and seasonal influences are important.

Key Processes and Interactions: The tidal range here is higher than in the western Panhandle, and wave energy is low; lunar, wind and seasonal tides make flooding irregular (Montague and Wiegert 1990).

Threats/Stressors: Many of the threats to coastal marshes are less along Florida's Big Bend coast than in other areas. This is due to less coastal development and other factors. Channelization and dredging are threats (Hackney and Cleary 1987). Tidal marshes depend on sources of sediments to maintain and increase their elevation with sea-level rise. This includes sediments transported down rivers and sand transported during storms from the ocean through inlets to marshes. Reduced natural sediment input to marshes is a threat. This includes reductions caused by dams upstream on major rivers (such as the Apalachicola River system), and from sand removal from certain subtidal areas for beach renourishment (Hackney and Cleary 1987). Filling of marsh is a threat, but is restricted by laws and regulations. Invasive species of plants such as exotic invasive *Phragmites australis, Triadica sebifera*, and invasive animals such as nutria (*Myocastor coypus*) and feral hogs (*Sus scrofa*) are threats. Shoreline development and the removal of woody vegetation between developed areas and marsh lead to increased high nitrogen runoff entering the marsh. This promotes the growth of exotic invasive *Phragmites australis*, which is strongly associated with developed shorelines (Bertness et al. 2004). Very high populations of the marsh snail (*Littoraria irrorata*) are associated with marsh dieback (Bertness et al. 2004). The marsh snail is a native and characteristic part of the marsh ecosystem, and is eaten by blue crabs. When blue crab populations decrease, the numbers of marsh snail can increase to levels which are detrimental to the salt marsh, known as a trophic cascade. Blue crab populations have been stressed by drought-caused increases in salinity, disease and overfishing (Bertness et al. 2004). The predation of marsh snail by healthy populations of blue crabs is needed to prevent very high numbers of marsh snail from contributing to marsh dieback. If killing frosts are reduced due to climate change, *Avicennia germinans* and *Rhizophora mangle* are likely to spread from the coast of the Florida Peninsula and become more abundant in historically colder areas. This could lead to conversion of tidal salt marsh areas to mangrove.

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from hydrological alteration such as channelization, dredging, and associated erosion, or the impacts of invasive exotic plants or animals. Coastal development contributed to ecological collapse, due to increased high nitrogen runoff entering the coastal marsh. Disruption of the natural marsh predator - prey dynamics can contribute to ecological collapse; populations of the marsh snail (*Littoraria irrorata*) are an example. Ecosystem collapse is characterized by conversion of the tidal herbaceous marsh to open water, or exotic species-dominated marsh, such as marsh dominated by exotic invasive *Phragmites australis* or *Triadica sebifera*. Conversion of the salt marsh to hypersaline flats, or loss of marsh due to coastal development also represents ecosystem collapse.

CES203.468 Gulf Coast Chenier Plain Salt and Brackish Tidal Marsh

CES203.468 CLASSIFICATION

Concept Summary: This system includes brackish to salt intertidal marshes in the Chenier Plain of Louisiana and Texas. This area was characterized historically by a prograding coastline replenished by sediments carried to the Gulf of Mexico by the Mississippi, Atchafalaya and other rivers. It is void of barrier islands. Shoreline sediments are deposited by longshore currents and reworked by waves into alternating beach ridges and mudflats depending on the amount of sediment input. This process started after the last glacial retreat and, as the coastline prograded over time, older beach ridges were left as interior ridges surrounded by marsh. Historically, natural connections between the marshes and the ocean were limited by these beach ridges, resulting in an abundance of fresh to oligohaline (intermediate) marsh, not as much brackish marsh, and even less salt marsh. In more recent times, with the increase of dredged canals connecting the marsh system to the gulf, an increase in salinity has occurred, to the detriment of plants adapted to freshwater environments. Significant fresh marsh loss has occurred in this area. Increases in salinity levels may be caused by saltwater intrusion and/or freshwater diversion. Both water level and salinity influence species composition. Salt marshes (about 16 ppt) receive regular daily tides and are typically dominated by *Spartina alterniflora*. Brackish marshes (about 8 ppt), under slightly less tidal influence and moderately influenced by freshwater, are typically dominated by *Spartina patens*, and degraded by saltwater intrusion. Brackish occurrences may be found along tidal creeks, smaller ponds and at the upper reaches of daily tides or in areas more influenced by wind tides. Inclusions of *Juncus roemerianus* and other brackish species are found in small to large patches. Through the control of the Mississippi River, historic chenier processes have been lost. Historically a progradational shoreline, today the Chenier Plain shoreline is dominated by erosion. However, coastal processes of progradation are still present in limited areas fed by sediments from the Atchafalaya River.

- Chenier Plain: Salt and Brackish High Tidal Shrub Wetland (5716) [CES203.468.16] (Elliott 2011) **<**
- Chenier Plain: Salt and Brackish Low Shrub Tidal Wetland (5706) [CES203.468.6] (Elliott 2011) **<**
- Chenier Plain: Salt and Brackish Low Tidal Marsh (5707) [CES203.468.7] (Elliott 2011) **<**

Distribution: This system extends from Vermillion Bay, Louisiana, to East Bay, Texas. Salt marsh is limited to areas fringing saltwater shorelines. Brackish marshes are found landward of the salt marshes (typically between fresh to oligohaline marshes and salt marshes) and are more prominent around coastal lakes.

Nations: US

Concept Source: J. Teague and R. Evans

Description Author: J. Teague, R. Evans, M. Pyne and L. Elliott

CES203.468 CONCEPTUAL MODEL

Environment: Salt marshes on the Gulf Coast receive regular daily microtides. Brackish marshes, under slightly less tidal influence and moderately influenced by freshwater, are degraded by saltwater intrusion. This ecological system is found flanking large bays, along tidal creeks, between saltwater and fresh to oligohaline marshes, and in areas more influenced by wind tides. Examples are found on recent alluvial deposits of coastlines, bay margins, bay inlets, along dredged canals, creeks, and river inlets where tidal influence is adequate to maintain mesohaline to polyhaline conditions. Soils are fine-textured, sometimes with high organic content at the surface. Ecoclasses (from Ecological Site Descriptions) include brackish and salt marsh types in Texas (Elliott 2011). Though progradation has been reduced from the loss of sediment as a result of the control of the Mississippi River, the Chenier Plain is prograding in some places, most notably west of the mouth of the Atchafalaya River. Historically a progradational shoreline, the Chenier Plain shoreline is now dominated by erosion.

Key Processes and Interactions: Historic natural processes of the Chenier Plain were tied to the deltaic processes of the Mississippi River and the natural hydrological processes of other rivers along the western coast of Louisiana and eastern coast of Texas. These natural processes have all been altered, but processes of freshwater and sediment input still persist even though in an altered state. Sediment input is critical to marsh persistence and becomes even more important under accelerated sea-level rise scenarios. Marsh vegetation plays an equally important role in maintaining marsh elevation (Baustian et al. 2012). The Chenier Plain of Louisiana has unusually high relative sea-level rise (Draut et al. 2005). This is a microtidal environment. Salt and brackish marshes are important habitats for many animal species.

Threats/Stressors: This system is primarily threatened by alteration of natural deltaic and Chenier Plain processes, relative sea-level rise and displacement by a range expansion of *Avicennia* spp. (Osland et al. 2012) due to climate change. Additional marsh loss is due to dredging, leveeing, erosion, and pollution (LDWF 2005). With rising sea levels, marsh loss is expected when sedimentation and organic matter accumulation cannot keep pace with rising waters.

Conversion of marsh to open water has been high in Louisiana (Couvillion et al. 2011, USGS 2013b, Williams 2013). Coastal Louisiana has the highest rates of relative sea-level rise (>9 mm/year) in the nation (Williams 2013). A global eustatic sea-level rise of 0.5 to 2.0 m by A.D. 2100 when coupled with subsidence and barriers to the landward migration of marshes could result in devastating impacts on the coastal marshes of Louisiana (Neubauer 2013, Williams 2013). "Louisiana has sustained more coastal wetland loss than all other states in the continental United States combined" (Glick et al. 2013). SLAMM models predict 42 to 99% marsh and swamp loss in southeastern Louisiana by 2100 if eustatic sea-level rise exceeds 0.75 m (Glick et al. 2013).

Ecosystem Collapse Thresholds: Ecological collapse in the system tends to result from a lack of sedimentation and organic matter accumulation to maintain marshes in the face of increased relative sea-level rise. Ecosystem collapse is characterized by conversion of the tidal herbaceous vegetation to mangroves or open water.

CES301.461 South Texas Salt and Brackish Tidal Flat

CES301.461 CLASSIFICATION

Concept Summary: This system includes regularly to irregularly flooded hypersaline tidal flats (often exceeding a thousand acres in size). Dominants include a variety of vascular and nonvascular species. The cyanobacteria (blue-green algae) *Lyngbya* spp. may dominate thousands of acres. Total vegetative cover is quite variable, from near total absence of vascular plants to a dense cover of one of several dominant species including *Batis maritima, Monanthochloe littoralis, Spartina spartinae, Borrichia frutescens*, and *Sarcocornia perennis*. In addition to the dominants, other halophytic plants of this system include *Atriplex matamorensis, Distichlis spicata, Sarcocornia perennis, Sporobolus virginicus, Maytenus phyllanthoides, Prosopis reptans, Borrichia frutescens, Suaeda linearis, Suaeda conferta, Monanthochloe littoralis, Lycium carolinianum var. quadrifidum, Spartina spartinae, Sesuvium portulacastrum, Rayjacksonia phyllocephala*, and *Blutaparon vermiculare*. In addition to dominating non-vegetated areas, algal mats of blue-green and sometimes green algae are characteristically present, visible even in densely vegetated pannes. Blue-green algae may contribute significantly more biomass than vascular species. Widely scattered *Avicennia germinans* (and, less frequently, other mangroves) may occur.

Distribution: This system ranges south of Corpus Christi Bay along the northern Gulf of Mexico.
Nations: US
Concept Source: J. Teague
Description Author: J. Teague, M. Pyne and L. Elliott

CES301.461 CONCEPTUAL MODEL

Environment: This system occurs in tidal and other hypersaline situations along upper marsh edges and in tidal flats ranging in scale from narrow bands to hundreds of hectares along the Gulf Coast of southern Texas and Mexico. It is regularly to irregularly flooded by shallow brackish waters as a result of lunar, wind and storm tides. As these waters evaporate, high concentrations of salt accumulate, producing hypersaline conditions, forming "salt pannes." It is found on recent wind-distributed coastal sands along barrier island and mainland shores of hypersaline lagoons and bays where evaporation often exceeds freshwater input. Tidal fluctuations and wind continue to redistribute these sands. Landforms are extensive, very gentle (nearly flat) slopes.

CES203.471 Mississippi Delta Salt and Brackish Tidal Marsh

CES203.471 CLASSIFICATION

Concept Summary: This system includes brackish to saline intertidal marshes in the Mississippi Delta area of Louisiana. Both water level and salinity influence species composition. The salt marsh component of this system receives regular daily tides; these areas are typically dominated by large to extensive expanses of *Spartina alterniflora*. Brackish marshes, under slightly less tidal influence and moderate freshwater influence, are typically dominated or codominated by *Spartina patens* and may cover larger expanses than salt marshes in this system. Inclusions of *Juncus roemerianus* and other brackish species are found in small to large patches. Significant brackish marsh loss has occurred in the deltaic plain of the Mississippi River. These losses are related to natural and anthropogenic causes. Subsidence and loss of wetlands are a natural part of the deltaic process, but they have been exacerbated by the reduction in sediment load into coastal areas caused by the impoundment and channelization of the Mississippi River. In addition dredged channels in the marsh facilitate saltwater intrusion, and spoil banks prevent marshes from draining. Increases in salinity cause shifts in composition to species more tolerant of salinity, ultimately resulting in loss of species diversity and potentially open saline waters when marsh accretion is outpaced by a rising sea level.

Related Concepts:

Distribution: This system is confined to the deltaic plain of Louisiana. Marshes in the Mississippi River deltaic plain encompass approximately 20% of the marshes in the conterminous U.S. and about half of these are salt and brackish marshes (Gosselink 1984, Field et al. 1991, Visser et al. 1998, Hester et al. 2005).

Nations: US

Concept Source: J. Teague and R. Evans

Description Author: J. Teague and R. Evans

CES203.471 CONCEPTUAL MODEL

Environment: This system occurs in the Mississippi River deltaic plain. Salt marshes in this system receive regular daily microtides. Brackish marshes, under slightly less tidal influence and moderately influenced by freshwater, are degraded by saltwater intrusion. This ecological system is found flanking large bays, along tidal creeks, between saline waters and fresh to oligohaline marshes, and in areas more influenced by wind tides. Examples are found on recent alluvial deposits of coastlines, bay margins, bay inlets, along dredged canals, creeks, and river inlets where tidal influence is adequate to maintain high salinities. Soils are fine-textured, sometimes with high organic content at the surface. Historically, these marshes have been protected from the Gulf of Mexico by a series of barrier islands associated with different delta lobes. With the alteration of the Mississippi River deltaic processes, these islands are undergoing increasing deterioration with potential negative effects on the marshes they protect.

Key Processes and Interactions: Historically, the deltaic processes of the Mississippi River helped to build and maintain this system. However, today there is a predominance of coastal loss and subsidence in the Mississippi River deltaic plain (Gosselink et al. 1998, Draut et al. 2005). The natural sediment load and freshwater entering the deltaic marshes are dependent on functioning hydrological processes in the Mississippi River. This marsh system is dependent upon freshwater input, sediment input and organic matter build-up. Historically, these marshes have been protected from the Gulf of Mexico by a series of barrier islands associated with different delta lobes. With the alteration of the Mississippi River deltaic processes, these islands are undergoing increasing deterioration with potential negative effects on the marshes they protect. Sediment input is critical to marsh persistence and becomes even more important under accelerated sea-level rise scenarios. Salt and brackish marshes are important habitats for many animal species.

Threats/Stressors: This system is primarily threatened by alteration of natural deltaic plain processes, relative sea-level rise and displacement by a range expansion of *Avicennia* spp. (Osland et al. 2012, USGS 2013b) due to climate change. Additional marsh loss is due to dredging, leveeing, erosion, and pollution (LDWF 2005). With rising sea levels, marsh loss is expected when sedimentation and organic matter accumulation cannot keep pace with rising waters. An increase in storm intensities and barriers to landward marsh migration could further exacerbate the impacts of subsidence and sea-level rise. Other threats include pollution entering the marsh from point and nonpoint sources.

Conversion of marsh to open water has been high in Louisiana (Couvillion et al. 2011, USGS 2013b, Williams 2013). Coastal Louisiana has the highest rates of relative sea-level rise (>9 mm/year) in the nation (Williams 2013). A global eustatic sea-level rise of 0.5 to 2.0 m by A.D. 2100 when coupled with subsidence and barriers to the landward migration of marshes could result in devastating impacts on the coastal marshes of Louisiana (Neubauer 2013, Williams 2013). "Louisiana has sustained more coastal wetland loss than all other states in the continental United States combined" (Glick et al. 2013). SLAMM models predict 42 to 99% marsh and swamp loss in southeastern Louisiana by 2100 if eustatic sea-level rise exceeds 0.75 m (Glick et al. 2013).

Ecosystem Collapse Thresholds: Ecological collapse in the system tends to result from relative sea-level rise and lack of sedimentation and organic matter accumulation to maintain marshes. Ecosystem collapse is characterized by conversion of the tidal herbaceous vegetation to mangroves or open water.

CES203.303 Mississippi Sound Salt and Brackish Tidal Marsh

CES203.303 CLASSIFICATION

Concept Summary: This ecological system includes salt and brackish tidal marshes of the north-central Gulf of Mexico, ranging from the Pearl River to northwestern Florida. These marshes are typically found bordering protected bays, sounds, lagoons and other low-energy shorelines. Wind-dominated tides and low tidal amplitudes (less than 1 m) characterize this region. This system includes predominately brackish marshes and supports what is probably the largest zone of *Juncus roemerianus* in the Atlantic and Gulf coastal plains outside of the North Carolina/Virginia Embayed Region estuarine marshes.

- Live Oak: 89 (Eyre 1980) **<**

Distribution: This system is found along the northern Gulf of Mexico in northwestern Florida, southern Alabama, and southern Mississippi. The eastern extent of this system coincides with the range of diurnal tides in the northeastern Gulf of Mexico. (East of Apalachicola Bay, where the tides are semi-diurnal (Stout 1984), ~Florida Big Bend Salt and Brackish Tidal Marsh (CES203.508)$$ replaces this system.) To the west, ~Mississippi Sound Salt and Brackish Tidal Marsh (CES203.471)$$ replaces this system in the Mississippi Delta.

Nations: US

Concept Source: R. Evans

Description Author: R. Evans, M. Pyne and J. Teague

CES203.303 CONCEPTUAL MODEL

Environment: This marsh system occurs along low-energy shorelines in a region characterized by diurnal tides usually less than 0.5 m in amplitude. Inundation is irregular and depends upon wind speed and direction, and the flow of water from nearby rivers; generally more flooding occurs in the summer than winter (Hackney and de la Cruz 1982). The climate is mixed, with subtropical conditions prevailing during years with mild winters and temperate conditions when strong arctic cold fronts extend to the Gulf of Mexico.

Key Processes and Interactions: Important processes and interactions in this system include the natural hydrological processes of rivers bringing freshwater and sediments to the coast, diurnal tides, and protection from high-energy wave actions (Morton et al. 2004). These natural processes have generally all been altered to some degree, but processes of freshwater and sediment input still persist even though in an altered state. Sediment input is critical to marsh persistence and becomes even more important under accelerated sea-level rise scenarios. Marsh vegetation plays an equally important role in maintaining marsh elevation (Baustian et al. 2012). Salt and brackish marshes are important habitats for many animal species.

Threats/Stressors: Thousands of hectares of this system have been lost due to dredging, filling, draining, erosion, and other factors (Stout 1984). These factors continue to impact coastal marshes in this system. In addition, these marshes are impacted by point and nonpoint source pollutants. With rising sea levels, marsh loss is expected when sedimentation and organic matter accumulation cannot keep pace with rising waters. Sea-level rise is expected to impact marshes with insufficient buffer to allow landward migration. Increased storm intensity predicted under future climate change also threatens this system.
Ecosystem Collapse Thresholds: Ecological collapse in the system tends to result from direct conversion of marshes caused by draining, dredging, filling, and erosion, and a lack of sedimentation and organic matter accumulation to maintain marshes in the face of increased relative sea-level rise. Ecosystem collapse is characterized by conversion of the tidal herbaceous vegetation to developed areas and open water.

CES203.519 Northern Atlantic Coastal Plain Tidal Salt Marsh

CES203.519 CLASSIFICATION

Concept Summary: This system encompasses the mesohaline to saline intertidal marshes of the North Atlantic Coastal Plain, ranging from Chesapeake Bay north to Cape Cod, Massachusetts, and sporadically to the southern Maine coast. It includes a number of different broad vegetation types including salt pannes, salt marshes, and salt shrublands. This system occurs on the bay side of barrier beaches and the outer mouth of tidal rivers where salinity is not much diluted by freshwater input. The typical salt marsh profile, from sea to land, can be summarized as follows: a low regularly flooded marsh strongly dominated by *Spartina alterniflora*; a higher irregularly flooded marsh dominated by *Spartina patens* and *Distichlis spicata*; low hypersaline pannes characterized by *Salicornia* spp.; and a salt scrub ecotone characterized by *Iva frutescens, Baccharis halimifolia*, and *Panicum virgatum*. Salt marsh "islands" of slightly higher elevation also support *Juniperus virginiana*. This system also includes the rare sea-level fen vegetation, which occurs at the upper reaches of the salt marsh where groundwater seepage creates a freshwater fen that differs from other poor fens in its generally higher species richness, absence of *Chamaedaphne calyculata*, and presence of *Eleocharis rostellata* and *Cladium mariscoides*.
Related Concepts:
- Loblolly Pine: 81 (Eyre 1980) **<**

Distribution: This system is found from the southern Maine coast south to the Chesapeake Bay.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, S.C. Gawler and L.A. Sneddon

CES203.519 CONCEPTUAL MODEL

Environment: Forms behind barrier beaches or at the outer mouths of tidal rivers where freshwater input is minimal and where vegetation is protected from high-energy wave action. Substrate is organic peat, which can reach 1-2 m in depth in low marsh.
Key Processes and Interactions: Tidal flooding regulated by elevation; flooding is diurnal in low marshes, decreasing to more irregular flooding in high marsh and fringing salt shrublands. Ponded water remains in depressions, causing hypersaline conditions and panne formation.
Threats/Stressors: Ditching, upland influx of water pollutants; dredging, spoil dumping, indirect effects caused by restricted tidal flow; invasive species (Kennish 2001). sea-level rise is expected to impact marshes with insufficient buffer to allow migration landward; high-emission scenarios predict up to 2-m sea level increase by the end of the century, which may overtake the rate of salt marsh migration landward. sea-level rise, as well as storm intensity, is expected to affect coastal areas everywhere, but

especially so in the northeastern U.S. sea-level rise from Cape Hatteras, North Carolina, to Boston, Massachusetts, is expected to proceed at a rate that is three to four times that of global projections (Boon 2012, Sallenger et al. 2012).
Ecosystem Collapse Thresholds: Extensive bare soils caused by erosion of marsh and channel banks; <50% relative cover of native plant species (usually *Phragmites australis*). Tidal channel sinuosity extensively altered. Tidal channels are extensively blocked by dikes and tide gates; evidence of extensive human channelization. Tidal flooding is totally or almost totally impeded by tidal gates or obstructed culverts. Area is subject to plus there is inadequate drainage, such that the marsh plain tends to remain flooded during low tide; Encroachment by terrestrial vegetation. Most or all diagnostic species absent, a few may remain in very low abundance (*Spartina alterniflora, Spartina patens, Iva frutescens*). Most examples are heavily reduced from original, natural extent (>50%). (Faber-Langendoen et al. 2011).

CES203.270 Southern Atlantic Coastal Plain Salt and Brackish Tidal Marsh

CES203.270 CLASSIFICATION

Concept Summary: This ecological system encompasses the brackish to saline intertidal marshes of the Atlantic Coast ranging from the vicinity of Morehead City, Carteret County, North Carolina (south of the Embayed Region), south to the vicinity of Marineland or Daytona Beach (Flagler/Volusia counties) in northern Florida. It is dominated by medium to extensive expanses of *Spartina alterniflora*, flooded twice daily by lunar tides. *Juncus roemerianus* and other brackish marshes occur on slightly higher marsh, including upstream along tidal creeks, and a variety of small-patch associations occur near the inland edges. Examples of this system may also support inclusions of shrublands dominated by either *Baccharis halimifolia* and/or *Borrichia frutescens*, as well as forests or woodlands with *Juniperus virginiana var. silicicola* in the overstory.
Related Concepts:

- Southern Redcedar: 73 (Eyre 1980) **<**

Distribution: This systems ranges from central North Carolina (Carteret County) south to the vicinity of Flagler and Volusia counties, Florida. The northern boundary is roughly the eastern end of Carteret County, North Carolina.
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, M. Pyne and C.W. Nordman

CES203.270 CONCEPTUAL MODEL

Environment: This system occurs on intertidal flats that are tidally-flooded with salt to brackish water along the Atlantic Coast south of the Embayed Region of North Carolina, extending to northern Florida (south to the vicinity of Flagler and Volusia counties). Regular tidal flooding occurs over most of the system, with irregular flooding in unusually high tides occurring in the upper zones. Tidal ranges vary but are 60 cm (2 feet) or more. The water is salty over most of the expanse of this system, grading to brackish upstream in tidal rivers and creeks. Upper zones tend to have vegetation suggestive of brackish water as well, but this is apparently the result of a combination of irregular saltwater flooding with freshwater input. Local depressions in upper zones may be hypersaline due to concentration of salt by evaporation. Flooding depth and salinity are the primary determinants of the boundary of this system and of the variation in associations within it. Soils are either sandy or clayey and often are sulfidic and high in organic matter. The input of cations in sea water prevents them from being strongly acidic, but they may rapidly become extremely acidic if drained.

Key Processes and Interactions: Tidal flooding is the ecological factor that distinguishes this system from others. Tides bring nutrients, making the regularly flooded marshes fertile. Storms may push saltwater into brackish areas and higher zones, acting as a disturbance to vegetation. In salt marshes, storms locally concentrate debris into piles or bands (wrack) that smother vegetation. For marshes on the back of barrier islands, storm overwash may deposit sand in the marsh. Marshes usually recover from this, but if sufficient sand is deposited, a different ecological system may develop on the site, such as ~Southern Atlantic Coastal Plain Dune and Maritime Grassland (CES203.273)$$. Fire may be a natural force in some patches that are connected to the mainland, such as *Juncus roemerianus* marsh. *Spartina alterniflora* salt marshes are more often flooded by tides and too wet to burn. Rising sea level will affect this system strongly, drowning some marsh areas, promoting shoreline erosion, and causing salt or brackish marshes to spread inland into freshwater marsh areas. However, elevated atmospheric CO2 increases the productivity of marsh grasses, which can lead to marsh elevation gain (Langley et al. 2009). The marsh snail (*Littoraria irrorata*) is a native and characteristic part of the marsh ecosystem, and is eaten by blue crabs. The disruption of marsh snail predation by blue crabs can lead to a trophic cascade (Silliman and Bertness 2002, Bertness et al. 2004).

Threats/Stressors: Channelization and dredging are threats (Hackney and Cleary 1987). Tidal marshes depend on sources of sediments to maintain and increase their elevation with sea-level rise. This includes sediments transported down rivers and sand transported during storms from the ocean through inlets to marshes. Reduced natural sediment input to marshes is a threat. This includes reductions caused by dams upstream on major rivers (such as the Great Pee Dee, Santee, Cooper and Savannah rivers), and from sand removal from certain subtidal areas for beach renourishment (Hackney and Cleary 1987). Filling of marsh is a threat, but is restricted by laws and regulations. Invasive species of plants such as exotic invasive *Phragmites australis, Triadica sebifera*, and invasive animals such as nutria (*Myocastor coypus*) and feral hogs (*Sus scrofa*) are threats. Shoreline development and the removal of woody vegetation between developed areas and marsh lead to increased high nitrogen runoff entering the marsh. This promotes the growth of exotic invasive *Phragmites australis*, which is strongly associated with developed shorelines (Bertness et al. 2004). Very high populations of the marsh snail (*Littoraria irrorata*) are associated with marsh dieback (Bertness et al. 2004). The marsh snail is a native and characteristic part of the marsh ecosystem, and is eaten by blue crabs. When blue crab populations decrease, the numbers of marsh snail can increase to levels which are detrimental to the salt marsh, known as a trophic cascade. Blue crab populations have been stressed by drought-caused increases in salinity, disease and overfishing (Bertness et al. 2004). The predation of marsh snail by healthy populations of blue crabs is needed to prevent very high numbers of marsh snail from contributing to marsh dieback. If killing frosts are reduced due to climate change, *Avicennia germinans* and *Rhizophora mangle* are likely to spread from the coast of the Florida Peninsula and become more abundant in historically colder areas (Cavanaugh et al. 2013). This could lead to conversion of tidal salt marsh areas to mangrove (Cavanaugh et al. 2013).

Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from hydrological alteration such as channelization, dredging, and associated erosion (Hackney and Cleary 1987), or the impacts of invasive exotic plants or animals. Coastal development contributed to ecological collapse, due to increased high nitrogen runoff entering the coastal marsh (Bertness et al. 2004). Disruption of the natural marsh predator - prey dynamics can contribute to ecological collapse, populations of the marsh snail (*Littoraria irrorata*) are an example (Bertness et al. 2004). Ecosystem collapse is characterized by conversion of the tidal herbaceous marsh to open water, or exotic species-dominated marsh, such as marsh dominated by exotic invasive *Phragmites australis* or *Triadica sebifera*. Conversion of the salt marsh to hypersaline flats, or loss of marsh due to coastal development also represents ecosystem collapse.

CES203.473 Texas Coast Salt and Brackish Tidal Marsh

CES203.473 CLASSIFICATION

Concept Summary: This ecological system encompasses all of the brackish to salt intertidal marshes of the Texas coast south of the Chenier Plain. It ranges from Galveston Bay in Chambers County, Texas, south. These marshes typically occur on the bay side of barrier islands. Representative examples are dominated by *Spartina alterniflora, Juncus roemerianus*, or *Avicennia germinans*. Significant areas of *Avicennia germinans* become more frequent towards the south, while extensive areas of *Spartina alterniflora* become rare south of Corpus Christi Bay. The system also includes extensive irregularly-flooded tidal flats and salt pannes, some vegetated by succulent herbs such as *Sarcocornia, Salicornia*, and *Batis*; some are nonvegetated.

Distribution: This salt and brackish marsh system of the Texas coast ranges from Galveston Bay in Chambers County, Texas, south.

Nations: US

Concept Source: J. Teague

Description Author: J. Teague, M. Pyne and L. Elliott

CES203.473 CONCEPTUAL MODEL

Environment: These marshes occupy relatively low-lying, coastal situations on level landforms influenced by microtidal fluctuations. Some sites are only influenced by storm tides or tides resulting from extreme wind events. These marshes typically occur on the bay side of barrier islands. This system also includes extensive irregularly-flooded tidal flats and salt pannes. The geology consists of recent marine, alluvial and eolian deposits along the coast. Landforms are nearly level to very gentle slopes and flats influenced by tides, including wind tides. Soils are coastal sands, and the system occupies various Salt Marsh Ecological Sites.

Key Processes and Interactions: Important processes and interactions in this system include the natural hydrological processes of rivers bringing freshwater and sediments to the coast, diurnal microtides, and protection from high-energy wave actions (Morton et al. 2004). The composition of these marshes is primarily influenced by the frequency and duration of tidal inundation. Salinity on some marshes, particularly in the south, is maintained by salt spray from prevailing southeasterly winds. Low marshes are regularly flooded. Areas of decreased frequency and/or duration of tidal inundation are often referred to as high, or irregularly flooded, marsh (Elliott 2011). Freshwater and sediment input are scarce in the southern part of this system's range. Sediment input is critical to marsh persistence and becomes even more important under accelerated sea-level rise scenarios. Marsh vegetation plays an equally important role in maintaining marsh elevation (Baustian et al. 2012). Salt and brackish marshes are important habitats for many animal species.

Threats/Stressors: This system may be degraded and lost due to dredging, filling, draining, erosion, and other factors. In addition these marshes are impacted by point and nonpoint source pollutants. With rising sea levels, marsh loss is expected when sedimentation and organic matter accumulation cannot keep pace with rising waters. Sea-level rise is expected to impact marshes with insufficient buffer to allow landward migration. Increased storm intensity predicted under future climate change also threatens this system.
Ecosystem Collapse Thresholds: Ecological collapse in the system tends to result from direct conversion of marshes caused by draining, filling, dredging, and erosion, and a lack of sedimentation and organic matter accumulation to maintain marshes in the face of increased relative sea-level rise. Ecosystem collapse is characterized by conversion of the tidal herbaceous vegetation to developed areas and open water.

CES203.543 Texas Saline Coastal Prairie

CES203.543 CLASSIFICATION

Concept Summary: This system encompasses grassland vegetation occurring along the Gulf Coast of Texas on saline and nonsaline soils on level topography of the Beaumont Formation and in brackish marshes. These areas are often saturated by local rainfall and periodically flooded by saline waters during major storm events. Outliers also occur as scattered patches in salt flats. It is characteristically dominated by *Spartina spartinae*, a tall (1.5 m) warm-season perennial bunchgrass; other dominants may include *Schizachyrium littorale* and *Muhlenbergia capillaris*. This system also includes depressions often dominated by *Spartina patens*. Saline prairie continues to occupy extensive areas, though quality of the system is often degraded by the invasion of woody shrubs due to the absence of regular fire. Fire is an important ecological process needed to maintain this system, though periodic submersion with saltwater during storm events also helps to control the invasion of woody species.
Related Concepts:

- Gulf Coast: Salty Prairie (2207) [CES203.543.7] (Elliott 2011) **<**
- Gulf Coast: Salty Shrubland (2206) [CES203.543.6] (Elliott 2011) **<**

Distribution: This system is restricted to the Gulf Coast of Texas.
Nations: US
Concept Source: J. Teague
Description Author: J. Teague, M. Pyne and L. Elliott

CES203.543 CONCEPTUAL MODEL

Environment: This system occurs on saline and nonsaline soils of the Pleistocene Beaumont Formation that are often saturated by local rainfall and periodically flooded by saline waters during major storm events. Landforms are mostly level or very gently undulating, and typically found near the coast. These sites may be inundated by saltwater during storm surges. Pimple mounds may lend some local topographic variation to the otherwise level surface. Soils are very deep, somewhat poorly to poorly drained, often with high salinity and/or sodicity, at least at some depth. These may be loams or clays. These soils may be saturated from local rainfall or occasionally from storm surges (Elliott 2011). This system often forms a band between coastal salt marshes and coastal nonsaline prairie.
Key Processes and Interactions: Fire is an important ecological process needed to maintain this system. Periodic submersion with saltwater during storm events also helps to control the invasion of woody species and contributes to higher soil salinity levels.
Threats/Stressors: Primary historic and current threats to this system include conversion to agriculture and coastal development, and alterations to the natural fire regime. In the absence of regular fire, this system will be invaded by woody shrubs. If changes in regional climate bring about an increase in precipitation, this could lead to an increase in woody encroachment; a decrease in precipitation could lead to loss of the wet prairie components of this system. Due to its proximity to the coast and coastal marshes, sea-level rise could further impact this system by saltwater inundation. Sea-level rise is expected to have a greater impact in places

with insufficient buffer to allow landward migration. Increased storm intensity predicted under future climate change also threatens this system.

Ecosystem Collapse Thresholds: Ecological collapse results from conversion of native prairie to agriculture and developed land uses, fragmenting the landscape and disrupting natural processes such as fire. Ecological collapse is characterized by fragmentation, loss of natural fire processes, dominance by native and non-native species, and complete conversion of the system to other land uses.

2.C.5.Nc. Temperate & Boreal Pacific Coastal Salt Marsh

M081. North American Pacific Coastal Salt Marsh

CES200.091 Temperate Pacific Tidal Salt and Brackish Marsh

CES200.091 CLASSIFICATION

Concept Summary: Intertidal salt and brackish marshes are found throughout the Pacific coast, from Kodiak Island and south-central Alaska to the central California coast. They are primarily associated with estuaries or coastal lagoons. Salt marshes are limited to bays and behind sand spits or other locations protected from wave action. Typically these areas form with a mixture of inputs from freshwater sources into coastal saltwater, so they commonly co-occur with brackish marshes. This is a small-patch system, confined to specific environments defined by ranges of salinity, tidal inundation regime, and soil texture. Patches usually occur as zonal mosaics of multiple communities. They vary in location and abundance with daily and seasonal dynamics of freshwater input from inland balanced against evaporation and tidal flooding of saltwater. Summer-dry periods result in decreased freshwater inputs from inland. Hypersaline environments within salt marshes occur in "salt pans" where tidal water collects and evaporates. Characteristic plant species include *Distichlis spicata, Limonium californicum, Jaumea carnosa, Salicornia* spp., *Suaeda* spp., and *Triglochin* spp. Low marshes are located in areas that flood every day and are dominated by a variety of low-growing forbs and low to medium-height graminoids, especially *Salicornia depressa, Distichlis spicata, Bolboschoenus maritimus, Schoenoplectus americanus, Carex lyngbyei*, and *Triglochin maritima*. In Alaska, tidal marshes are often dominated by near-monotypic stands of *Carex lyngbyei*, while the frequently inundated lower salt marshes are often dominated by *Eleocharis palustris* or *Puccinellia* spp. Other common species in Alaska include *Hippuris tetraphylla, Plantago maritima, Cochlearia groenlandica, Spergularia canadensis, Honckenya peploides*, or *Glaux maritima*. In the Cook Inlet and Alaska Peninsula, *Carex ramenskii* may be an associated species. High marshes are located in areas that flood infrequently and are dominated by medium-tall graminoids and low forbs, especially *Deschampsia cespitosa, Argentina egedii, Juncus arcticus ssp. littoralis*, and *Symphyotrichum subspicatum*, and in Alaska *Poa eminens, Argentina egedii, Festuca rubra*, and *Deschampsia cespitosa*. Transition zone (slightly brackish) marshes are often dominated by *Typha* spp. or *Schoenoplectus acutus*. *Atriplex prostrata, Juncus mexicanus, Phragmites* spp., *Cordylanthus* spp., and *Lilaeopsis masonii* are important species in California. The invasive weed *Lepidium latifolium* is a problem in many of these marshes. Rare plant species include *Cordylanthus maritimus ssp. maritimus*.

Distribution: This system is found throughout the Pacific coast, from Kodiak Island and south-central Alaska to the California coast.

Nations: CA, MX, US

Concept Source: K. Boggs, C. Chappell, G. Kittel

Description Author: K. Boggs, C. Chappell, G. Kittel, T. Keeler-Wolf and M.S. Reid

CES200.091 CONCEPTUAL MODEL

Environment: The frequency of tidal flooding and salinity vary widely. Soils are usually fine-textured and saturated. Tidal marshes have a limited distribution along the Gulf of Alaska and British Columbia coastline due to the topography and geomorphology of the coast, which features steep slopes and deep fjords and offers limited protection from wave action (National Wetlands Working Group 1988).

Key Processes and Interactions: Tidal marsh zonal mosaics of multiple communities vary in location and abundance with daily and seasonal dynamics of freshwater input from inland balanced against evaporation and tidal flooding of saltwater. Summer-dry periods result in decreased freshwater inputs from inland. Hypersaline environments within salt marshes occur in "salt pans" where tidal water collects and evaporates. High marshes flood infrequently, mid marshes flood usually at higher tides and are usually brackish waters, while low marshes are inundated with saltwater daily.

Threats/Stressors: Conversion of this type has commonly come from coastal development, road building, seawall construction, and cessation of freshwater inputs. Water diversions, ditches, roads, and human land uses in the contributing watershed can also have a substantial impact on the hydrological regime. Channel flow, tidal inundation, and fresh water discharges are disrupted by construction of seawalls, jetties, dikes, and dams. Direct alteration of hydrology (i.e., channeling, draining, damming) or indirect alteration (i.e., road building or removing vegetation on adjacent slopes) results in changes in amount and pattern of herbaceous wetland habitat. Human land uses both within the marshes as well as in adjacent upland areas have reduced connectivity between wetland patches and upland areas. Land uses in the contributing watershed have the potential to contribute excess nutrients into to the system which could lead to the establishment of non-native species and/or dominance of native increasing species. The invasive weeds, such as *Spartina* spp. are problems in many of these marshes. In general, excessive livestock or native ungulate use leads to a shift in plant species composition. Non-native plants or animals, which can have wide-ranging impacts, also tend to increase with these stressors. Although most wetlands receive regulatory protection at the national, state, and county level, many have been and continued to be filled, drained, grazed, and farmed extensively (Chappell and Christy 2004). Additionally, these regulations only pertain to the filling of these wetlands and do not regulate alterations in ecological conditions of these sites (WNHP 2011).

In the Pacific Northwest Regionally downscaled climate models project increases in annual temperature of, on average, 3.2°F by the 2040s. Projected changes in annual precipitation, averaged over all models, are small (+1 to +2 inches), but some models project wetter autumns and winters and drier summers. Increases in extreme high precipitation (falling as rain) in the western Cascades and reductions in snowpack are key projections from high-resolution regional climate models (Littell et al. 2009). Warmer temperatures will result in more winter precipitation falling as rain rather than snow throughout much of the Pacific Northwest, particularly in mid-elevation basins where average winter temperatures are near freezing. This change will result in: Less winter snow accumulation, Higher winter streamflows, Earlier spring snowmelt, Earlier peak spring streamflow and lower summer streamflows in rivers that depend on snowmelt (most rivers in the Pacific Northwest) (Littell et al. 2009).

Potential climate change effects could include: within San Francisco Bay, sea-level rise may completely obliterate these marshes as coastal development exists where the likely migration of this system would occur (SFBCDC 2011); reduction in freshwater inflows through the further reduction in summer flows (Littell et al. 2009); but models also predict increases in extreme high precipitation over the next half-century, particularly around Puget Sound (Littell et al. 2009), which may provide freshwater pulses that are intermittent, less predictable; drop in groundwater table; increased fire frequency due to warmer temperatures resulting in drier fuels the area burned by fire regionally is projected to double by the 2040s and triple by the 2080s (Littell et al. 2009); and some regional sea-level rise (IUCN 2013a). A recent analysis of sea-level rise for California indicates that by 2035-2064, projected ranges of global sea-level rise are ~6-32 cm above 1990 levels, with no discernable inter-scenario differences (Cayan et al. 2008a, as cited in PRBO Conservation Science 2011). "The combination of severe winter storms with sea-level rise and high tides would result in extreme sea levels that could expose the coast to severe flooding and erosion, damage to coastal structures and real estate, salinity intrusion into delta areas and coastal aquifers, and the degradation of the quality and reliability of freshwater supplies" (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result when channel flow, tidal inundation, and freshwater discharges are disrupted by construction of seawalls, jetties, dikes, and dams. Direct alteration of hydrology (i.e., channeling, draining, damming) or indirect alteration (i.e., road building or removing vegetation on adjacent slopes) results in significant changes in amount and pattern of herbaceous wetland (WNHP 2011). All of the following criteria and thresholds are from WNHP (2011), whose information is relevant for the entire range of the tidal salt marsh ecosystem on the Pacific Coast: Environmental Degradation: Any of these conditions or combination of conditions rates as high-severity: Freshwater flow has been substantially diminished by human activity; Average tidal channel sinuosity <1.0. Tidal channels are extensively blocked by dikes and tide gates; evidence of extensive human channelization. Tidal flooding is totally or almost totally impeded by tidal gates or obstructed culverts. Any of these conditions or combination of conditions rates as moderate-severity: Freshwater source is primarily urban runoff, direct irrigation, pumped water, artificially impounded water, or other artificial hydrology; Average tidal channel sinuosity = 1.0-2.4. Marsh channels are frequently blocked by dikes or tide gates. Tidal flooding is somewhat impeded by small culvert size, as evidenced by obvious differences in vegetation on either side of the culvert.

Disruption of Biotic Processes: Any of these conditions or combination of conditions rates as high-severity: Cover of native plants <50%; non-native plant absolute cover >10%; vegetation severely altered from reference standard. Expected strata are absent or dominated by ruderal ("weedy") species, or comprised of planted stands of non-characteristic species, or unnaturally dominated by a single species. Most or all indicator/diagnostic species are absent. Salt tolerant species absent to rare in expected locations or established in unexpected locations. Additional thresholds can be developed by using vegetation indicators for mid and lower tidal plants and sessile organisms, (e.g., if *Salicornia* replaced by *Spartina foliosa* or eel grass, we know something has changed (T. Keeler-Wolf pers. comm. 2013). Any of these conditions or combination of conditions rates as moderate-severity: Cover of native plants 50-85%; non-native invasive species prevalent (3-10%) absolute cover; species diversity/abundance is different from reference standard condition in, but still largely composed of native species characteristic of the type. This may include ruderal ("weedy") species. Many indicator/diagnostic species may be absent. Salt tolerant species decreasing in expected locations in expected abundance or increasing in unexpected locations.

M082. Warm & Cool Desert Alkali-Saline Marsh, Playa & Shrubland

CES304.998 Inter-Mountain Basins Alkaline Closed Depression

CES304.998 CLASSIFICATION

Concept Summary: This ecological system occurs on playas that are seasonally to semipermanently flooded, usually retaining water into the growing season and drying completely only in drought years. Many are associated with hot and cold springs, located in basins with internal drainage. Soils are alkaline to saline clays with hardpans. Seasonal drying exposes mudflats colonized by both annual and perennial wetland vegetation. Salt encrustations can occur on the surface in some examples of this system, and the soils are severely affected and have poor structure. Species that typify this system are salt-tolerant and halophytic species such as *Distichlis spicata, Puccinellia lemmonii, Poa secunda, Muhlenbergia* spp., *Leymus triticoides, Bolboschoenus maritimus, Schoenoplectus americanus, Triglochin maritima*, and *Salicornia* spp. During exceptionally wet years, an increase in precipitation can dilute the salt concentration in the soils of some examples of this system which may allow for less salt-tolerant species to occur. Communities found within this system may also occur in floodplains (i.e., more open depressions), but probably should not be considered a separate system unless they transition to areas outside the immediate floodplain. Types often occur along the margins of perennial lakes, in alkaline closed basins, with extremely low-gradient shorelines. This system can occur throughout the Columbia Plateau and the northern Great Basin but is most common in eastern Oregon and northern Nevada. It occurs in the Wyoming basins (central Wyoming) where it is surrounded by sage steppe systems and in Colorado. This system is very similar to ~Western Great Plains Closed Depression Wetland (CES303.666)$$.

CES304.998 CONCEPTUAL MODEL

Environment: This system occurs in cooler context than the playas found further south in the southern Great Basin and Mojave/Sonoran deserts. This ecological system occurs on sites that are seasonally to semipermanently flooded, usually retaining water into the growing season and drying completely only in drought years. Many are associated with hot and cold springs, located in basins with internal drainage. Soils are alkaline to saline clays with hardpans. Seasonal drying exposes mudflats colonized by annual wetland vegetation. The soils are severely affected by salts and have poor structure. This system is distinct from the freshwater depression systems by its brackish nature caused by strongly saline soils. Salt encrustations could occur near the surface in some examples of this system.

Key Processes and Interactions: This ecological system is primarily driven by hydrological processes. It occurs on sites that are seasonally to semipermanently flooded, usually retaining water into the growing season, drying completely only in drought years. Increases in precipitation and/or runoff can dilute the salt concentration and allow for less salt-tolerant species to occur.

Threats/Stressors: Historic and contemporary land-use practices have impacted hydrologic, geomorphic, and biotic structure and function of playas in the Columbia Basin and northern Great Basin. Reservoirs, water diversions, ditches, roads, and human land uses in the contributing watershed can also have a substantial impact on the hydrological regime of vernal pools and playas. Direct alteration of hydrology, particularly the ubiquitous excavation for livestock watering holes (stock tanks), or indirect alteration (i.e., roads or removing vegetation on adjacent slopes) results in changes in the amount and pattern of herbaceous wetland habitat (Dlugolecki 2010, Reuter et al. 2013). In general, excessive livestock use leads to a shift in plant species composition. Native species such as *Juncus balticus* increase with excessive livestock use. Non-native plants or animals, which can have wide-ranging impacts, also tend to increase with these stressors. Several exotic species invade playas, including *Bassia hyssopifolia, Bassia scoparia (= Kochia scoparia), Cardaria* spp., *Chenopodium glaucum, Chenopodium rubrum*, and *Salsola* spp. Although most wetlands receive regulatory protection at the national, state, and county level, many wetlands have been and continued to be filled, drained, grazed, and farmed extensively. Conversion of hydric soils has caused a net loss of playa and vernal pool map units in recent soil surveys (Johnson et al. 2011). In addition, recent Supreme Court decisions on isolated wetlands exclude many, if not most, occurrences of this system from protection under the Clean Water Act (Haukos and Smith 1994). Minor changes in the water table depth or duration of inundation can have profound effects on soil salinity and, consequently, wetland vegetation (Cooper and Severn 1992). Wetland animals such as waterbirds, amphibians, or invertebrates are affected by changes in hydrology.

Conversion of this type has commonly come from agriculture (mostly non-native hay production) and pasture. Water diversion and alteration of hydrologic inputs will remove the additional water that is the driving environmental factor for this ecosystem and convert them to drier upland types. Invasive non-native plants such as *Bassia hyssopifolia, Bassia scoparia, Cardaria* spp., *Chenopodium glaucum, Chenopodium rubrum*, and *Salsola* spp. can convert sites to non-native-dominated vegetation types (WNHP 2011). Common stressors and threats include fragmentation from roads, altered hydrology, excessive livestock use, and conversion to dominance by non-native species (WNHP 2011). Potential climate change effects could alter the amount and seasonality of precipitation, changing hydrological processes and converting sites to upland vegetation types by shifting species composition to those more tolerant of on hotter, drier conditions (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from altered hydrological regime from water diversions, excavation of livestock watering holes, groundwater pumping, severe overgrazing where perennial plant cover is reduced enough to allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<2 acres) and have evidence of excessive livestock grazing (low perennial cover) (WNHP 2011). Bare soil areas are substantial and contribute to altered hydrology or other long-lasting impacts. Deep ruts from ORVs or machinery may be present, or livestock pugging and/or trails are widespread. Altered hydrological regime from high-intensity alteration such as roads, large dikes, diversions, or ditches (>3 ft. deep) capable to lowering water table, large amount of fill, or excessive groundwater pumping or high amounts of flow additions. (WNHP 2011). Area has very narrow buffer width of <50 m of natural landscape (WNHP 2011). Moderate-severity environmental degradation appears where occurrences tend to be relatively small (2-10 acres) and have evidence of excessive livestock grazing (low perennial cover) (WNHP 2011). Bare soil areas due to human causes are common. There may be pugging due to livestock resulting in several inches of soil disturbance. ORVs or other machinery may have left some shallow ruts (WNHP 2011). Altered hydrological regime from Moderate intensity alteration such as roads, low dikes, roads w/culverts adequate for stream flow, medium diversion or ditches (1-3 ft. deep) or moderate flow additions. (WNHP 2011). Area has narrow buffer width of 50-100 m of natural landscape (WNHP 2011).

High-severity disruption appears where occurrences have low cover of native species (<50% relative cover) (WNHP 2011). Invasive non-native species are abundant (>10% absolute cover to dominant) (CNHP 2010b, WNHP 2011). Connectivity is severely disrupted by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring and hydrological function, and create barriers to natural movement of animal and plant populations. Native plant and animal species diversity is very low when compared to an intact ecosystem. Moderate-severity disruption appears where occurrences have low cover of native grassland species (50-85% relative cover) (WNHP 2011). Invasive non-native species are abundant (3-10% absolute cover) (CNHP 2010b, WNHP 2011). Connectivity is severely disrupted by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring and hydrological function, and create barriers to natural movement of animal and plant populations. Native plant and animal species diversity is low when compared to an intact ecosystem.

CES304.780 Inter-Mountain Basins Greasewood Flat

CES304.780 CLASSIFICATION

Concept Summary: This ecological system occurs throughout much of the western U.S. in intermountain basins and extends onto the western Great Plains and into central Montana. It typically occurs near drainages on stream terraces and flats or may form rings around more sparsely vegetated playas. Sites typically have saline soils, a shallow water table and flood intermittently, but remain dry for most growing seasons. The water table remains high enough to maintain vegetation, despite salt accumulations. This system usually occurs as a mosaic of multiple communities, with open to moderately dense shrublands dominated or codominated by *Sarcobatus vermiculatus*. In high salinity areas, greasewood often grows in nearly pure stands, and on less saline sites, it commonly grows with other shrub species and typically has a grass understory. Other shrubs that may be present to codominant in some occurrences include *Atriplex canescens, Atriplex confertifolia, Atriplex gardneri, Atriplex parryi, Artemisia tridentata ssp. wyomingensis, Artemisia tridentata ssp. tridentata, Artemisia cana ssp. cana*, or *Krascheninnikovia lanata*. Occurrences are often surrounded by mixed salt desert scrub or big sagebrush shrublands. The herbaceous layer, if present, is usually dominated by graminoids. There may be inclusions of *Sporobolus airoides, Pascopyrum smithii, Distichlis spicata* (where water remains ponded the longest), *Calamovilfa longifolia, Eleocharis palustris, Elymus elymoides, Hordeum jubatum, Leymus cinereus, Poa pratensis, Puccinellia nuttalliana*, or herbaceous types. In more saline environments, *Allenrolfea occidentalis, Nitrophila occidentalis*, and *Suaeda moquinii* may be present.

Description Author: K.A. Schulz

CES304.780 CONCEPTUAL MODEL

Environment: This ecological system occurs throughout much of the intermountain western U.S. from the Mojave Desert and extends onto the western Great Plains and into central Montana. Elevation ranges from 100 to 2400 m. *Sarcobatus vermiculatus* commonly occurs in areas with a seasonally high water table and is often the only green shrub in pluvial desert sites with available groundwater.

Climate: This system is tolerant of a wide range of climatic conditions: warm or cool, temperate, semi-arid and continental, but is most abundant in areas with hot, dry summers. Average annual precipitation ranges from 12.7 to 25.4 cm (5-10 inches).

Physiography/landform: Stands occur on dry, sunny, flat valley bottoms, on lowland floodplains, in ephemeral stream channels, at playa margins, on slopes and in sand dune complexes. Greasewood communities generally occur at lower elevations than moister sagebrush or shadscale zones. In high saline areas, greasewood often grows in nearly pure stands, although on less saline sites, it commonly grows with other shrub species and typically has a grass understory. It typically occurs near drainages on stream terraces and flats or may form rings around more sparsely vegetated playas. Some *Sarcobatus vermiculatus* stands occur on sandsheets when associated with a shallow water table such as near the Great Sand Dunes National Park and Preserve in Colorado.

Soil/substrate/hydrology: Sites typically have saline/alkaline soils, with a shallow or perched water table and flood intermittently, seasonally to semipermanently (West 1983b). The water table is usually within 5 m of surface, generally well within the root zone of greasewood and saltbush (Donovan et al. 1996). Sites can become dry for much of the growing season, or remain saturated due to poor drainage; however, the water table generally remains high enough to maintain vegetation, which can thrive despite salt accumulations (West 1983b, Knight 1994). Stands occur on floodplains, along the margins of perennial lakes, and in alkaline closed basins with low-gradient shorelines. Substrates are fine-textured saline or alkaline soils, or occasionally coarse-textured non-saline soils (USU 2002). Greasewood flats are typically subirrigated and rarely have open water except when associated with playas. As the water evaporates, salinity increases, affecting the biota.

Key Processes and Interactions: Greasewood flats are tightly associated with saline soils and groundwater that is near the surface. The primary ecological process that maintains greasewood flats is groundwater recharge, rather than surface water. *Sarcobatus vermiculatus* is a wetland obligate phreatophyte that taps into groundwater generally at less than 5 m, but taproots may reach great depth (>10 m). Hansen et al. (1995) reported that it can tolerate saturated soil conditions for up to 40 days. Like many facultative halophytes, greasewood is tolerant of alkaline and saline soil conditions that allow the species to occur in sites with less interspecific competition (Ungar et al. 1969, Branson et al. 1976).

Floristic variation within *Sarcobatus vermiculatus*-dominated vegetation varies with depth to water table, salinity and alkalinity, soil texture, and past land use or disturbance. Hanson (1929) described stands in south-central Colorado and found that pure stands of *Sarcobatus vermiculatus* and *Distichlis spicata* are more common on strongly saline/alkaline sites with fine-textured soil and shallow water tables, whereas stands with mixed shrubs such as *Chrysothamnus* or *Artemisia* are more common on drier, coarser-textured, low-alkaline sites. Understory dominated by *Sporobolus airoides* is found on dry, strongly alkaline sites, while stands dominated by *Pascopyrum smithii* are more common on less alkaline, moist sites in low-lying areas. The degree of salinity can vary seasonally as well as from year to year. During exceptionally wet years, the salt concentration drops, allowing less salt-tolerant species to appear, such as cattails (*Typha* spp.) or bulrushes (*Scirpus* and/or *Schoenoplectus* spp.) (Knight 1994). Some areas only flood during wet years, sometimes only once or twice in a decade. Others will have standing water every spring, except in the driest of years. As stands dry out, strong evaporation concentrates salt in the soils.

Fires are uncommon in this system because many stands are open and lack a continuous fuel layer (Sawyer et al. 2009). Severe hot fires can kill *Sarcobatus vermiculatus*, while after low- to moderate-severity fire it commonly sprouts after being top-killed (Anderson 2004b). Vigorously sprouting following fire can increase growth and stem density, growing up to 0.76 m (2.5 feet) in height within three years, with 90% of the plants surviving one year after burning (Daubenmire 1970, Anderson 2004b, Sawyer et al. 2009). Fire regime for greasewood communities is reported as generally less than a 100-year return interval (Anderson 2004b) although LANDFIRE (2007a) applied fire regime V (200+ years) and treated fire as a minor ecological driver within this system.

LANDFIRE (2007a) VDDT model for this system (BpS 2311530) has three classes:

A) Early Development 1 All Structures (5% of type in this stage): Shrub cover is 10-20%. Some grasses, with greasewood sprouts present. Some representation of other sprouting species may be present (creosotebush, rabbitbrush). Grass species vary geographically but include the following for Utah and Nevada: inland saltgrass, bottlebrush squirreltail, Sandberg bluegrass and alkali sacaton. Succession to class B after two years.

B) Mid Development 1 Open (30% of type in this stage): Shrub cover (21-60%): Greasewood shrubs are maturing, with a good mix of perennial grasses. Other shrub species that may be found with greasewood include creosotebush and rabbitbrush, and in transition zones to Mojave Desert, it may occur with various sagebrush species and salt desert shrub vegetation (shadscale, saltbushes, winterfat, budsage and spiny hopsage). Greasewood communities would stay in this class for 3-20 years, then succeed to class C. Vegetation will revert to class A with flooding (mean return interval of 75 years) or replacement fire (mean FRI of 200 years).

C) Late Development 1 Closed (65% of type in this stage): Shrubs (41-70%): Greasewood shrubs have reached maturity and will increase canopy closure. Perennial grasses will still be in the understory. Vegetation will revert to class A with replacement fire (mean FRI of 200 years). Flooding (mean return interval of 75 years) causes two transitions: to class A (50% of the time) or to class B (50% of the time).

There was some question in the model about whether flooding in class C (late-development) would send the entire system back to class A (early-development), or Class B (mid-development). As a compromise, flooding was attributed to take both pathways with equal probability.

Threats/Stressors: The major land uses that alter the natural processes of this system are associated with alteration of hydrology, livestock practices, annual exotic species invasion, fire regime alteration, and fragmentation (WNHP 2011). Any activity resulting in hydrological alterations, sedimentation, nutrient inputs, and/or physical disturbance may negatively shift species composition and allow for non-native species establishment. Declining water tables create perennially dry soils, stop surface salt accumulation, and allow salts to leach deeper and create a drier, less saline soil resulting in a change in vegetation composition and pattern (Cooper et al. 2006).

Although *Sarcobatus vermiculatus* is not ordinarily browsed by livestock, Daubenmire (1970) found that under heavy stocking rates, the shrubs will develop a compact canopy. Hansen et al. (1995) also reported browsing damage with heavy spring and summer grazing. *Sarcobatus vermiculatus* is noted to be important winter browse for domestic sheep, cattle, big game animals, as well as jackrabbits (Hanson 1929, Anderson 2004b). The shrub provides quality forage throughout the growing season although it contains soluble sodium and potassium oxalates that may cause poisoning and death in domestic sheep and cattle when it makes up too much of their diet (Anderson 2004b). Livestock grazing is reported to decrease small mammal numbers in *Sarcobatus vermiculatus / Distichlis spicata (= Distichlis stricta)* vegetation in Nevada and adjacent California (Page et al. 1978). *Distichlis spicata* is considered a grazing increaser. Grazing early when the upper part of the soil may be wet can sometimes cause compaction (WNHP 2011). Grazing and other disturbances can lead to biomass increases in the spring associated with an increase in *Bromus tectorum* and other fine fuel annuals which influence fire regime (Brown and Smith 2000).

The presence of invasive, exotic plant species such as *Acroptilon repens, Cardaria draba, Centaurea diffusa, Centaurea stoebe, Euphorbia esula, Lepidium latifolium, Linaria vulgaris*, and *Tamarix* spp. reduces habitat quality for numerous wildlife species, decreases forage for livestock, reduces ecosystem native species richness, increases soil erosion potential and decreases ecosystem resiliency and resistance to damage from impacts, including climate change. These non-native invasive species decrease the abundance of shorter native grasses and forbs and have the potential to alter structure and composition if they become dominant. The introduction of *Bromus tectorum* and other annual exotic species into these shrublands has altered fuel loads and fuel distribution allowing for increased fire frequency and severity (Anderson 2004b). Fire drastically alters the community composition because salt-desert shrubs are not adapted to periodic fire (WNHP 2011).

Human development has impacted many locations throughout the range of this system resulting in altered hydrologic regimes, fragmentation, altered fire regime, increased non-native plant species which reduces habitat quality for numerous wildlife species, decreases forage for livestock, reduces ecosystem native species richness, increases soil erosion potential and decreases ecosystem resiliency and resistance to damage from impacts, including climate change.

Ecosystem Collapse Thresholds: Ecological collapse tends to result on sites where the natural hydrologic regime is severely affected by alteration to local drainage, such as by diking, filling, digging, dredging or groundwater pumping. These activities lower the water table below the reach of *Sarcobatus vermiculatus*.

High-severity environmental degradation appears where occurrences tend to be relatively small (<50 acres) in size and the hydrologic regime is severely altered and not restorable, leaving it fundamentally compromised despite restoration of some processes (CNHP 2010). Other indicators of high-severity degradation are that groundwater pumping affects greater than 20% of the area, bare soil due to human/livestock causes is widespread (>50% cover), ORVs or other machinery may have left shallow ruts throughout the occurrence, and/or adjacent lands are mostly converted to agricultural or urban uses (WNHP 2011). Connectivity is typically severely hampered (CNHP 2010). FRCC 3 is also typical with severe departure from historic fire regime. Surrounding landscape is missing fundamental system components that render restoration unfeasible (CNHP 2010).

Moderate-severity environmental degradation appears where occurrences tend to be relatively small (50-100 acres) and the hydrologic regime is extensively altered by local drainage, diking, filling, digging, or dredging, but potentially restorable over several decades (CNHP 2010). Vehicle use or grazing disturbance is extensive and significant enough to have notable impact on species composition (CNHP 2010). Some bare soil due to human/livestock causes, but the extent and impact is minimal (WNHP 2011). Adjacent grasslands, shrublands, and wet meadows are fragmented by alteration (20-60% natural). Landscape is restorable over years or decades (CNHP 2010). There is limited connectivity, some barriers are present and restrict movement across system boundaries (CNHP 2010). FRCC 2 is also typical with slight-moderate departure from historic fire regime.

High-severity disruption of biotic processes appears where alteration of vegetation is extensive with low restoration potential or ecosystem remains fundamentally compromised despite restoration of some processes (CNHP 2010). Cover of native plants is <50% (WNHP 2011). Invasive exotics with major potential to alter structure and composition, such as *Acroptilon repens, Cardaria draba, Centaurea diffusa, Centaurea stoebe, Euphorbia esula, Lepidium latifolium, Linaria vulgaris*, and *Tamarix* spp., may be dominant over significant portions of the area with little potential for control (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity disruption of biotic processes appears where alteration of vegetation is extensive but is potentially restorable over several decades (CNHP 2010). Cover of native plants is 50 to 79% (WNHP 2011). Vehicle use or grazing disturbance is extensive and significant enough to have notable impact on species composition. Invasive exotics with major potential to alter structure and composition, such as *Acroptilon repens, Cardaria draba, Centaurea diffusa, Centaurea stoebe, Euphorbia esula, Lepidium latifolium, Linaria vulgaris* and *Tamarix* spp., may be widespread, but potentially manageable with restoration of most natural processes (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.786 Inter-Mountain Basins Playa

CES304.786 CLASSIFICATION

Concept Summary: This ecological system is composed of barren and sparsely vegetated playas (generally <10% plant cover) found in the intermountain western U.S. Salt crusts are common throughout, with small saltgrass beds in depressions and sparse shrubs around the margins. These systems are intermittently flooded. The water is prevented from percolating through the soil by an impermeable soil subhorizon and is left to evaporate. Soil salinity varies greatly with soil moisture and greatly affects species composition. Characteristic species may include *Allenrolfea occidentalis, Sarcobatus vermiculatus, Grayia spinosa, Puccinellia lemmonii, Leymus cinereus, Distichlis spicata*, and/or *Atriplex* spp.

Related Concepts:

Distribution: This system occurs throughout the Intermountain western U.S., extending east into the southwestern Great Plains.

Nations: US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES304.786 CONCEPTUAL MODEL

Environment:

Key Processes and Interactions: Playas are shallow, seasonal wetlands that lie in the lowest point of a closed watershed. Their basins are lined with clay soils, which collect and hold water from rainfall and runoff events. Water evaporates, leaving high salt concentrations in the soils. Some playas will only flood with water during years with high precipitation, sometimes only once or twice in a decade. Others will have standing water every spring, except in the driest of years. During flooded years, some salt-tolerant marsh plant species may grow, such as cattails (*Typha* spp.) or bulrush (*Scirpus* spp.).

CES302.751 North American Warm Desert Playa

CES302.751 CLASSIFICATION

Concept Summary: This ecological system is composed of barren and sparsely vegetated playas (generally <10% plant cover) found across the warm deserts of North America, extending into the extreme southern end of the San Joaquin Valley in California. Playas form with intermittent flooding, followed by evaporation, leaving behind a saline residue. Salt crusts are common throughout, with small saltgrass beds in depressions and sparse shrubs around the margins. Subsoils often include an impermeable layer of clay or caliche. Large desert playas tend to be defined by vegetation rings formed in response to salinity. Given their common location in windswept desert basins, dune fields often form downwind of large playas. In turn, playas associated with dunes often have a deeper water supply. Species may include *Allenrolfea occidentalis, Suaeda* spp., *Distichlis spicata, Eleocharis palustris, Oryzopsis* spp., *Sporobolus* spp., *Tiquilia* spp., or *Atriplex* spp. Ephemeral herbaceous species may have high cover periodically. Adjacent vegetation is typically ~Sonora-Mojave Mixed Salt Desert Scrub (CES302.749)$$, ~Chihuahuan Mixed Salt Desert Scrub (CES302.017)$$, ~Gulf of California Coastal Mixed Salt Desert Scrub (CES302.015)$$, ~Baja California del Norte Gulf Coast Ocotillo-Limberbush-Creosotebush Desert Scrub (CES302.014)$$, or ~Chihuahuan Creosotebush Desert Scrub (CES302.731)$$.

Distribution: Found across the warm deserts of North America, extending into the extreme southern end of the San Joaquin Valley in California.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES302.751 CONCEPTUAL MODEL

Environment: Playas are internally draining basins often with an impermeable layer of clay or caliche subsoil.

Key Processes and Interactions:

Threats/Stressors: [from M083] Conversion of this type has commonly come from dewatering and conversion to agricultural land use (Sawyer et al. 2009). Common and threats include changes in the hydrologic input (usually reduction but increases can shift the marsh from alkaline to freshwater). Minor changes in the water table depth or duration of inundation can have profound effects on soil salinity, and consequently, wetland vegetation (WNHP 2011).

In the Central Valley, regional climate models project mean annual temperature increases of 1.4-2.0°C (1.8-3.6°F) by 2070. The projected impacts will be warmer winter temperatures; earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 47-175 mm (1-7 inches) by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions. Projections include a decrease in total annual streamflows and earlier snowmelt, with streamflows increasing slightly in January and

February but decreasing in all other months. Annual streamflows statewide are projected to decrease by 27%, with inflows from surrounding mountains to the Sacramento Valley projected to decrease by 22% (summarized from PRBO 2011). However, dewatering may be a much more immediate threat, and increase in summer precipitation projected by some climate models may balance out loss of winter ppt in some parts (deserts and southern coast) of the range of this ecosystem (T. Keeler-Wolf pers. comm. 2013).

Potential climate change effects could include further reduction in high flows; drop in groundwater table, reducing seep flows, shrinking and drying the marsh; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006, Coffman 2007); and increased competition for water from all users, stresses the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

CES301.717 Tamaulipan Saline Lake

CES301.717 CLASSIFICATION

Concept Summary: This ecological system includes small to medium-sized, highly saline, interior drainage basins in the Tamaulipan region of south Texas. The edges of these basins may be sparsely to moderately vegetated by halophytic grasses and subshrubs.

Related Concepts:

- Tamaulipan Saline Lake Flats (7700) (Elliott 2011) **<**
- Tamaulipan Saline Lake Grassland (7707) (Elliott 2011) **<**

Distribution: This system occurs in the Tamaulipan region of south Texas and possibly Mexico.

Nations: MX?, US

Concept Source: L. Elliott, D. Diamond, A. Treuer-kuehn, D. German, J. Teague

Description Author: L. Elliott and J. Teague

CES301.717 CONCEPTUAL MODEL

Environment: This system occupies broad, gently sloping, interior draining basins receiving runoff from the surrounding landscape. Solution of salts from parent material, deposition from runoff, and subsequent evaporation has lead to a highly saline situation. These areas occur over the Goliad Formation on the edge of the Texas Sandsheet on highly saline sands or sandy loams in south Texas and may be related to the formation of Quaternary-aged clay dunes that sometimes occur nearby.

Key Processes and Interactions:

Threats/Stressors: [from M083] Conversion of this type has commonly come from dewatering and conversion to agricultural land use (Sawyer et al. 2009). Common and threats include changes in the hydrologic input (usually reduction but increases can shift the marsh from alkaline to freshwater). Minor changes in the water table depth or duration of inundation can have profound effects on soil salinity, and consequently, wetland vegetation (WNHP 2011).

In the Central Valley, regional climate models project mean annual temperature increases of 1.4-2.0°C (1.8-3.6°F) by 2070. The projected impacts will be warmer winter temperatures; earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 47-175 mm (1-7 inches) by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions. Projections include a decrease in total annual streamflows and earlier snowmelt, with streamflows increasing slightly in January and February but decreasing in all other months. Annual streamflows statewide are projected to decrease by 27%, with inflows from surrounding mountains to the Sacramento Valley projected to decrease by 22% (summarized from PRBO 2011). However, dewatering may be a much more immediate threat, and increase in summer precipitation projected by some climate models may balance out loss of winter ppt in some parts (deserts and southern coast) of the range of this ecosystem (T. Keeler-Wolf pers. comm. 2013).

Potential climate change effects could include further reduction in high flows; drop in groundwater table, reducing seep flows, shrinking and drying the marsh; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006, Coffman 2007); and increased competition for water from all users, stresses the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

2.C.5.Ue. Tropical Atlantic Coastal Salt Marsh

M735. Tropical Western Atlantic-Caribbean Salt Marsh

CES411.460 Caribbean Salt Flat and Pond

CES411.460 CLASSIFICATION

Concept Summary: This system is found in semipermanently flooded coastal ponds, or tidally flooded salt flats, as well as sand and mudflats behind barrier beaches and in the surrounding of the mangroves. The following list of species is diagnostic for this system: *Blutaparon vermiculare (= Philoxerus vermicularis), Bacopa monnieri, Sesuvium portulacastrum, Sporobolus virginicus, Heliotropium curassavicum, Amaranthus crassipes, Sesbania sericea, Annona glabra, Atriplex cristata (= Atriplex pentandra), Heterostachys ritteriana*, and *Batis maritima*.

Related Concepts:

- (ESU 4) Graminoid Supratidal Scrub (Ross et al. 1992) **<**
- (ESU 5) Succulent Supratidal Scrub (Ross et al. 1992) **<**

Distribution: This system is found in the Greater Antilles, Puerto Rico, Virgin Islands, and Venezuela.

Nations: PR, US, VE, VI, XC

Concept Source: C. Josse

Description Author: C. Josse

CES411.460 CONCEPTUAL MODEL

Environment: Where hypersaline conditions develop in the upper intertidal zone, extensive salt flats may occur above the level of mangrove (Adams 1990). West (1977) states that extensive salt marshes can occur as (1) a pioneer community on the ocean side of mangroves, (2) as a zone on the inner edge or within a mangrove stand, or (3) as a secondary or disturbance type on disturbed or degraded mangrove stands. These disturbed types may be dominated by *Spartina alterniflora* or the fern *Acrostichum aureum*. Salt marshes and pannes are regularly to irregularly flooded by shallow polyhaline waters as a result of lunar, wind and storm tides. Brackish tidal marshes develop along estuaries where freshwater mixes with ocean saltwater moving up the estuary from the tidal force. They also occur near uplands where freshwater inputs reduce the salinity of the salt marsh. Waters in brackish marshes are generally in the salinity range of 0.5-18 ppt, and the vegetation is subject to flooding from the twice-daily tides. Salt marsh soils range from deep mucks with high clay and organic content in the deeper portions to silts and fine sands in higher areas. The organic soils have a high salinity, neutral reaction, and high sulfur content (FNAI 2010a).

Key Processes and Interactions: The main natural factors that are responsible for the vegetation composition and processes in the estuarine and coastal wetland habitats where these marshes develop are freshwater flow, seasonal freshwater pulsing, estuarine

salinity, tidal flushing, coastal geomorphology, and depositional area for sediment and nutrient input. Adams (1990) states that there may be a dynamic relationship between mangroves and salt marsh; as the salt marsh advances seaward, so the upper part of the marsh is invaded and replaced by mangrove.
Threats/Stressors: Any land use or infrastructure development that alters the hydrodynamics of the system. Dewatering or drainage for livestock raising, and replacement by shrimp farms.
Ecosystem Collapse Thresholds: Land use and infrastructure that permanently alters the geomorphology and the hydrology of the system.

3.A.1.Ea. Caribbean-Northern Mesoamerican Xeromorphic Scrub & Woodland

M765. Caribbean-Northern Mesoamerican Xeromorphic Scrub & Woodland

CES401.291 Guerreran Thornscrub

CES401.291 CLASSIFICATION

Concept Summary: This tropical thornscrub system is found throughout southern Sonora and western Sinaloa. It is found along low foothills, bajada, and arroyos with sandy alluvial soils. This forms a transition between succulent-rich Sonoran Desert scrub types and ~Sinaloan Dry Deciduous Forest (CES401.302)$$. The following list of species is diagnostic for this system: *Prosopis laevigata, Pithecellobium dulce, Acacia cymbispina, Ziziphus amole, Guaiacum coulteri, Cercidium praecox, Haematoxylon brasiletto, Manihot tomatophylla, Backebergia militaris, Opuntia* spp.
Related Concepts:
Nations: MX
Concept Source: C. Josse
Description Author: C. Josse

CES401.291 CONCEPTUAL MODEL

Environment: These are found along low foothills, bajadas, and flat plains with sandy, alluvial soils. In many instances, soils are deep and rich in organic matter. Precipitation varies considerably, but estimates from Michoacan indicate some 620 mm/year, with 5 dry months (November-March).
Key Processes and Interactions: Successional dynamics exist between savanna-grassland, thornscrub and deciduous forest. Natural fire regimes are not documented.
Threats/Stressors:

CES401.308 Xerophytic Scrub of Motagua Valley

CES401.308 CLASSIFICATION

Concept Summary: Este sistema corresponde a las comunidades que se encuentran en las laderas áridas y arenosas del Valle de Motagua en Guatemala. La vegetación es la de un matorral o arbustal bajo y abierto con numerosos cactus y especies espinosas. En el fondo del valle, hay comunidades riparias que soportan menor aridez. En la lista de especies diagnósticas de este ecosistema dominan los cactus, algunos de los cuales tienen un papel clave en el mantenimiento de la diversidad ya que sus flores son polinizadas y sirven de alimento a numerosas especies de murciélagos, aves, insectos, e incluso una iguana endémica. La siguientes especies de cactus son son diagnósticas del sistema: *Cephalocereus maxonii, Nyctocereus guatemalensis, Lemairocereus eichlamii, Nopalea guatemalensis, Nopalea lutea, Opuntia decumbens, Pereskiopsis* sp., *Opuntia* spp., *Stenocereus pruinosus, Pilosocereus leucocephalus, Acanthocereus* sp., *Hylocereus, Melocactus, Mamillaria, Mirtillocactus eichlamii*. Entre los arbustos y árboles bajos: *Acacia* spp., *Achatocarpus nigricans, Bursera schlechtendalii, Cordia gerascanthus, Cordia pringlei, Cordia truncatifolia, Guaiacum sanctum, Bucida macrostachya, Cnidoscolus tubulosus, Jacquinia aurantiaca, Jacquinia pungens, Jacquinia macrocarpa, Leucaena diversifolia, Mimosa platycarpa, Mimosa* spp.

Description Author: C. Josse

CES401.308 CONCEPTUAL MODEL

Environment: Laderas muy inclinadas del valle, con suelos arenosos y muy áridos y fondo del valle. La precipitación promedio anual para esta regiones es de 974 mm, con máxima en ciertos puntos de 1.600 mm, una biotemperatura media anual de entre 19° a 24°C y presentan al menos 5 meses al año con precipitaciones menores a los 100 mm de lluvia (INSIVUMEH 2009). La época lluviosa es entre junio a octubre. Estas zonas son de importancia ecológica tanto por sus singulares sistemas productivos, como por las condiciones de aislamiento geográfico que han desarrollado varios endemismos (Castañeda 2003, Lott y Atkinson 2006).

Key Processes and Interactions: La abundancia de cactus que caracteriza al sistema son evidencia de que los incendios no son parte de su dinámica natural, ya que los cactus generalmente no están adaptados para sobrevivir al fuego (Martinez-Yrízar 1995, Pennington et al. 2004). Sin embargo las condiciones de aridez en que se desarrollan estas comunidades las hacen bastante resilientes a degradaciones severas.

Threats/Stressors: En este tipo de sistema se mantiene todavía el sistema de ganadería bajo sistemas de bosque con cobertura natural, en el cual el alimento proviene de los rebrotes de herbáceas que ocurren en el sotobosque de estas regiones durante las primeras lluvias. Mas recientemente se han instalado en la zona cultivos extensivos de exportación, principalmente los cultivos de melón y sandía. En los últimos 15 años estas regiones se han incrementado significativamente. La mayor parte del incremento de las áreas para cultivo de melón se ha realizado por sustitución de otros cultivos. Sin embargo en años recientes han existido ampliaciones de este cultivo a expensas de áreas con cobertura natural. Se ha estimado una remanencia de este sistema ecológico de aproximadamente un 50% al 2009. La principales amenazas son: Fragmentación de hábitat, destrucción o pérdida de hábitat físico, cambio en la composición y estructura de la comunidad debido utilización de recursos como leña, ganadería extensiva, y cambio en composición y estructura de la comunidad debido al cambio climático (Ariano et al. 2009).

3.A.2.Na. North American Warm Desert Scrub & Grassland

M086. Chihuahuan Desert Scrub

CES302.731 Chihuahuan Creosotebush Desert Scrub

CES302.731 CLASSIFICATION

Concept Summary: This matrix ecological system is the common lower elevation *Larrea tridentata*-dominated desert scrub that occurs throughout much of the Chihuahuan Desert and has recently expanded into former lower elevation desert grasslands in the northern portion of its range. Stands typically occur in flat to gently sloping desert basins and on alluvial plains, extending up into lower to mid positions of piedmont slopes (bajada). Substrates range from coarse-textured loams on gravelly plains to finer-textured silty and clayey soils in basins. Soils are alluvial, typically loamy and non-saline, and frequently calcareous as they are often derived from limestone, and to a lesser degree igneous rocks. The vegetation is characterized by a moderate to sparse shrub layer (<10% cover on extremely xeric sites) that is typically strongly dominated by *Larrea tridentata* with *Flourensia cernua* often present to codominant. A few additional shrubs or succulents may also be present, such as *Agave lechuguilla, Parthenium incanum, Jatropha dioica, Koeberlinia spinosa, Lycium* spp., and *Yucca* spp. Additionally, *Flourensia cernua* can often be abundant and the sole dominant in silty basins which are included in this ecological system. In general, shrub diversity is low as this ecological system lacks thornscrub and other mixed desert scrub species that are common on the gravelly mid to upper piedmont slopes. However, on deeper soils and along minor drainages, shrub diversity and cover may increase with occasional *Atriplex canescens, Gutierrezia sarothrae*, or *Prosopis glandulosa*. Herbaceous cover is usually low and composed of grasses. Common species may include *Bouteloua eriopoda, Dasyochloa pulchella, Muhlenbergia porteri, Pleuraphis mutica, Scleropogon brevifolius*, and *Sporobolus airoides*. Included in this ecological system are *Larrea tridentata*-dominated shrublands with a sparse understory that occur on gravelly to silty, upper basin floors and alluvial plains. A pebbly desert pavement may be present on the soil surface.

Distribution: This extensive, lower elevation desert scrub ecological system occurs in the Chihuahuan Desert in broad desert basins and alluvial plains extending up into the lower bajada.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: K.A. Schulz, L. Elliott and J. Teague

CES302.731 CONCEPTUAL MODEL

Environment: *Climate:* Climate is semi-arid to arid with annual precipitation ranging from 200-250 mm that falls mostly in the summer. Summers are hot and winters can be cold with freezing temperature occurring in the northern extent.

Physiography/landform: This ecological system is the common lower elevation desert scrub that occurs throughout much of the Chihuahuan Desert and has recently expanded into former desert grasslands in the northern portion of its range. Elevation ranges from 1000-2000 m. Stands typically occur in flat to gently sloping, desert basins and on alluvial plains, extending up into the lower to mid positions of piedmont slopes (bajada), sometimes on colluvium.

Soil/substrate/hydrology: Substrates range from coarse-textured loams on gravelly plains to finer-textured silty and clayey soils in basins. Soils are alluvial, typically loamy and non-saline, and frequently calcareous as they are often derived from limestone, and to a lesser degree igneous rocks (Brown 1982a, MacMahon and Wagner 1985, Henrickson and Johnston 1986, MacMahon 1988, Dick-Peddie 1993). In Texas, this system typically occurs on flat and gently rolling landforms, often on gravelly alluvial plains, outwash plains and intermountain basins. A pebbly desert pavement may be present on the soil surface.

Key Processes and Interactions: This is a stable ecosystem that is well suited to the hot, very dry basins and low hills where it occurs. The dominant and diagnostic species, *Larrea tridentata*, is a very long-lived species (some clones have been estimated to be over 10,000 years old). It is highly adapted to minimized evapotranspiration both daily and seasonally using stomatal regulation, resinous leaves, and a leaf structure and habit to minimize self-shading and maximize photosynthesis during favorable growing periods (Hamerlynck et al. 2002, Ogle and Reynolds 2002). *Larrea tridentata* is poorly adapted to fire because of its highly flammable, resinous leaves and limited sprouting ability after burning, although it may survive lower-intensity fires (Humphrey 1974, Brown and Minnich 1986, Marshall 1995, Paysen et al. 2000). McLaughlin and Bowers (1982) reported that burned individuals surviving a fire regained their former size in five years.

Historic fire regimes for Chihuahuan Creosotebush Desert Scrub are difficult to quantify but fires were rare with a fire-return interval (FRI) ranging from 300-1000 years and 500 years on average (from LANDFIRE BpS Model 2510740). The fire characteristics range from low- to moderate- to high-intensity, moderate-severity, stand-replacing crown fires that occur during spring, summer and fall seasons. Fires tend to be small or medium in size and need unusual conditions (e.g., a drought following an unusually wet year so there are adequate fine fuels that are available to carry a fire) (Brown and Minnich 1986, Paysen et al. 2000).

Weather stress such as drought also affects this community by reducing vegetation cover (especially grasses) every 80 years or so but does cause significant shrub mortality although shrubs may die back some (from LANDFIRE BpS Model 2510740) (Humphrey 1974). Drought is a relatively common occurrence in this desert scrub, generally occurring every 10-15 years and lasting 2-3 years with occasional long-term drought periods (10-15 years duration). *Larrea tridentata* and other shrubs have extensive root systems that allow them to exploit deep-soil water that is unavailable to shallower rooted grasses and cacti (Burgess 1995).

Biotic pollination by bees is important for creosotebush (Cane et al. 2000). Seed dispersal is primarily by wind and gravity as fruits are adapted for tumbling (Maddox and Carlquist 1985). However, seed burial by rodents may improve germination and survival of creosotebush (Chew and Chew 1970) so biotic dispersal may enhance regeneration especially in undisturbed, smooth desert pavement areas where seed burial is unlikely. Most seed germination requires between 80-150 mm (3-6 inches) of summer precipitation (Marshall 1995).

Herbivory by native herbivores in Chihuahuan Creosotebush Desert Scrub includes small mammals, reptiles and invertebrates. *Larrea* leaves are not edible to most animals; however, seeds are eaten by many small mammals (Paysen et al. 2000).

LANDFIRE developed a VDDT model for this system which has three classes (LANDFIRE 2007a, BpS 2510740):

A) Early Development 1 All Structures (15% of type in this stage): Under natural conditions shrub cover generally represents <10% canopy cover and is likely not affected by disturbance. The grass community may be as low as 10% canopy cover after a combination of drought and fire. Little disturbance was considered in class A, modeled drought every 50 years on average keeping the class in A (option 2). In the historic condition where invasive annual grasses are absent, the fire-return interval is virtually nonexistent except for areas near the base of mountains experiencing locally higher rainfall and fine fuel buildup. After 100 years, class A transitions to class B. However, if the upper soil horizon and/or microbes are lost, then a longer recovery time is required. Or complete recovery is not possible.

B) Late Development 1 Open (85% of type in this stage): Typically <30% shrub canopy cover. Replacement fire followed by prolonged drought every 500 years (min-max: 300-1000 years) on average (Option 1). Wind/weather stress also affected this community on average every 80 years but did not cause a transition to class A. Class B is likely over-represented on the landscape today.

Threats/Stressors: Although Chihuahuan Creosotebush Desert Scrub is a widespread ecosystem that has increased in abundance at the expense of native desert grasslands, it is sensitive to altered fire regimes caused by invasive species, as well as anthropogenic disturbance such as mechanical/chemical shrub removal. Currently much of the extent in the U.S. of this desert scrub is the result of recent expansion of *Larrea tridentata* into former desert grasslands in the last 150 years from the combined effects of drought, overgrazing by livestock, and/or decreases in fire frequency over the last 70-250 years (Buffington and Herbel 1965, Ahlstrand 1979, Donart 1984, Dick-Peddie 1993, Gibbens et al. 2005). This system now includes vast areas of loamy plains that have been converted from *Pleuraphis mutica* and *Bouteloua eriopoda* desert grasslands to *Larrea tridentata* scrub. This system also includes expanding *Flourensia cernua* shrublands that occur in former (now degraded) tobosa (*Pleuraphis mutica*) flats and loamy plains. Presence of *Scleropogon brevifolius* is common on these degraded sites. Dick-Peddie (1993) suggested that absence of *Flourensia cernua* as codominant and presence of *Acourtia nana (= Perezia nana), Dasyochloa pulchella*, and *Yucca elata* may be indicators of recent conversion of desert grasslands into desert scrub, but more research is needed. Conversely, *Larrea tridentata* shrublands with a sparse understory on remnant early Holocene erosional surfaces (often with desert pavement) may indicate historical distributions of *Larrea tridentata* desert scrub in the Chihuahuan Desert (Stein and Ludwig 1979, Muldavin et al. 2000b).

Altered (uncharacteristic) fire regimes greatly influence ecosystem processes. The historical desert scrub has a very long fire-return interval (FRI) ranging from 300-1000 years (500 years on average) (from LANDFIRE BpS Model 2510740). *Larrea tridentata* and other desert scrub plant species did not evolve with fire and are sensitive to burning; most of them do not resprout after burning and are slow to recover, and therefore fires should be rare events to be avoided. Invasion of non-native grasses provides fine fuels that can increase fire frequency, intensity and severity. Fires in desert scrub are becoming more common, especially after a series of wet years when fine fuels from non-native herbaceous species build up enough to carry fire.

The impact of livestock grazing to the historical stands of desert scrub is expected to be relatively small because there is little forage available for them in this type, but where livestock grazing or other anthropomorphic disturbance occurs there may be increased soil erosion (Milchunas 2006).

Human development has impacted many locations throughout the ecoregion. These sites represent a poor-condition/non-functioning ecosystem that is highly fragmented, or much reduced in size from its historical extent; the surrounding landscape is in poor condition either with highly eroding soils, many non-native species or a large percentage of the surrounding landscape has been converted to pavement or disturbed by off-road vehicles; the biotic condition is at the limit or beyond natural range of variation, e.g., vegetation composition is altered and is not dominated by native shrubs such as *Larrea tridentata* and *Flourensia cernua*. Characteristic birds, mammals, reptiles, and insect species are not present at expected abundances or the ratio of species shows an imbalance of predator-to-prey populations; abiotic condition is poor with evidence of high soil erosion, rill and gullies present or exposed soil subhorizons. Non-native grass invasion provides fine fuels that may increase fire frequency, intensity and severity.

Ecosystem Collapse Thresholds: Ecological collapse tends to result in sites where: invasion of exotic annuals has increased fine fuels in the understory which allowed a large, intense fire to burn in this open-canopied scrub and kill the highly flammable creosotebush and other shrubs; creosotebush is eliminated from the landscape leaving introduced annuals; where there is not enough fuel to carry a fire, excessive livestock trampling, vehicle use (motorbikes, off-road vehicles, construction vehicles), filling and grading, plowing, other mechanical disturbance could lead to excessive soil movement (erosion or deposition) as evidenced by gully, rill, or dune formation resulting in ecosystem collapse.

High-severity environmental degradation appears where occurrences tend to be small (<5000 acres) in size for this matrix type. System remains fundamentally compromised despite restoration of some processes. Bare soil areas due to human/livestock causes are common. ORVs or other machinery may have left some shallow ruts in desert pavement. Soil erosion and deposition from wind is evident and sometime severe. Landscapes are missing fundamental system components that render restoration unfeasible. Connectivity is severely hampered. FRCC 3 severe departure from historic fire regime.

Moderate-severity environmental degradation appears where occurrences tend to be relatively small (5000-20,000 acres) in size for this matrix type. Alteration is extensive but potentially restorable over several decades. Vehicle use or grazing disturbance is extensive and significant enough to have notable impact on species composition. Soil erosion and deposition from wind is evident. Adjacent grasslands and shrublands are fragmented by alteration (20-60% natural). Landscape is restorable over years or decades. Limited connectivity; some barriers present restricting movement across system boundaries. FRCC 2 slight-moderate departure from historic fire regime.

High-severity biotic disruption appears where alteration of vegetation is extensive and restoration potential is low and system remains fundamentally compromised despite restoration of some processes. Relative cover of native plants <50%. Invasive exotics with major potential to alter structure and composition may be dominant over significant portions of the area, with little potential for control. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where alteration of vegetation is extensive but potentially restorable over several decades. Relative cover of native plants 50-75%. Vehicle use or grazing disturbance is extensive and significant enough to have notable impact on species composition. Invasive exotics with major potential to alter structure and composition may be widespread (3-7% of the occurrence with some patches larger than 1 acre) but potentially manageable with restoration of most natural processes. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES302.734 Chihuahuan Mixed Desert and Thornscrub

CES302.734 CLASSIFICATION

Concept Summary: This ecological system is the widespread desert scrub that occurs on gravelly mid to upper bajadas, foothills and dissected gravelly alluvial fans in the Chihuahuan Desert and has recently expanded at the expense of desert grasslands in the northern portion of its range. It generally occurs on mid to upper piedmonts above the desert plains ~Chihuahuan Creosotebush Desert Scrub (CES302.731)$$ and extends up to the chaparral zone. Soils are typically well-drained, non-saline, gravelly loams often with a petrocalic layer. Substrates are frequently derived from limestone although igneous rocks are common in some areas. In Texas, this system is best developed over limestone substrates. Vegetation is characterized by the presence of *Larrea tridentata*, typically mixed with thornscrub or other desert scrub such as *Agave lechuguilla, Aloysia wrightii, Baccharis pteronioides, Dasylirion leiophyllum, Flourensia cernua* (not bottomland), *Fouquieria splendens, Koeberlinia spinosa, Krameria erecta, Leucophyllum minus, Mimosa aculeaticarpa var. biuncifera, Mortonia scabrella, Opuntia engelmannii, Parthenium incanum, Prosopis glandulosa*, and *Rhus microphylla* (in drainages). Grasses are common but generally have lower cover than shrubs. Common species may include *Bouteloua curtipendula, Bouteloua eriopoda, Bouteloua gracilis, Bouteloua hirsuta, Bouteloua ramosa, Dasyochloa pulchella*, and *Muhlenbergia porteri*. Stands of *Acacia constricta*-, *Acacia neovernicosa*- or *Acacia greggii*-dominated thornscrub are included in this system, and limestone substrates appear important for at least these species. If present, *Prosopis glandulosa* has relatively low cover and does not strongly dominate the shrub layer.

This system also includes upper piedmont stands of desert scrub that are strongly dominated by *Larrea tridentata*, as wells as *Larrea tridentata* shrublands with a sparse understory that occur on gravelly piedmont slopes that may extend down gravelly upper basins.

In western Texas, this scrub is best developed over limestone substrates. *Acacia constricta, Agave lechuguilla, Condalia ericoides, Dasylirion leiophyllum, Larrea tridentata, Leucophyllum* spp., *Mimosa aculeaticarpa var. biuncifera, Parthenium incanum, Prosopis glandulosa, Viguiera stenoloba*, and *Yucca torreyi* are often present to dominant, but numerous shrub species may be present. The herbaceous cover is generally low with species such as *Aristida purpurea, Bouteloua curtipendula, Bouteloua eriopoda, Bouteloua ramosa, Bouteloua trifida, Dasyochloa pulchella*, and *Muhlenbergia setifolia*. Historically, much of this desert scrub was thought to be a more open steppe, characterized by perennial desert grasses (typically *Bouteloua eriopoda*) and an open creosotebush - mixed desert shrub layer. Remnant stands of this historic composition of *Larrea tridentata* desert scrub in the Chihuahuan Desert can be seen on remnant early Holocene erosional surfaces that can often have pebbly desert pavement on the soil surface.

Description Author: K.A. Schulz, L. Elliott and J. Teague

CES302.734 CONCEPTUAL MODEL

Environment: *Climate:* Climate is semi-arid with annual precipitation ranging from 200-250 mm that falls mostly in the summer.

Physiography/landform: This ecological system is the widespread desert scrub that occurs on gravelly mid to upper bajadas, foothills and dissected gravelly alluvial fans in the Chihuahuan Desert and has recently expanded into former desert grasslands in the northern portion of its range. It generally occurs on mid to upper piedmonts above the xeric basins and plains dominated by ~Chihuahuan Creosotebush Desert Scrub (CES302.731)$$ and extends up to the chaparral zone.

Soil/substrate/hydrology: Soils are typically well-drained, non-saline, gravelly loams often with a petrocalic layer. Substrates are frequently derived from limestone, although igneous rocks are common in some areas (Brown 1982a, MacMahon and Wagner 1985, Henrickson and Johnston 1986, MacMahon 1988, Dick-Peddie 1993).

Key Processes and Interactions: In the U.S., much of this scrub is thought to be a result of recent expansion of *Larrea tridentata* into former desert grasslands and steppe in the last 150 years as a result of drought, overgrazing by livestock, and/or decreases in fire over the last 70-250 years (Buffington and Herbel 1965, Ahlstrand 1979, Donart 1984, Dick-Peddie 1993, Gibbens et al. 2005). This expansion has created challenges in determining ecologically historic stands from more recent ones. Dick-Peddie (1993) suggested that absence of *Flourensia cernua* as codominant and presence of *Dasyochloa pulchella, Acourtia nana*, and *Yucca elata* may be indicators of recent conversion of desert grasslands into desert scrub, but more research is needed. Conversely, sparse understory *Larrea tridentata* shrublands on remnant early Holocene erosional surfaces (often with shallow calcareous soils and a pebbly desert pavement) may indicate historic distributions of *Larrea tridentata* desert scrub in the Chihuahuan Desert (Stein and Ludwig 1979, Muldavin et al. 2000b).

Larrea tridentata, a dominant and diagnostic species, is very long-lived (some clones have been estimated to be over 10,000 years). It is highly adapted to minimized evapotranspiration both daily and seasonally using stomatal regulation, resinous leaves, and a leaf structure and habit to minimize self-shading and maximize photosynthesis during favorable growing periods (Hamerlynck et al. 2002, Ogle and Reynolds 2002). *Larrea tridentata* is poorly adapted to fire because of its highly flammable, resinous leaves and limited sprouting ability after burning although it may survive lower-intensity fires (Humphrey 1974, Brown and Minnich 1986, Marshall 1995, Paysen et al. 2000). McLaughlin and Bowers (1982) reported that burned individuals surviving a fire regained their former size in five years. Other dominant shrubs such as *Acacia constricta, Acacia greggii, Acacia neovernicosa, Fouquieria splendens, Flourensia cernua, Mimosa aculeaticarpa var. biuncifera, Mortonia scabrella*, and *Parthenium incanum* are generally top-killed by low- to moderate-severity fires, while severe fires may kill them. The nitrogen-fixing ability of *Acacia neovernicosa* and other leguminous shrubs in this system allow it to colonize harsh environments well (Muldavin et al. 1998a).

This system also includes invasive *Flourensia cernua* shrublands that occur in former (degraded) tobosa (*Pleuraphis mutica*) flats and loamy plains (Muldavin et al. 1998a). Presence of *Scleropogon brevifolius* is common in these invasive stands. *Flourensia cernua* is relatively shallow-rooted and therefore competes strongly with grasses for soil moisture (Muldavin et al. 1998a). Buffington and Herbel (1965) report that *Larrea tridentata* has displaced many stands of *Flourensia cernua* and cite that it may be because *Larrea tridentata* only competes with grasses during the shrub's seedling stage. Muldavin et al. (1998a) state that stands with no graminoid layer are unlikely to develop one; but stands with a graminoid layer are likely to maintain it if not overgrazed. Impermeable caliche and argillic horizons are not uncommon on these sites. These layers restrict deep percolation of soil-water and may favor the shallower root grasses and shrubs such as *Flourensia cernua* over more deeply rooted shrubs such as *Larrea tridentata* and *Prosopis* spp. (McAuliffe 1995).

Drought is a relatively common occurrence in this desert scrub, generally occurring every 10-15 years and lasting 2-3 years with occasional long-term drought periods (10-15 years duration). *Larrea tridentata* and other shrubs have extensive root systems that allow them to exploit deep-soil water that is unavailable to shallower rooted grasses and cacti (Burgess 1995).

LANDFIRE (2007a) developed three VDDT model for this system, all have two classes. (1) Chihuahuan Mixed Desert and Thorn Scrub (BpS 2511001) occurs in basins, plains and into foothills in the Chihuahuan Desert. Substrates are generally fine-textured, saline soils. Does not do well in poorly aerated soils. Stands of *Acacia constricta*-, Acacia neovernicosa- or *Acacia greggii*-dominated thornscrub are included in this creosotebush system, and limestone substrates appear important for at least these species.

A) Early Development 1 All Structures (15% of type in this stage): Characterized by low shrub cover (typically 5-10%). Little disturbance was considered in Class A, except for replacement fire every 300 years on average. In the historic condition where invasive annual grasses are absent, the fire-return interval is virtually nonexistent except for areas near the base of mountains experiencing locally higher rainfall and fine fuel buildup from native annuals. After 100 years, class A transitions to class B.

B) Late Development 1 Closed (85% of type in this stage): Typically, >10% shrub cover and <10% grass and forb cover; associated with more productive soils. *Larrea tridentata* characteristically dominates shrub layer. *Acacia* species may dominate locally in patches. Few fine fuels are associated with this community, therefore the MFRIs for replacement fire and mixed-severity fire is 650 years (min-max: 300-1000 years). Wind/weather stress also affected this community on average every 80 years, but did not cause a transition to class A.

(2) Chihuahuan Mixed Desert Shrubland (BpS 2511002) a minor desert scrub that occurs on gravelly mid to upper bajadas, foothills and dissected gravelly alluvial fans in the Chihuahuan Desert and has recently expanded into former desert grasslands in the northern portion of its range. It generally occurs on mid to upper piedmonts above the desert plains ~Chihuahuan Creosotebush Desert Scrub (CES302.731)$$ and extends up to the chaparral zone (LANDFIRE 2007a, BpS 2511002).

A) Early Development 1 Open (25% of type in this stage): Under natural conditions shrub cover represents <20% canopy cover and is likely not affected by disturbance. The grass community may be as low as 10% canopy cover after a combination of drought/fire. Little disturbance was considered in Class A, modeled drought every 50 years on average, resetting the age to zero (Option 2). In the historic condition where invasive annual grasses are absent, the fire-return interval is virtually nonexistent except for areas near the base of mountains experiencing locally higher rainfall and fine fuel buildup. After 100 years, class A transitions to class B. However, if the upper soil horizon and/or microbes are lost, then a longer recovery time is required or complete recovery is not possible.

B) Late Development 1 Open (75% of type in this stage): Typically, <40% shrub canopy cover and as much as 25% grass and forb canopy cover; associated with more productive soils. Shrubs characteristically dominate the upper layer. Replacement fire followed by prolonged drought every 500 years (min-max: 300-1000 years) on average (Option 1). Wind/weather stress also affected this community on average every 80 years, but did not cause a transition to class A.

(3) Chihuahuan Grama Grass-Steppe (BpS 2511003) a minor desert scrub steppe that occurs on the bajadas and into foothills in the Chihuahuan Desert. Substrates are generally coarse-textured, gravelly soils and may have a petrocalic layer. This site exhibits a high degree of topographic diversity, including limy uplands (LANDFIRE 2007a, BpS 2511003).

A) Early Development 1 Open (20% of type in this stage): Under natural conditions shrub cover represents <10% canopy cover and is likely not affected by disturbance. The grass community may be as low as 10% canopy cover after a combination of drought/fire. Little disturbance was considered in class A. Modeled drought every 50 years on average, resetting the age to zero (Option 2). In the historic condition where invasive annual grasses are absent, the fire-return interval is virtually nonexistent except for areas near the base of mountains experiencing locally higher rainfall and fine fuel buildup. After 100 years, class A transitions to class B. However, if the upper soil horizon and/or microbes are lost, then a longer recovery time is required. Or complete recovery is not possible.

B) Late Development 1 Open (80% of type in this stage): Typically, <10% shrub canopy cover and as much as 40% grass and forb canopy cover; associated with more productive soils. Grasses characteristically dominate shrub layer. Replacement fire followed by prolonged drought every 500 years (min-max: 300-1000 years) on average (Option 1). Wind/weather stress also affected this community on average every 80 years, but did not cause a transition to class A.

In the northern Chihuahuan Desert, this creosotebush mixed desert and thornscrub shrubland ecological system is thought to occur in presettlement conditions largely as mixed desert shrub-steppe on upper bajada gravelly soils and dissected gravelly alluvial fans (S. Yanoff pers. comm. 2006). This grama grass steppe with an open canopy of desert scrub species is a mostly historical grama grass steppe BpS that was described during LANDFIRE MZ25 BpS modeling workshops as Chihuahuan Grama Grass Creosote Steppe (LANDFIRE 2007a, BpS 2511003). It is distinct from creosotebush mixed shrublands on similar sites because it has an open shrub layer characterized by dense perennial grasses (typically black grama).

Threats/Stressors: Chihuahuan Mixed Desert and Thornscrub is a widespread, long-lived ecosystem that occurs above ~Chihuahuan Creosotebush Desert Scrub (CES302.731)$$ in the xeric desert basin. Although thornscrub occurring on limestone rock outcrops is stable, other stands may be sensitive to altered fire regimes caused by invasive species, as well as anthropogenic disturbance such as mechanical/chemical shrub removal. Altered (uncharacteristic) fire regimes greatly influence ecosystem processes.

The historical desert scrub has a very long fire-return interval (FRI) ranging from 300-1000 years (500 years on average) (from LANDFIRE BpS Model 2510740). *Larrea tridentata* and other desert scrub plant species did not evolve with fire and are sensitive to burning; most of them do not resprout after burning and are slow to recover, and therefore fires should be rare events to be avoided. Invasion of non-native grasses provides fine fuels that can increased fire frequency, intensity and severity. Fires in desert scrub are becoming more common, especially after a series of wet years when fine fuels from non-native herbaceous species build up enough to carry fire.

The impact of livestock grazing to the historical stands of desert scrub is expected to be relatively small because there is little forage available for them in this type, but where livestock grazing or other anthropomorphic disturbance occurs there may be increased soil erosion (Milchunas 2006).

Human development has impacted many locations throughout the ecoregion. These sites represent a poor-condition/non-functioning ecosystem that is highly fragmented, or much reduced in size from its historical extent; the surrounding landscape is in poor condition either with highly eroding soils, many non-native species or a large percentage of the surrounding landscape has been converted to pavement or disturbed by off-road vehicles; the biotic condition is at the limit or beyond natural range of variation, e.g., vegetation composition is altered and is not dominated by native shrubs such as *Larrea tridentata* and *Flourensia cernua*. Characteristic birds, mammals, reptiles, and insect species are not present at expected abundances or the ratio of species shows an imbalance of predator-to-prey populations; abiotic condition is poor with evidence of high soil erosion, rill and gullies present or exposed soil sub horizons. Non-native grass invasion provides fine fuels that may increase fire frequency, intensity and severity.

Ecosystem Collapse Thresholds: Ecological collapse tends to result in sites where: invasion of exotic annuals has increased fine fuels in the understory which allowed a large, intense fire to burn in this open-canopied scrub and kill the highly flammable creosotebush and other shrubs; creosotebush is eliminated from the landscape leaving introduced annuals; where there is not enough fuel to carry a fire, excessive livestock trampling, vehicle use (motorbikes, off-road vehicles, construction vehicles), filling and grading, plowing, other mechanical disturbance could lead to excessive soil movement (erosion or deposition) as evidenced by gully, rill, or dune formation resulting in ecosystem collapse.

High-severity environmental degradation appears where occurrences tend to be small (<5000 acres) in size for this matrix type. System remains fundamentally compromised despite restoration of some processes. Bare soil areas due to human/livestock causes are common. ORVs or other machinery may have left some shallow ruts in desert pavement. Soil erosion and deposition from wind is evident and sometime severe. Landscapes are missing fundamental system components that render restoration unfeasible. Connectivity is severely hampered.

Moderate-severity environmental degradation appears where occurrences tend to be relatively small (5000-20,000 acres) in size for this matrix type. Alteration is extensive but potentially restorable over several decades. Vehicle use or grazing disturbance is extensive and significant enough to have notable impact on species composition. Soil erosion and deposition from wind is evident. Adjacent grasslands and shrublands are fragmented by alteration (20-60% natural). Landscape is restorable over years or decades. There is limited connectivity. Some barriers are present restricting movement across system boundaries.

High-severity biotic disruption appears where alteration of vegetation is extensive and restoration potential is low and system remains fundamentally compromised despite restoration of some processes. There is relative cover of native plants <50%. Invasive exotics with major potential to alter structure and composition are dominant over significant portions of the area, with little potential for control. Native plant species diversity is low and the diversity and abundance of animal populations are also low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where alteration of vegetation is extensive but potentially restorable over several decades. Relative cover of native plants is between 50-75%. Vehicle use or grazing disturbance is extensive and significant enough to have notable impact on species composition. Invasive exotics with major potential to alter structure and composition are widespread (3-7% of the occurrence with some patches larger than 1 acre) but are potentially manageable with restoration of most natural processes. Native plant species diversity is low as well as the diversity and abundance of animal populations when compared to an intact ecosystem.

CES302.017 Chihuahuan Mixed Salt Desert Scrub

CES302.017 CLASSIFICATION

Concept Summary: This ecological system includes extensive open-canopied shrublands of typically saline basins in the Chihuahuan Desert. Stands often occur on alluvial flats and around playas, as well as in floodplains along the Rio Grande and Pecos River, possibly also extending into the San Simon of southeastern Arizona. Substrates are generally fine-textured, saline soils. Vegetation is typically composed of one or more *Atriplex* species, such as *Atriplex canescens, Atriplex obovata*, or *Atriplex polycarpa*, along with species of *Allenrolfea, Flourensia, Salicornia, Suaeda*, or other halophytic plants. Graminoid species may include *Sporobolus airoides, Pleuraphis mutica*, or *Distichlis spicata* at varying densities.

CES302.017 CONCEPTUAL MODEL

Environment: This system includes extensive open-canopied shrublands of typically saline basins in the Chihuahuan Desert. Stands often occur on alluvial flats, around playas and floodplains of the Rio Grande and Pecos River, possibly also extending into the San Simon of southeastern Arizona. Sites are flat to gently sloping with slopes up to 3%. Elevation ranges from 1000-1300 m (3300-4300 feet). Substrates are generally fine-textured, saline soils but may include moderately coarse-textured alluvium in the floodplains. In Texas, this system is associated with Salty desert grassland, Salty Clay Fan, and Salty Bottomland Ecological Sites. Water tables are generally shallow but fluctuate within reach of deep-rooted plants, and in most places are high enough that salts accumulate on the surface of the soil.

Key Processes and Interactions: [from M086] In the U.S., much of this desert scrubland is thought to be a result of recent expansion of *Larrea tridentata* and *Prosopis glandulosa* into former desert grasslands and steppe in the last 150 years as a result of a combination of drought, overgrazing by livestock, wind and water erosion, and/or decreases in fire over the last 70-250 years from fire suppression and fine-fuel removal by livestock, and changes in the seasonal distribution of precipitation (Buffington and Herbel 1965, Herbel et al. 1972, Humphrey 1974, Ahlstrand 1979, McLaughlin and Bowers 1982, Gibbens et al. 1983, Hennessy et al. 1983, Donart 1984, Brown and Archer 1987, Schlesinger et al. 1990, Dick-Peddie 1993, McPherson 1995, Gibbens et al. 2005). Seed dispersion by livestock is an additional factor in the increase of *Prosopis glandulosa* (Brown and Archer 1987). It is believed that *Prosopis glandulosa* stands formerly occurred in relatively minor amounts and were largely confined to drainages until cattle distributed seed upland from the bosques into desert grasslands (Brown and Archer 1987, 1989). This macrogroup also includes invasive *Flourensia cernua* shrublands that occur in former (degraded) tobosa (*Pleuraphis mutica*) flats and loamy plains. Presence of *Scleropogon brevifolius* is common in these invasive stands. Dick-Peddie (1993) suggested that absence of *Flourensia cernua* as codominant and presence of *Dasyochloa pulchella, Acourtia nana*, and *Yucca elata* may be indicators of recent conversion of desert grasslands into desertscrub, but more research is needed. Conversely, sparse understory *Larrea tridentata* shrublands on remnant early Holocene erosional surfaces often with shallow calcareous soils and desert pavement may indicate pre-historic distributions of *Larrea tridentata* desertscrub in the Chihuahuan Desert (Stein and Ludwig 1979, Muldavin et al. 2000b).

Historical natural-ignition fires were relatively small, probably 10-15 acres in size. Repeated fire is thought to help maintain a general mosaic pattern between open grassland and shrub-dominated areas (Johnston 1963). Wright et al. (1976) found that *Prosopis glandulosa* is very fire-tolerant when only 3 years old. Most plants resprout after being top-killed by fire. Thus, prior to livestock grazing reducing fire frequency, repeated grassland fires probably maintained lower stature of shrubs and prevented new establishment by killing seedlings.

Drought is a relatively common occurrence in this desertscrub, generally occurring every 10-15 years and lasting 2-3 years with occasional long-term drought periods (10-15 years duration). *Prosopis* spp. and other shrubs have extensive root systems that allow them to exploit deep-soil water that is unavailable to shallower rooted grasses and cacti (Burgess 1995). This strategy works well, especially during drought. However, on sites that have well-developed argillic or calcic soil horizons that limit infiltration and storage of winter moisture in the deeper soil layers, *Prosopis* spp. invasion can be limited to a few, small individuals (McAuliffe 1995). This has implications in plant geography and desert grassland restoration work in the southwestern United States.

On sandsheet and dune sites, *Prosopis glandulosa* is more common on warmer, drier sites on sandsheets with subsoils composed of clays or carbonate substrates, whereas *Artemisia filifolia* is more common on relatively cooler/moisture sites with coarse, deep sand (S. Yanoff pers. comm. 2007). These sites are also more susceptible to grazing pressure.

CES302.737 Chihuahuan Stabilized Coppice Dune and Sand Flat Scrub

CES302.737 CLASSIFICATION

Concept Summary: This ecological system includes the open desert scrub of vegetated coppice dunes and sandsheets associated with eolian sands found in the Chihuahuan Desert. Stands are usually dominated by *Prosopis glandulosa* or *Artemisia filifolia* but also include *Atriplex canescens, Ephedra torreyana, Ephedra trifurca, Poliomintha incana*, and *Rhus microphylla* coppice and sand flat scrub usually with 10-30% total vegetation cover. *Yucca elata, Gutierrezia sarothrae, Bouteloua eriopoda, Cylindropuntia imbricata*, and *Sporobolus flexuosus* are commonly present. Herbaceous species of the adjacent grasslands may be common. In northern stands, *Artemisia filifolia* dominates and *Prosopis glandulosa* becomes less common or absent. This system includes degraded sandy desert plains grasslands now dominated by *Artemisia filifolia*.

CES302.738 Chihuahuan Succulent Desert Scrub

CES302.738 CLASSIFICATION

Concept Summary: This ecological system is found in the Chihuahuan Desert on colluvial slopes, upper bajadas, sideslopes, ridges, canyons, hills and mesas. Sites are hot and dry, typically with southerly aspects. Gravel and rock are often abundant on the ground surface. In Texas, this system is typically associated limestone. The vegetation is characterized by the relatively high cover of succulent species such as *Agave lechuguilla, Dasylirion leiophyllum, Dasylirion texanum, Euphorbia antisyphilitica, Fouquieria splendens, Ferocactus* spp., *Opuntia engelmannii, Cylindropuntia imbricata, Cylindropuntia spinosior, Yucca baccata, Yucca torreyi*, and many others. Perennial grass cover is generally low. The abundance of succulents is diagnostic of this desert scrub system, but desert shrubs are usually present. In Texas, shrub species such as *Larrea tridentata, Parthenium incanum, Viguiera stenoloba*, and *Forestiera angustifolia* may be present. Herbaceous cover is low with grasses such as *Bouteloua eriopoda, Bouteloua ramosa*, and *Bouteloua curtipendula* sometimes present. Fern and fern allies such as *Astrolepis* spp., *Cheilanthes* spp., and *Selaginella lepidophylla* are often common. Stands in rolling topography may form a mosaic with more mesic desert scrub or desert grassland ecological systems that would occur on less xeric northerly slopes. *Agave lechuguilla* is more abundant in stands in the southern part of the mapzone. This system does not include loamy plains desert grasslands or shrub-steppe with a strong cacti component such as cholla grasslands.

Distribution: This Chihuahuan Desert ecological system occurs on colluvial slopes, upper bajadas, sideslopes and mesas. It extends east to the Devils River in Texas.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: L. Elliott and J. Teague

CES302.738 CONCEPTUAL MODEL

Environment: Occurrences are found on a variety of hot, dry sites, typically rocky or gravelly slopes with southerly aspects. Gravel and rock are often abundant on the ground surface. In Texas, it is typically associated with limestones, but can also be found on calcareous gravels, igneous and sandstone substrates on rocky or gravelly slopes associated with Igneous Hill and Mountain, Limestone Hill and Mountain, Sandstone Hill, Limestone Hill, Gravelly, and similar ecoclasses.

Key Processes and Interactions: [from M086] In the U.S., much of this desert scrubland is thought to be a result of recent expansion of *Larrea tridentata* and *Prosopis glandulosa* into former desert grasslands and steppe in the last 150 years as a result of a combination of drought, overgrazing by livestock, wind and water erosion, and/or decreases in fire over the last 70-250 years from fire suppression and fine-fuel removal by livestock, and changes in the seasonal distribution of precipitation (Buffington and Herbel 1965, Herbel et al. 1972, Humphrey 1974, Ahlstrand 1979, McLaughlin and Bowers 1982, Gibbens et al. 1983, Hennessy et al. 1983, Donart 1984, Brown and Archer 1987, Schlesinger et al. 1990, Dick-Peddie 1993, McPherson 1995, Gibbens et al. 2005). Seed dispersion by livestock is an additional factor in the increase of *Prosopis glandulosa* (Brown and Archer 1987). It is believed that *Prosopis glandulosa* stands formerly occurred in relatively minor amounts and were largely confined to drainages until cattle distributed seed upland from the bosques into desert grasslands (Brown and Archer 1987, 1989). This macrogroup also includes invasive *Flourensia cernua* shrublands that occur in former (degraded) tobosa (*Pleuraphis mutica*) flats and loamy plains. Presence of *Scleropogon brevifolius* is common in these invasive stands. Dick-Peddie (1993) suggested that absence of *Flourensia cernua* as codominant and presence of *Dasyochloa pulchella, Acourtia nana*, and *Yucca elata* may be indicators of recent conversion of desert grasslands into desertscrub, but more research is needed. Conversely, sparse understory *Larrea tridentata* shrublands on remnant early Holocene erosional surfaces often with shallow calcareous soils and desert pavement may indicate pre-historic distributions of *Larrea tridentata* desertscrub in the Chihuahuan Desert (Stein and Ludwig 1979, Muldavin et al. 2000b).

Historical natural-ignition fires were relatively small, probably 10-15 acres in size. Repeated fire is thought to help maintain a general mosaic pattern between open grassland and shrub-dominated areas (Johnston 1963). Wright et al. (1976) found that *Prosopis glandulosa* is very fire-tolerant when only 3 years old. Most plants resprout after being top-killed by fire. Thus, prior to livestock grazing reducing fire frequency, repeated grassland fires probably maintained lower stature of shrubs and prevented new establishment by killing seedlings.

Drought is a relatively common occurrence in this desertscrub, generally occurring every 10-15 years and lasting 2-3 years with occasional long-term drought periods (10-15 years duration). *Prosopis* spp. and other shrubs have extensive root systems that allow them to exploit deep-soil water that is unavailable to shallower rooted grasses and cacti (Burgess 1995). This strategy works well, especially during drought. However, on sites that have well-developed argillic or calcic soil horizons that limit infiltration and storage of winter moisture in the deeper soil layers, *Prosopis* spp. invasion can be limited to a few, small individuals (McAuliffe 1995). This has implications in plant geography and desert grassland restoration work in the southwestern United States.

On sandsheet and dune sites, *Prosopis glandulosa* is more common on warmer, drier sites on sandsheets with subsoils composed of clays or carbonate substrates, whereas *Artemisia filifolia* is more common on relatively cooler/moisture sites with coarse, deep sand (S. Yanoff pers. comm. 2007). These sites are also more susceptible to grazing pressure.

M087. Chihuahuan Semi-Desert Grassland

CES302.735 Apacherian-Chihuahuan Semi-Desert Grassland and Steppe

CES302.735 CLASSIFICATION

Concept Summary: This ecological system is a broadly defined desert grassland, mixed shrub-succulent steppe, or xeromorphic oak savanna that is typical of the Borderlands of Arizona, New Mexico and northern Mexico (Apacherian region) but extends west to the Sonoran Desert, north into the Mogollon Rim in Arizona and up the Rio Grande Valley into central New Mexico. It also extends east into the Chihuahuan Desert. It is found on gently sloping alluvial erosional fans and piedmonts (bajadas) that lie along mountain fronts of the isolated basin ranges throughout the Sky Island mountain archipelago and on to foothill slopes up to 1670 m elevation in the Chihuahuan Desert. The vegetation in this mixed semi-desert grassland ecosystem is variable. It is characterized by the dominance of a typically diverse layer of warm-season, perennial grasses with scattered stem succulents and shrubs. Frequent species include the grasses *Aristida ternipes, Bouteloua barbata, Bouteloua chondrosioides, Bouteloua curtipendula, Bouteloua eriopoda, Bouteloua gracilis, Bouteloua hirsuta, Bouteloua ramosa, Bouteloua repens, Bouteloua rothrockii, Dasyochloa pulchella, Digitaria californica, Eragrostis intermedia, Heteropogon contortus, Hilaria belangeri, Leptochloa dubia, Muhlenbergia porteri*, with

Muhlenbergia emersleyi, Muhlenbergia setifolia at upper foothill elevation, rosettophyllous, often succulent species of *Agave, Dasylirion, Nolina, Opuntia*, and *Yucca*, and short-shrub species of *Calliandra*, and *Parthenium*. Tall-shrub/short-tree species of *Acacia, Prosopis, Juniperus, Mimosa*, and various oaks (e.g., *Quercus grisea, Quercus emoryi, Quercus arizonica, Quercus oblongifolia*) may be present with low cover (usually <10%). *Pleuraphis mutica*-dominated semi-desert grasslands often with *Bouteloua eriopoda* or *Bouteloua gracilis* occurring on lowlands and loamy plains in the Chihuahuan Desert are classified as ~Chihuahuan Loamy Plains Desert Grassland (CES302.061)$$. Many of the historical desert grassland and savanna areas have been converted through intensive grazing and other land uses, some to ~Apacherian-Chihuahuan Mesquite Upland Scrub (CES302.733)$$ (*Prosopis* spp.-dominated).

Distribution: This system is found in the Borderlands of Arizona, New Mexico and northern Mexico (Apacherian region), extending to the Sonoran Desert and throughout much of the northern Chihuahuan Desert.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: K.A. Schulz and M.S. Reid

CES302.735 CONCEPTUAL MODEL

Environment: This system is found on gently sloping alluvial erosional fans and piedmonts (bajadas) that lie along mountain fronts of the isolated ranges throughout the Sky Island mountain archipelago and on to foothill slopes from 1000 m to 1670 m and up to 1800 m elevation in the Chihuahuan Desert and up to 2200 m in lower montane grasslands.

Climate: Climate is semi-arid, warm-temperate with a highly variable, bimodally distributed precipitation. Approximately two-thirds of the 20-40 cm mean annual precipitation occurs in the late summer and early fall, usually as localized high-intensity thunderstorms.

Physiography/landform: Sites are typically gently sloping mesas and piedmonts (LANDFIRE 2007a).

Soil/substrate/hydrology: Substrates are variable, ranging from fine- to coarse-textured soils depending on site. However, most are typically deep, coarser-textured, gravelly soils derived from limestone, sandstone, conglomerate or igneous substrates such as tuff.

Key Processes and Interactions: Semi-desert grasslands are complex with many stands having a shrub or stem succulent component (*Agave* and *Yucca* spp.) under natural conditions (Burgess 1995). This woody component increases in density over time in the absence of disturbance such as fire (Burgess 1995, Gori and Enquist 2003, Schussman 2006a). Under historic natural conditions (also called natural range of variability or NRV), this ecosystem ranges from open perennial grasslands with low cover of shrubs to grasslands with a moderately dense shrub layer and succulent layer (Burgess 1995, Gori and Enquist 2003). An exception is that some stands with deep argillic horizons appear resistant to shrub and tree invasion without disturbance (McAuliffe 1995).

It is well-documented that frequent stand-replacing fire (fire-return interval (FRI) of 2.5 to 10 years) was a key ecological attribute of this semi-desert grassland ecosystem historically before 1890 (Wright 1980, Bahre 1985, McPherson 1995, Kaib et al. 1996). Other evidence of the importance of fire in maintaining desert grasslands includes the widespread conversion of grasslands to shrublands during the century of fire suppression (McPherson 1995) and the results of prescribed burning on decreasing shrub cover and increasing grass cover (Bock and Bock 1992, Robinett 1994). Additional evidence that frequent fire is a key ecological attribute of this ecosystem is that many common invasive shrubs, subshrubs and cacti are fire-sensitive and individuals are killed when top-burned, at least when they are young (<10 years old) (McPherson 1995), while native perennial grasses generally quickly recover from burning (Wright 1980, Martin 1983, Bock and Bock 1992).

Herbivory by native herbivores in the system is varied and ranges from invertebrates and rodents to pronghorn (Parmenter and Van Devender 1995, Whitford et al. 1995, Finch 2004). Soil-dwelling invertebrates include tiny nematodes and larger termites and ants, are important in nutrient cycling and affect soil properties, such as bulk density (Whitford et al. 1995). Above-ground invertebrates such as grasshoppers can significantly impact herbaceous cover when populations are high. Herbivory by native mammals also impacts these grasslands. Historically, populations of large mammals such as pronghorn (*Antilocarpa americana*) and mule deer (*Odocoileus hemionus*) were once abundant in this ecosystem (Parmenter and Van Devender 1995). Populations were greatly reduced and, in the case of pronghorn, extirpated during the 1800s and early 1900s, but effective game management has restored many populations, although habitat changes will limit restoration in other areas (Parmenter and Van Devender 1995). The historic impact of large native ungulates on this ecosystem is not known; however, in the case of wintering elk, it may have been significant locally. The current impact is assumed to be relatively small in this ecosystem.

Herbivory from native small mammals such as rodents is significant as they are the dominant mammals in the semi-desert grassland ecosystem. There is also high diversity of these rodents, especially ground-dwelling ones such as spotted ground squirrels (*Xerospermophilus spilosoma*), and bannertail and Ord kangaroo rats (*Dipodomys spectabilis* and *Dipodomys ordii*). These burrowing rodents have a substantial effect on vegetation composition, soil structure and nutrient cycling (Parmenter and Van Devender 1995, Finch 2004). Historically, black-tail prairie dogs (*Cynomys ludovicianus*) had extensive colonies in the Great Plains that extended west to southeastern Arizona but were greatly reduced. Although abundant in southeastern Arizona and southwestern New Mexico in the 1800s, the black-tailed prairie dog populations were decimated by 1930 and considered extirpated in Arizona by 1960 (Alexander 1932, Hoffman 1986, Parmenter and Van Devender 1995, Van Pelt 1999, Underwood and Van Pelt 2008). Although there have been several reintroductions of black-tailed prairie dogs, their numbers and impacts are still small in this region. Because of the nature of black-tail prairie dogs (large towns and major impacts to the local ecosystem), they may have historically functioned as a keystone species in lower elevation stands in the northern extent of ~Apacherian-Chihuahuan Semi-Desert Grassland and Steppe (CES302.735)$$. However, historically black-tailed prairie dogs were likely more abundant in the deeper soiled ~Chihuahuan Loamy Plains Desert Grassland (CES302.061)$$ that occurs on lower elevation alluvial flats and plains. More research is needed to determine the role of black-tailed prairie dogs in these semi-grassland and steppe systems.

Invertebrate animals are also significant in semi-desert grassland. They are both abundant and extremely diverse, ranging from single-celled protozoans, bacterial and soil nematodes and mites to larger arachnids, millipedes, cockroaches, crickets, grasshoppers, ants, beetles, butterflies, moths, flies, bees, wasps, and true bugs (Whitford et al. 1995). Invertebrates are important for nutrient cycling and pollination, and subterranean species of ants and termites can impact soil properties such as bulk density, infiltration permeability and storage (Whitford et al. 1995). Grasshoppers feed on grasses and forbs and can consume significant amounts of forage when their populations are high. Many species of butterflies, flies, bees, and moths are important for pollination. Some species such as Yucca moths (*Tegeticula* spp.) and *Yucca* species have obligate/mutualistic relationships (Whitford et al. 1995, Althoff et al. 2006). In these grasslands, *Yucca* spp. are typically dependent on a single species of *Tegeticula* for pollination, which is usually dependent on a single *Yucca* host plant species for habitat and food for larvae, for example, *Tegeticula baccatella* and *Yucca baccata, Tegeticula carnerosanella* and *Yucca faxoniana, Tegeticula elatella* and *Yucca elata, Tegeticula maderae* and *Yucca x schottii*, and *Tegeticula yuccasella* and *Yucca glauca*. More study and review are needed to fully understand the many functional roles animals have within the semi-desert grassland ecosystem.

LANDFIRE developed a VDDT model for this system which has three classes (LANDFIRE 2007a, BpS 2711210).

A) Early Development 1 All Structures (20% of type in this stage): Herbaceous cover (0-20%). Grass and herbs, 0-5 years (predicated on moisture regime). Early-succession post-fire grass and herb community. This class encompasses the time period required to recover sufficient fuel loads to carry fire. Perennial bunchgrasses, annual grass, and herb community. Upper layer of shrubs, canopy cover less than 5%.

B) Mid Development 1 All Structures (35% of type in this stage): Perennial grass species dominate with 35-50% canopy cover; <0.5 m height. Shrub cover is 5-10% with shrubs 0-1 m tall. Grass with some low shrubs, 6-50 years old. Perennial bunchgrasses regenerated and young shrubs begin growing. Species are perennial bunchgrasses and shrubs. Canopy cover of shrubs is 5-10%. Maintenance disturbance is drought, occurring approximately every 30 years. Maintenance replacement fire is more frequent with less frequent replacement fire returning to class A. This was modeled to occur every 10 years on average, half the time causing a transition to class A, and half the time maintaining this class.

C) Late Development 1 All Structures (50% of type in this stage): Perennial grass species dominate with 10-35% canopy cover; 1-2 m height. Shrubs continue to increase in size and/or number of individuals. Species are perennial bunchgrasses and shrubs. Canopy cover of shrubs is 10-20%. (Shrub cover will be similar to species composition found in ~Apacherian-Chihuahuan Mesquite Upland Scrub (CES302.733)$$). Shrub species diversity increases. FRI=10 years, half are replacement (to class A) and half take class back to class B. The wind/weather stress in this model is drought, occurring approximately every 30 years. It is thought that this is the class that might result with lack of fire and that more would be present in this class currently versus historically.

In the LANDFIRE BpS 2611210 model, mixed-severity fire was modeled for MZ26; however, this was removed for MZ27, as it is thought that only patchy replacement fire would occur in this system (LANDFIRE 2007a). It was noted that the amount of moisture following fire has a significant impact on plant response/recovery. Because historical fire data in this system are lacking, there is uncertainty over the role fire plays in maintaining this system. Some modelers think fire has a major impact on control of woody species, whereas others think fire is less important in control of woody species than maintenance of perennial grass cover in this system (LANDFIRE 2007a).

Threats/Stressors: During the last century, the area occupied by this desert grassland and steppe decreased through conversion of desert grasslands as a result of drought, overgrazing and *Prosopis glandulosa* seed dispersion by livestock, and/or decreases in fire frequency (Buffington and Herbel 1965, Brown and Archer 1987). Conversion of this type has also commonly come from urban and exurban development near cities such as Sierra Vista, Arizona, altered hydrological regimes (water developments/reservoirs) (Cooke and Reeves 1976), and irrigated agriculture, especially hay meadows dominated by non-native forage grasses. Fire suppression has allowed succession and conversion to shrublands, desert scrub and woodlands, especially from oak, pinyon or juniper tree invasion (Gori and Enquist 2003). This grassland has also been converted to invasive non-native, perennial forage grasses *Eragrostis lehmanniana* and *Eragrostis curvula* (Cable 1971, Anable et al. 1992, Gori and Enquist 2003).

It is believed that mesquite formerly occurred in relatively minor amounts and was largely confined to drainages until cattle distributed seed upland into desert grasslands (Brown and Archer 1987, 1989). Shrublands dominated by *Prosopis* spp. have replaced large areas of desert grasslands, especially those formerly dominated by *Bouteloua eriopoda*, in Trans-Pecos Texas, southern New Mexico and southeastern Arizona (York and Dick-Peddie 1969, Hennessy et al. 1983). Studies on the Jornada Experimental Range suggest that combinations of drought, overgrazing by livestock, wind and water erosion, seed dispersal by livestock, fire suppression, shifting dunes, and changes in the seasonal distribution of precipitation have caused this recent, dramatic shift in vegetation physiognomy (Buffington and Herbel 1965, Herbel et al. 1972, Humphrey 1974, McLaughlin and Bowers 1982, Gibbens et al. 1983, Hennessy et al. 1983, Schlesinger et al. 1990, McPherson 1995).

These native mixed semi-desert grasslands are the dominant grassland type and range from open grasslands with low shrub canopy cover (less than 10% cover) to denser grassland with higher shrub and succulent cover. Over time without fire or other disturbance, stands become dominated by woody vegetation and convert to shrublands or woodlands (Gori and Enquist 2003). Conversion to juniper woodlands or mesquite shrublands is common when trees or mesquite exceed 15% cover (Gori and Enquist 2003). These grasslands were historically maintained as open grasslands with low shrub cover by fire-return intervals of 2.5 to 10 years (Wright 1980, Robinett 1994, McPherson 1995, Brown and Archer 1999). Both drought and livestock grazing interact with grass cover and fire-return intervals can affect the rate of shrub increase (Wright 1980, Robinett 1994, McPherson 1995, Brown and Archer 1999). Gori and Enquist (2003) found that after grassland conversion to shrubland there is a loss of perennial grasses and increases of bare ground. If not protected by surface rock, topsoil erosion can occur changing the site to be less suitable for grass recolonization (McAuliffe 1995).

Hydrological alterations also occurred in many semi-desert grasslands during early Anglo-American settlement time with a period of arroyo formation from 1865 to 1915 (Cooke and Reeves 1976). During this time many broad valley bottom drainages were incised, lowering water tables. This resulted in changes to more xeric vegetation because of decreased water availability, as well as increased sediment movement, altered hydrologic relationships, and loss of productive land (Cooke and Reeves 1976). Although there is debate of causes of these hydrologic changes (arroyo formation), Cooke and Reeves (1976) found strong evidence that arroyo formation was initiated by building ditches, canals, roads and embankments along channels that altered valley floor hydrology.

The introduction of the invasive non-native, perennial grasses *Eragrostis lehmanniana* and *Eragrostis curvula* has greatly impacted many semi-desert grasslands in this ecoregion (Cable 1971, Anable et al. 1992, Gori and Enquist 2003). Anable et al. (1992) and Cable (1971) found *Eragrostis lehmanniana* is a particularly aggressive invader and alters ecosystem processes, vegetation composition, and species diversity.

Common stressors and threats include fragmentation from housing and water developments, altered fire regime from fire suppression and indirect fire suppression from livestock grazing and fragmentation, introduction of invasive non-native species, and overgrazing by livestock which can lead to severe soil compaction and reduce vegetation cover exposing soils to erosion of topsoil, especially if soil surface does not significant rock cover.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing often combined with drought or other major disturbance where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion, which alter ecosystem so it cannot return to previous state on its own. These disturbed areas are vulnerable to invasive non-native species which if become established will outcompete and replace the dominant native perennial species and further increase the irreversibility of this altered state.

High-severity environmental degradation often appears where occurrences tend to be relatively small (<1000 acres) with evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in significant soil compaction and sheet and rill erosion. Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval well beyond 2.5 to 10 years resulting in a significant increase in shrub cover (>35%) and/or tree cover (>15%) (oak, juniper or mesquite) causing a reduction of perennial grass cover (Gori and Enquist 2003). Sites may be highly fragmented with roads. Alteration of abiotic processes is extensive and restoration potential is low or development.

Moderate-severity environmental degradation appears where occurrences are moderate (5000-1000 acres) in size. There is usually evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval beyond 2.5 to 10 years resulting in an increase in shrub cover (10-35%) and/or tree cover (5-15%) (oak, juniper and mesquite) (Gori and Enquist 2003). Sites may be fragmented with roads or development.

High-severity disruption appears where occurrences have low cover of native grassland species (<10% cover and <20% relative cover). There is typically significant cover of shrubs (>35%) and juniper trees and mesquite (>15%) because of fire suppression (Gori and Enquist 2003). Invasive non-native species may be abundant (>10% cover). Other non-native species dominate the herbaceous layer. Connectivity is severely hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Characteristic birds, mammals, reptiles, and insects are not present at expected abundances or the ratio of species shows an imbalance of predator to prey populations. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low.

Moderate-severity disruption appears where occurrences have moderate cover of native grassland species (>10% cover and >20% relative cover). There is often significant shrub cover (10-35%) and/or tree cover (5-15%) (oak, juniper or mesquite) because of fire suppression (Gori and Enquist 2003). Non-native invasive species are present, but still controllable. Species composition has shifted from dominance of late-seral, palatable midgrasses such as *Bouteloua curtipendula, Bouteloua eriopoda, Digitaria californica, Eragrostis intermedia, Heteropogon contortus, Leptochloa dubia, Muhlenbergia porteri, Muhlenbergia emersleyi*, and *Muhlenbergia setifolia* to more early-seral species (grazing-increasers) such as *Aristida* spp., *Sporobolus cryptandrus, Gutierrezia sarothrae, Heterotheca villosa*, and grazing-tolerant species such as *Bouteloua gracilis, Bouteloua repens*, or *Hilaria belangeri*. Connectivity is moderately hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and reduce the natural movement of some animal and plant populations. Characteristic birds, mammals, reptiles, and insects are not present at expected abundances or the ratio of species shows an imbalance of predator to prey populations. Alteration of vegetation structure and biotic processes is significant; however, restoration potential is moderate.

CES302.732 Chihuahuan Gypsophilous Grassland and Steppe

CES302.732 CLASSIFICATION

Concept Summary: This ecological system is restricted to gypsum outcrops or sandy gypsiferous and often alkaline soils that occur in basins and slopes in the Chihuahuan Desert. Elevation range is from 1100-2000 m. These typically sparse grasslands, steppes or dwarf-shrublands are dominated by a variety of gypsophilous plants, many of which are endemic to these habitats. Characteristic species include *Tiquilia hispidissima, Atriplex canescens, Calylophus hartwegii, Ephedra torreyana, Frankenia jamesii, Bouteloua breviseta, Mentzelia perennis, Nama carnosum, Calylophus hartwegii, Selinocarpus lanceolatus, Sporobolus nealleyi, Sporobolus airoides*, and *Sartwellia flaveriae* with gypsophilous species diagnostic of this system. This system does not include the sparsely vegetated gypsum dunes that are included in ~North American Warm Desert Active and Stabilized Dune (CES302.744)$$. Additional species that may be encountered in this system in Texas include *Anulocaulis* spp., *Atriplex canescens, Calylophus hartwegii, Condalia ericoides, Ephedra torreyana, Gaillardia multiceps, Larrea tridentata, Poliomintha incana, Prosopis glandulosa, Scleropogon brevifolius, Selinocarpus* spp., *Sporobolus airoides, Sporobolus cryptandrus*, and *Yucca torreyi*.

Distribution: This system is found on basins and slopes in the Chihuahuan Desert at elevations ranging from 1100-2000 m.
Nations: MX, US
Concept Source: K.A. Schulz
Description Author: K.A. Schulz

CES302.732 CONCEPTUAL MODEL

Environment: This ecological system is restricted to gypsum outcrops and strongly gypseous soils (Powell and Turner 1974, Henrickson et al. 1985, Meyer 1986, Dick-Peddie 1993). Sites occur in warm, semi-desert and desert regions with hot summers, and occasionally cold winters from the Chihuahuan Desert to eastern Mojave Desert and may extend up into the southern Colorado Plateau (Powell and Turner 1974, Meyer 1986, Dick-Peddie 1993). Elevation range is from 1100-2000 m. Some occurrences may be windswept gypsum "pavement" where much of the gypsum sand has been removed by wind, but these are not open/moving dunes dominated by eolian processes. Substrates are typically fine-textured, alkaline clay soils but include some sandy gypsiferous soils that occur in closed basins in the Chihuahuan Desert, but not gypsum dunes at White Sands National Monument (Reid 1980, Dick-Peddie 1993, Muldavin et al. 2000b). Eolian processes drive the dune system so many of the same common sand scrub plants, e.g., *Atriplex canescens*, may characterize vegetation on both quartz and gypsum active dunes, although some gypsophiles will occur on gypsum dunes (Shields 1956, Reid 1980, 1980, Dick-Peddie 1993). In Texas, extensive occurrences are associated with the Permian

Castile Formation and alluvium within evaporative bolsons; scattered occurrences are associated with exposed gypsite and alluvium of evaporative ponds and swales receiving deposition from eroding gypsiferous formations.

Key Processes and Interactions: Gypsophile endemism is common in the North American deserts, especially the Chihuahuan Desert where much of the region is underlain by limestone, with occasional gypsum exposures. These gypsum deposits are distributed in a discontinuous, island-like fashion that facilitates endemism. Gypsum is a difficult substrate for plants to grow on because it typically forms a hard crust when dry, erodes quickly when wet, and is relatively low in available nutrients. However, a large and diverse group of gypsophilous plants only occur on this substrate, several of which are considered rare and at risk.

This is a substrate-driven ecosystem occurring in extreme environments on chemically harsh substrates. Fire plays little to no role in this ecosystem as vegetation is generally too sparse to carry fire. Normal climate conditions are warm and arid (6-10 inches annually) with drought not uncommon. Climatic fluctuations (precipitation cycles) have been speculated to affect plant vigor and recruitment (Landfire 2007a), but this is not likely significant considering the hardiness of these plants and the harshness of the environments (E. Muldavin pers. comm.). Variation in abundance of subshrubs and grasses is likely more related to fine-scale differences in the soil environment then climatic factors (E. Muldavin pers. comm.). Some occurrences may be windswept, but these are not open/moving dunes with eolian processes. Some occurrences may be gypsum "pavement" or outcrop where much of the gypsum sand has been removed by wind.

Threats/Stressors: Gypsum mining occurs in many southwestern states and is a threat to undisturbed gypsum deposits with gypsophiles. These lands are often considered "badlands" and are subject to disturbance from ORV use, which could cause direct mortality and increase rate of erosion on sites. Additionally, sites occurring on military installations may be impacted by training activities. Possible threats from fragmentation are not known because this is a naturally isolated ecosystem and the isolated nature of the ecosystem has promoted much of local species endemism. At a species level, populations of some local endemics could be threatened by fragmentation from local disturbances such as mining, roads, herbicide drift from agricultural fields, and housing developments that could eliminate or further isolate populations.

This ecosystem occurs on harsh substrates and it is not clear If invasive non-native species can tolerate these conditions enough to threaten occurrences of this ecosystem. It is believed that invasive non-native species have limited impact. Impacts from grazing by livestock from adjacent desert grasslands could impact the few palatable species such as *Sporobolus nealleyi* further reducing plant cover and compacting/disturbing soils.

Conversion of this type has commonly come from gypsum mining and other major disturbances such as road building, buried pipelines, and transmission lines. Common stressors and threats include gypsum mining and fragmentation and disturbance from roads, ORV or other mechanical disturbance that can increase the rate of erosion on this highly erodible substrate. Potential climate change effects will likely be minimal on this substrate-driven ecosystem that is adapted to hot, droughty conditions.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from mining or some other major disturbance that could remove gypsum substrate and its characteristic biota, locally. High-severity environmental degradation appears where occurrences tend to be small (<1 acres) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in significant soil compaction and sheet and rill erosion. Sites may be highly fragmented with roads. Impacts from gypsum mining are extensive and restoration potential is low. Moderate-severity environmental degradation appears where occurrences are moderate (1-10 acres) in size and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Sites may be fragmented with roads or development. Impacts from gypsum mining are limited and restoration potential is moderate.

High-severity disruption appears where occurrences have low cover of gypsophilous species (<1%). Characteristic birds, mammals, reptiles, and insect species are not present at expected abundances. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low. This ecosystem occurs on harsh substrates and it is not clear If invasive non-native species can tolerate these conditions enough to threaten stands of this ecosystem. Moderate-severity disruption appears where occurrences have moderate cover of gypsophilous species (2-10% cover). Characteristic birds, mammals, reptiles, and insect species are not present at expected abundances or the ratio of species shows an imbalance of predator to prey populations. Alteration of vegetation structure and biotic processes is extensive and restoration potential is moderate.

CES302.061 Chihuahuan Loamy Plains Desert Grassland

CES302.061 CLASSIFICATION

Concept Summary: This ecological system occurs in the northern Chihuahuan Desert and extends into limited areas of the southern Great Plains on alluvial flats, loamy plains, and basins sometimes extending up into lower piedmont slopes. Although there is some localized topography with hills and bluffs, sites are typically flat or gently sloping to moderately steep and may be somewhat mesic if they receive runoff from adjacent areas, but these are not wetlands or mesic, bottomland grassland. Soils are non-saline, finer textured loams or clay loam. Vegetation is characterized by perennial grasses and is typically dominated by *Pleuraphis mutica* or with *Bouteloua eriopoda* codominant (more historically) or *Bouteloua gracilis*. In degraded stands, *Scleropogon brevifolius, Dasyochloa pulchella*, or *Aristida* spp. may codominate. *Pleuraphis jamesii* may become important in northern stands and *Bouteloua gracilis* in the Great Plains and on degraded stands. If present, mesic graminoids such as *Pascopyrum smithii, Panicum obtusum, Sporobolus airoides*, and *Sporobolus wrightii* typically have low cover and are restricted to drainages and moist depressions (inclusions). Scattered shrubs such as *Ephedra torreyana, Flourensia cernua, Gutierrezia sarothrae, Larrea tridentata, Cylindropuntia imbricata, Prosopis glandulosa*, and *Yucca* spp. may be present, especially on degraded sites.

Distribution: This grassland system is found from the northern to central Chihuahuan Desert and extends across the Trans-Pecos and into areas of the southwestern Great Plains. It extends from western Texas across New Mexico and into southeastern Arizona. Stands are described from Jornada del Muerto Basin, Marfa grasslands and Marathon Basin, south to central Chihuahua and Coahuila, Mexico.

Description Author: K.A. Schulz, L. Elliott and J. Teague

CES302.061 CONCEPTUAL MODEL

Environment: These upland grasslands occur at approximately 1150-2320 m (3500-7610 feet) elevation and are found on various sedimentary and igneous substrates, including alluvial flats, loamy plains, and desert basins sometimes extending up into lower piedmont slopes including mesatops. Sites are typically flat or gently sloping so precipitation does not run off and may be somewhat mesic if they receive runoff from adjacent areas, but these are not wetlands or bottomland grasslands described in ~Chihuahuan-

Sonoran Desert Bottomland and Swale Grassland (CES302.746)$$. Annual precipitation is usually from 20-40 cm (7.9-15.7 inches). Soils are non-saline, finer-textured loams or clay loam that are often derived from sedimentary parent materials but are quite variable and may include fine-textured soils derived from igneous and metamorphic rocks. These grasslands can occur on a variety of aspects and slopes ranging from flat to moderately steep. When they occur near foothill grasslands, they will be at lower elevations (Landfire 2007a). In Texas, this system occurs primarily on Quaternary alluvium but is also found on other formations at higher elevations of mountain foothills. Two somewhat distinct areas are loams of the intermountain basins, and foothill grasslands over shallow soils at the basin edges. The foothill grasslands often occupy Shallow Ecological Sites over Perdiz Conglomerate, but may also occur on gravelly sites.

Key Processes and Interactions: Historic fire frequency in this ecosystem is not known, but is likely less frequent than other denser desert grasslands because of less fuel in this typically open grassland ecosystem (Humphrey 1963). The effects of burning tobosa-dominated grasslands is variable depending upon soil moisture and plant phenology at the time of the fire, precipitation in the months following the fire, and site characteristics that influence soil moisture availability, and fire intensity based on research in the Great Plains (Innes 2012). However, the dominant grass *Pleuraphis mutica* is likely to survive most fires and can sprout from rhizomes and grow quickly after top-kill by fire (Britton and Steuter 1983).

These grasslands are prone to flooding during high precipitation events because of slow infiltration. This may result in overland flow and erosion of topsoil and some short-term loss of vegetative cover. Landfire (2007a) modeled this system and predicted that during a >500-year flooding event in a swale or stream channel, sites could downcut, thus lowering the water table, and favor woody species in an altered state. Drought cycles likely resulted in a reduction in vegetative cover and production of these sites (Landfire 2007a). Annual growth of woody vegetation depends on annual rainfall; drought negatively affected woody species. Cyclic drought impacts vegetation growth two to three years out of every 10 years, and vegetation-killing drought has a mean return interval of 100 years (Landfire 2007a).

Some grasslands with deep argillic horizons in the San Rafael valley in Arizona and Animas valley in New Mexico have not shown shrub or tree encroachment and/or conversion in the absence of fire or presence of livestock grazing (McAuliffe 1995, Muldavin et al. 2012c). These deep-soil systems have maintained open grassland characteristics despite fire suppression, drought, and livestock grazing. However, there are other valley bottom areas that once supported grasslands, such as the San Simon valley, that have been converted to shrublands due to soil erosion. It is unclear exactly what mechanisms are responsible for the resilience seen in some areas and not in others. McAuliffe (1995) highlighted research on the Santa Rita Experimental Range in Arizona that shows sites of the mid-Pleistocene fan remnants with strongly developed argillic horizons that have not been significantly invaded by deep-rooted shrubs when compared to nearby younger substrates with weakly developed or absent argillic horizons. McAuliffe (1995) suggested these impermeable argillic layers restrict deep percolation of soil-water and may favor the shallower-rooted grasses like tobosa. These soil - water - vegetation relationships may apply to these grasslands in the Chihuahuan Desert.

Threats/Stressors: These native semi-desert grasslands are a dominant grassland type within this ecoregion and range from open to moderately dense grasslands sometimes with low-shrub canopy cover (less than 10% cover). Over time without fire or other disturbance, stands become dominated by woody vegetation and convert to shrublands or woodlands (Gori and Enquist 2003). Conversion to juniper woodlands or mesquite shrublands is common when trees or mesquite exceed 15% cover (Gori and Enquist 2003). Gori and Enquist (2003) found after grassland conversion to shrubland there is a loss of perennial grasses and increases of bare ground. If not protected by surface rock, topsoil erosion can occur changing the site to be less suitable for grass recolonization (McAuliffe 1995).

Hydrological alterations also occurred in many semi-desert grasslands during early Anglo-American settlement time with a period of arroyo formation from 1865 to 1915 (Cooke and Reeves 1976). During this time many broad valley bottom drainages were incised, lowering water tables. This resulted in changes to more xeric vegetation because of decreased water availability, as well as increased sediment movement, altered hydrologic relationships, and loss of productive land (Cooke and Reeves 1976). There is debate of causes of these hydrologic changes. Cooke and Reeves (1976) found strong evidence that arroyo formation in this ecoregion was initiated by building ditches, canals, roads and embankments along channels that altered valley floor hydrology.

The introduction of invasive non-native, perennial grasses *Eragrostis lehmanniana* and *Eragrostis curvula* has greatly impacted many semi-desert grasslands in this ecoregion (Cable 1971, Anable et al. 1992, Gori and Enquist 2003). Cable (1971) and Anable et al. (1992) found that *Eragrostis lehmanniana* is a particularly aggressive invader and alters ecosystem processes, vegetation composition, and species diversity.

Conversion of this type has commonly come from overgrazing by livestock and drought. Fire suppression may have contributed to succession and conversion to shrublands, desert scrub and woodlands especially from oak, pinyon or juniper tree invasion (Gori and Enquist 2003). This grassland has also converted to invasive non-native, perennial forage grasses *Eragrostis lehmanniana* and *Eragrostis curvula* (Cable 1971, Anable et al. 1992, Gori and Enquist 2003).

Common stressors and threats include fragmentation from housing and water developments, altered fire regime from direct fire suppression and indirect fire suppression from livestock grazing and fragmentation, introduction of invasive non-native species, and overgrazing by livestock which can lead to severe soil compaction and reduce vegetation cover exposing soils to erosion of topsoil, especially if soil surface does not significant rock cover. Some of these sites are impacted by head-cutting of drainages that decreased functionality of systems. Potential climate change effects could include a reduction in the current extent of the ecosystem

and conversion to desert scrub or expanding woodlands, if climate change has the predicted effect of less effective moisture with increasing mean temperature (TNC 2013).
Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<1000 acres) with evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in significant soil compaction and sheet and rill erosion. Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval well beyond 2.5 to 10 years resulting in a significant increase in shrub cover (>35%) and/or tree cover (>15%) (oak, juniper or mesquite) causing a reduction of perennial grass cover (Gori and Enquist 2003). Sites may be highly fragmented with roads. Alteration of abiotic processes is extensive and restoration potential is low or development. Moderate-severity environmental degradation appears where occurrences are moderate (1000-5000 acres) in size and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval beyond 2.5 to 10 years resulting in an increase in shrub cover (10-35%) and/or tree cover (5-15%) (oak, juniper and mesquite) (Gori and Enquist 2003). Sites may be fragmented with roads or development.

High-severity disruption appears where occurrences have low cover of native grassland species (<10% cover and <20% relative cover). There is typically significant cover of shrubs (>35%) and juniper trees and mesquite (>15%) because of fire suppression (Gori and Enquist 2003). Invasive non-native species may be abundant (>10% cover). Other non-native species dominate the herbaceous layer. Connectivity is severely hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Characteristic birds, mammals, reptiles, and insects are not present at expected abundances or the ratio of species shows an imbalance of predator to prey populations. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low. Moderate-severity disruption appears where occurrences have moderate cover of native grassland species (>10% cover and >20% relative cover). There is often significant shrub cover (10-35%) and/or tree cover (5-15%) (oak, juniper or mesquite) because of fire suppression (Gori and Enquist 2003). Non-native invasive species are present, but still controllable. Species composition has shifted from codominance of late-seral, palatable grasses such as *Bouteloua gracilis*, and *Bouteloua eriopoda, Muhlenbergia setifolia* to more early-seral/grazing-tolerant/low-palatability grass species (grazing-increasers) such as *Aristida* spp., *Dasyochloa pulchella (= Erioneuron pulchellum), Pleuraphis mutica, Scleropogon brevifolius*; and shrubs *Flourensia cernua, Gutierrezia sarothrae, Heterotheca villosa, Larrea tridentata*, and *Prosopis glandulosa*. Connectivity is moderately hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes from occurring, and reduce the natural movement of some animal and plant populations. Characteristic birds, mammals, reptiles, and insects are not present at expected abundances or the ratio of species shows an imbalance of predator to prey populations. Alteration of vegetation structure and biotic processes is significant; however, restoration potential is moderate.

CES302.736 Chihuahuan Sandy Plains Semi-Desert Grassland

CES302.736 CLASSIFICATION

Concept Summary: This ecological system occurs across the Chihuahuan Desert and extends into the southern Great Plains where soils have a high sand content. These dry grasslands or steppe are found on sandy plains and sandy mesatops. The graminoid layer is typically dominated or codominated by *Bouteloua eriopoda* and *Sporobolus flexuosus*. Other common species are *Aristida purpurea, Bouteloua gracilis, Hesperostipa neomexicana* (minor), *Muhlenbergia arenicola, Pleuraphis jamesii, Sporobolus airoides, Sporobolus contractus*, and *Sporobolus cryptandrus*. Typically, there are scattered desert shrubs and stem succulents present, such as *Ephedra torreyana, Ephedra trifurca, Larrea tridentata, Cylindropuntia imbricata, Prosopis glandulosa, Yucca baccata, Yucca elata, Yucca campestris*, and *Yucca torreyi*, that are characteristic of the Chihuahuan Desert. The widespread shrub *Artemisia filifolia* is also frequently present along with *Atriplex canescens*, especially in the northern extent. In Texas, non-native species *Eragrostis lehmanniana* and *Eragrostis barrelieri* are frequently found in this system.

Description Author: K.A. Schulz

CES302.736 CONCEPTUAL MODEL

Environment: This grassland or steppe system occurs on sandy, gently sloping, undulating piedmont slopes or plains at elevations ranging from 1065-1525 m (3500-5000 feet). Mean annual precipitation ranges from 20-27 cm (8-10.5 inches), although rainfall is highly variable ranging from 5-50 cm (2-20 inches). Half of the precipitation or more typically falls during summer monsoonal events. Annual frost-free season exceeds 200 days. Spring southwesterly winds are an important factor for soil/sand distribution (Landfire

2007a). Historically the grassland type was widespread in the northern Chihuahuan Desert occupying sandy sites and dominated by *Bouteloua eriopoda* and other grasses, especially *Sporobolus flexuosus* and *Sporobolus cryptandrus*. Natural spatial variation in the vegetation of this ecological system may be governed by slight variations in soil texture. For example, dropseeds may dominate on loamy sands. Variation in the depth to a restrictive horizon, such as caliche, may also drive variation in grass cover (Landfire 2007a). Frequently, mesquite shrublands have invaded former black grama grassland sites, including the development of coppice dunes (Landfire 2007a). In Texas, this system occurs on eolian sands, sometimes as a thin veneer over surrounding formations, such as caliche, and sandstone. Soils are sandy, loamy sands, and shallow sandy loams.

Key Processes and Interactions: Wind is an important disturbance agent in this grassland system. The grassland is highly sensitive to grazing and frequent drought. Fire is relatively infrequent, but can result in a significant change of dominant vegetation (Landfire 2007a). The role of fire in New Mexico's black grama-dominated grasslands is unclear, as studies of historical records do not document fires in these grasslands (Wright 1960, Buffington and Herbal 1965). However, in contrast to other desert grasslands, fire has been shown to decrease black grama cover (Buffington and Herbel 1965, Drewa and Havstad 2000). Several other New Mexico studies have shown that black grama decreases with other disturbances, such as drought, livestock grazing, and clipping, recovering slowly, if at all, after such events (Buffington and Herbel 1965, Gibbens and Beck 1988, Gosz and Gosz 1996, Whitford et al. 1999, Drewa and Havstad 2000, Gibbens et al. 2005). While drought was a conflicting factor in many of these studies, it is important to note that studies in Arizona were also conducted during times of drought and resulted in longer recovery times, not a lack of recovery in perennial grasses (Schussman 2006a).

Bouteloua eriopoda is a key plant due to its dominance under pristine conditions, its high forage value and its consequent sensitivity to grazing. Shifts away from black grama dominance are thought to be due to overgrazing and/or multi-year periods of summer or spring drought, or due to the introduction of *Prosopis glandulosa* seeds with or without grazing. With continuous heavy grazing, the proportional representation of black grama declines because it is preferred by cattle over species of *Sporobolus, Aristida*, and *Gutierrezia* (Paulsen and Ares 1962). *Sporobolus* spp. are more palatable than *Aristida* spp., so dropseeds may also decline relative to threeawns and *Gutierrezia* spp. Under climatic conditions that are not conducive to black grama reproduction, or due to the loss of components of the soil biota, demographic limitations may lead to persistent absence of black grama, even without shrub invasion. Shrub invasion is, however, very common. Loss of soil stability and/or a reduction in black grama cover may permit either the survival or establishment of mesquite seedlings due to reduced competition or fire frequency. These grasslands have been shown to trend towards shrublands over the last 100 years (Buffington and Herbel 1965, Gibbens et al. 2005). Subsequent grazing by livestock and native herbivores, competition from shrubs, erosion, and concentration of nutrients under adult shrubs eventually lead to persistent reductions of grass cover and mesquite-dominated coppice dunes with bare or snakeweed-dominated interdunal areas. A substantial number of studies document states and potential causes of transitions. There are multiple competing and complementary explanations for individual transitions that have not been formally tested. If the operation of these mechanisms is case-contingent, it may be especially problematic to define the causes of transitions quantitatively (e.g., a threshold cover of black grama). Nonetheless, careful monitoring of black grama health should be a key feature of management. Overall, the high palatability of black grama during times of year when most other species are less palatable, coupled with the limited capacity of this grass to regenerate under current climatic conditions (Neilson 1986), leads to a relatively high probability of transition with poor range management.

As degradation continues, grasses are replaced by shrubs. Current species dominance is sand-sage and broom dalea in the northern extent and mesquite and broom snakeweed in the southern extent of these grasslands. A significant proportion of the extent of these grasslands have been converted to dune shrubland with mesquite dominance and soil redistribution by wind erosion in the southern portion. There is a lack of research regarding thresholds in response to disturbance and restoration techniques (Landfire 2007a).

Threats/Stressors: Conversion of this type has commonly come with overgrazing by livestock and drought that has allowed succession and conversion to desert scrub dominated by mesquite and sometimes creosotebush (Gori and Enquist 2003). This grassland also has been invaded by non-native perennial forage grasses *Eragrostis lehmanniana* and *Eragrostis curvula*, particularly in the eastern portion of its range (Cable 1971, Anable et al. 1992, Gori and Enquist 2003). Common stressors and threats include fragmentation from housing and water developments, drought, altered fire regime from fire suppression and indirect fire suppression from livestock grazing and fragmentation, introduction of invasive non-native species, and overgrazing by livestock which can lead to severe soil compaction and reduce vegetation cover exposing soils to erosion of topsoil, especially if soil surface does not contain significant rock cover. Potential climate change effects could include a reduction in the current extent of the ecosystem and conversion to desert scrub, if climate change has the predicted effect of less effective moisture with increasing mean temperature (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing especially during drought where perennial plant cover is reduced enough to allow removal of topsoil by wind erosion and invasion by shrubs such as mesquite and creosotebush. Additionally, invasive non-native herbaceous species such as *Eragrostis lehmanniana* and *Eragrostis curvula* can become established and outcompete and replace the dominant native perennial grass species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<100 acres) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in significant soil compaction and wind erosion from heavy grazing during drought. Sites may be highly fragmented with roads. Alteration of abiotic processes is extensive and restoration potential is low or development. Moderate-severity environmental degradation appears where occurrences are moderate (500-1000 acres) in size and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and wind erosion from heavy grazing during drought. Sites may be fragmented with roads or development.

High-severity disruption appears where occurrences have low cover of native grassland species. There is typically significant cover of mesquite (>15%) or other shrubs (>35%). Invasive non-native species may be abundant (>10% cover). Other non-native species dominate the herbaceous layer. Connectivity is severely hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes from occurring and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Characteristic birds, mammals, reptiles, and insects species are not present at expected abundances or the ratio of species shows an imbalance of predator to prey populations. Alteration of vegetation structure and biotic processes is extensive and restoration potential is low. Moderate-severity disruption appears where occurrences have moderate cover of native grassland species. There is often significant mesquite cover (5-15 %) or other shrub cover (10-35%). Non-native invasive species are present but still controllable. Species composition has shifted from dominance of late-seral, palatable midgrasses such as *Achnatherum hymenoides, Bouteloua eriopoda, Sporobolus cryptandrus*, and *Sporobolus flexuosus* to more early-seral species (grazing-increasers) such as *Aristida* spp., *Dasyochloa pulchella (= Erioneuron pulchellum), Gutierrezia sarothrae, Heterotheca villosa, Muhlenbergia arenicola*, and *Scleropogon brevifolius*. Connectivity is moderately hampered by fragmentation from roads, housing and water developments, and/or agriculture that severely restrict or prevent natural ecological processes such as fire from occurring, and reduce the natural movement of some animal and plant populations. Characteristic birds, mammals, reptiles, and insects are not present at expected abundances or the ratio of species shows an imbalance of predator to prey populations. Alteration of vegetation structure and biotic processes is significant however restoration potential is moderate.

CES302.746 Chihuahuan-Sonoran Desert Bottomland and Swale Grassland

CES302.746 CLASSIFICATION

Concept Summary: This ecological system is named based on the regions (Chihuahuan and Sonoran deserts) where it is best developed and occupies significant areas, however, it does occur well outside these regions, at least as far north and east as the Rolling Plains of Texas. The system occurs in relatively small depressions or swales and along drainages throughout the northern and central Chihuahuan Desert and adjacent Sky Islands and Sonoran Desert, as well as limited areas of the southern Great Plains on broad mesas, plains and valley bottoms that receive runoff from adjacent areas. Occupying low topographic positions, these sites generally have deep, fine-textured soils that are neutral to slightly or moderately saline/alkaline. During summer rainfall events, ponding is common. Vegetation is typically dominated by *Sporobolus airoides, Sporobolus wrightii, Pleuraphis mutica* (tobosa swales), or other mesic graminoids such as *Pascopyrum smithii* or *Panicum obtusum*. With tobosa swales, sand-adapted species such as *Yucca elata* may grow at the swale's edge in the deep sandy alluvium that is deposited there from upland slopes. *Sporobolus airoides* and *Sporobolus wrightii* are more common in alkaline soils and along drainages. Other grass species may be present, but these mesic species are diagnostic. Scattered shrubs such as *Atriplex canescens, Prosopis glandulosa, Ericameria nauseosa, Fallugia paradoxa, Krascheninnikovia lanata*, or *Rhus microphylla* may be present.

Description Author: K.A. Schulz, M. Pyne and L. Elliott

CES302.746 CONCEPTUAL MODEL

Environment: This ecological system occurs in relatively small depressions or swales and along drainages on broad mesas, plains and valley bottoms that receive runoff from adjacent areas. These sites occupy low topographic positions and generally have deep, fine-textured soils that are neutral to slightly or moderately saline/alkaline. The system typically occurs in local topographic lows that may be associated with drainages, or may represent swales or basins, but typically receives run-off from the surrounding landscape. Soils are generally clayey, and in some cases the shrink-swell characteristics of the soil may limit the development of woody species. Stands of the system typically occur on Quaternary alluvium, but may be local in nature and mapped within various geological formations. It is generally found on local topographic lows that may be associated with a drainage or may occur as basins or swales. Soils are typically tight ones, and Clay Flat Ecological Sites are typical.

Key Processes and Interactions: [from M087] During the last century, the area occupied by this desert grassland and steppe decreased through conversion of desert grasslands as a result of drought, overgrazing and *Prosopis glandulosa* seed dispersion by livestock, and/or decreases in fire frequency (Buffington and Herbel 1965, Brown and Archer 1987). It is believed that mesquite formerly occurred in relatively minor amounts and was largely confined to drainages until cattle distributed seed upland into desert grasslands (Brown and Archer 1987, 1989). Shrublands dominated by *Prosopis* spp. have replaced large areas of desert grasslands, especially those formerly dominated by *Bouteloua eriopoda*, in Trans-Pecos Texas, southern New Mexico and southeastern Arizona (York and Dick-Peddie 1969, Hennessy et al. 1983). Studies on the Jornada Experimental Range suggest that combinations of drought, overgrazing by livestock, wind and water erosion, seed dispersal by livestock, fire suppression, shifting dunes, and changes in the seasonal distribution of precipitation have caused this recent, dramatic shift in vegetation physiognomy (Buffington and Herbel 1965, Herbel et al. 1972, Humphrey 1974, McLaughlin and Bowers 1982, Gibbens et al. 1983, Hennessy et al. 1983, Schlesinger et al. 1990, McPherson 1995).

Impermeable caliche and argillic horizons are common on these sites. These layers restrict deep percolation of soil water and may favor the shallower rooted grasses over more deeply rooted shrubs such as *Larrea tridentata* and *Prosopis* spp. (McAuliffe 1995). *Pleuraphis mutica* is relatively tolerant of livestock grazing. In west-central Arizona, livestock have nearly eliminated all native grasses except *Pleuraphis mutica* from semi-desert grassland (Brown 1982a). Stands codominated by *Scleropogon brevifolius* are characteristic of sites with past heavy grazing by livestock (Whitfield and Anderson 1938).

In gypsophilous grassland *Sporobolus nealleyi* is dominant with *Tiquilia hispidissima* and *Opuntia polyacantha* on crusted gypsum ridges, but not on unstable gypsum dunes (Burgess and Northington 1977). The eolian processes and sand substrate on gypsum dunes may be as important ecologically as the chemical properties of the gypsum parent material as seen by presence of sand-loving plant species such as *Achnatherum hymenoides, Andropogon hallii, Artemisia filifolia, Muhlenbergia pungens*, and *Psorothamnus scoparius* on gypsum dunes.

Threats/Stressors: [from M087] These native mixed semi-desert grasslands are the dominant grassland type and range from open grasslands with low shrub canopy cover (less than 10% cover) to denser grassland with higher shrub and succulent cover. Over time without fire or other disturbance, stands become dominated by woody vegetation and convert to shrublands or woodlands (Gori and Enquist 2003). Conversion to juniper woodlands or mesquite shrublands is common when trees or mesquite exceed 15% cover (Gori and Enquist 2003). These grasslands were historically maintained as open grasslands with low shrub cover by fire-return intervals of 2.5 to 10 years (Wright 1980, Robinett 1994, McPherson 1995, Brown and Archer 1999). Both drought and livestock grazing interact with grass cover and fire-return intervals can affect the rate of shrub increase (Wright 1980, Robinett 1994, McPherson 1995, Brown and Archer 1999). Gori and Enquist (2003) found that after grassland conversion to shrubland there is a loss of perennial grasses and increases of bare ground. If not protected by surface rock, topsoil erosion can occur changing the site to be less suitable for grass recolonization (McAuliffe 1995).

Hydrological alterations also occurred in many semi-desert grasslands during early Anglo-American settlement time with a period of arroyo formation from 1865 to 1915 (Cooke and Reeves 1976). During this time many broad valley bottom drainages were incised, lowering water tables. This resulted in changes to more xeric vegetation because of decreased water availability, as well as increased sediment movement, altered hydrologic relationships, and loss of productive land (Cooke and Reeves 1976). Although there is debate of causes of these hydrologic changes (arroyo formation), Cooke and Reeves (1976) found strong evidence that arroyo formation was initiated by building ditches, canals, roads and embankments along channels that altered valley floor hydrology.

The introduction of the invasive non-native, perennial grasses *Eragrostis lehmanniana* and *Eragrostis curvula* has greatly impacted many semi-desert grasslands in this ecoregion (Cable 1971, Anable et al. 1992, Gori and Enquist 2003). Anable et al. (1992) and Cable (1971) found *Eragrostis lehmanniana* is a particularly aggressive invader and alters ecosystem processes, vegetation composition, and species diversity.

Conversion of this type has commonly comes from urban and exurban development near cities such as Sierra Vista, Arizona, altered hydrological regimes (water developments/reservoirs) (Cooke and Reeves 1976), and irrigated agriculture especially hay meadows dominated by non-native forage grasses. Fire suppression has allowed succession and conversion to shrublands, desert scrub and woodlands especially from oak, pinyon or juniper tree invasion (Gori and Enquist 2003). This grassland has also converted to invasive non-native, perennial forage grasses *Eragrostis lehmanniana* and *Eragrostis curvula* (Cable 1971, Anable et al. 1992, Gori and Enquist 2003).

Common and threats include fragmentation from housing and water developments, altered fire regime from fire suppression and indirect fire suppression from livestock grazing and fragmentation, introduction of invasive non-native species, and overgrazing by livestock which can lead to severe soil compaction and reduce vegetation cover exposing soils to erosion of topsoil, especially if soil surface does not significant rock cover. Potential climate change effects could include a reduction in the current extent of the ecosystem and conversion to desert scrub, if climate change has the predicted effect of less effective moisture with increasing mean temperature (TNC 2013).

M088. Mojave-Sonoran Semi-Desert Scrub

CES302.744 North American Warm Desert Active and Stabilized Dune

CES302.744 CLASSIFICATION

Concept Summary: This ecological system occurs across the warm deserts of North America and is composed of unvegetated to sparsely vegetated (generally <10% plant cover) active dunes and sandsheets derived from quartz or gypsum sands. Common vegetation includes *Ambrosia dumosa, Abronia villosa, Artemisia filifolia, Atriplex canescens, Eriogonum deserticola, Larrea tridentata, Pleuraphis rigida, Poliomintha* spp., *Prosopis* spp., *Psorothamnus* spp., *Rhus microphylla*, and *Sporobolus flexuosus*. Dune "blowouts" and subsequent stabilization through succession are characteristic processes. Species composition shifts across the range of this system. Texas examples are characterized by species such as *Amsonia tomentosa var. stenophylla, Aristida purpurea, Artemisia filifolia, Bouteloua eriopoda, Croton dioicus, Dimorphocarpa wislizeni, Eriogonum annuum, Helianthus petiolaris, Heliotropium convolvulaceum, Ipomopsis wrightii, Palafoxia sphacelata, Proboscidea althaeifolia, Prosopis glandulosa, Psorothamnus scoparius, Schizachyrium scoparium, Sporobolus contractus, Sporobolus cryptandrus, Sporobolus flexuosus, Sporobolus giganteus, Tripterocalyx carneus*, and *Yucca elata*.

- Trans-Pecos: Sand Dune (11300) [CES302.744.1] (Elliott 2013) **<**

Distribution: This system occurs across the warm deserts of North America. In Texas, it is found on deep sands adjacent to the Salt Basin west of the Guadalupe Mountains, and the Hueco Basin along the Rio Grande.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: K.A. Schulz

CES302.744 CONCEPTUAL MODEL

Environment: This ecological system occurs across the warm deserts of North America and is a mosaic of barren active dunes and partially stabilized and stabilized dunes and sandsheets (vegetated). The climate is arid and hot with low annual precipitation ranging from 25 mm in the Gran Desierto to 60-90 mm at Algodones Dunes, and 205 mm at White Sands National Monument (Felger 1980, Bowers 1982). Summer temperatures usually exceed 40°C. Below freezing temperatures may occur in northern transition zones, but are rare events. The system is defined by the presence of migrating dunes or, where the dunes are entirely anchored or stabilized, evidence that the substrate is eolian and not residual and that the substrate is likely to become actively migrating again with disturbance or increased aridity. There are some smaller, active and partially vegetated dunes along some of the larger washes and on sides of playas and basins (where sand is blown out of a wash or basin and forms dunes) and some larger dunes, but many of the larger dunes were formed during the Pleistocene when sand was blown from large drying lake basins into dunes. Prominent dune systems are the Kelso, Corn Creek and Death Valley dunes in the Mojave Desert; Algodones, Salton Sea, Mohawk, Yuma and the vast Gran Desierto dunes in the Sonoran Desert; and White Sands, Guadalupe Mountains, Samalayuca, Monahans Sandhills and Cuarto Cienegas Dunes in the Chihuahuan Desert. Substrates are usually deep, eolian quartz sand with salinity varying depending on substrate. In Texas, this system occurs on Quaternary eolian sand deposits associated with the Hueco Bolson and the Salt Basin on Sand Hills and Deep Sand Ecological Sites. Several dunefields are composed of pure gypsum in the Chihuahuan Desert. Adjacent systems include various desert scrub systems forming the regional matrix such as ~Sonora-Mojave Creosotebush-White Bursage Desert Scrub (CES302.756)$$, or ~Chihuahuan Creosotebush Desert Scrub (CES302.731)$$, ~North American Warm Desert Playa (CES302.751)$$ and rarely ~North American Warm Desert Cienega (CES302.747)$$ (Cuarto Cienagas wetland). The environmental description is based on several other references, including Powell and Turner (1974), Felger (1980), Reid (1980), Bowers (1982, 1984), MacMahon (1988), Muldavin et al. (1994b), Holland and Keil (1995), Reid et al. (1999), Comer et al. (2003), Thomas et al. (2004), Keeler-Wolf (2007), Schoenherr and Burk (2007), and Sawyer et al. (2009).

Key Processes and Interactions: The major dynamic process is sand movement. Dune "blowouts" and subsequent stabilization through succession are characteristic processes. Plant species that occur in this system are at risk of burial and excavation by the wind and have evolved adaptions such as rapid growth of stems and rapid elongation of radicals (Bowers 1982). Some plants have extensive lateral roots that anchor the plants and stabilize sand. Symbiotic associations with mycorrhizal fungi or nitrogen-fixing bacteria are common with many psammophytic plants (Bowers 1982). Salinity and soil moisture are also driving ecological variables that determine species composition. Rapid infiltration of precipitation in dunes reduces evaporation making dunes relatively mesic environments for plants in desert and semi-desert environments (Bowers 1982).

Threats/Stressors: Invasion by introduced annual vegetation such as *Bromus rubens* and *Salsola tragus* can alter dune processes by stabilizing dunes and depleting soil moisture.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES302.756 Sonora-Mojave Creosotebush-White Bursage Desert Scrub

CES302.756 CLASSIFICATION

Concept Summary: This ecological system forms a desert scrub matrix blanketing broad valleys, lower bajadas, plains and low hills in the Mojave and lower Sonoran deserts. This desert scrub is characterized by a sparse to moderately dense layer (2-50% cover) of xeromorphic microphyllous and broad-leaved shrubs. *Larrea tridentata* and *Ambrosia dumosa* are typically dominants, but many different shrubs, dwarf-shrubs, and cacti may codominate or form typically sparse understories. Associated species may include *Atriplex canescens, Atriplex hymenelytra, Encelia farinosa, Ephedra nevadensis, Fouquieria splendens, Lycium andersonii*, and *Opuntia basilaris*. The herbaceous layer is typically sparse but may have abundant seasonal ephemerals. Herbaceous species such as *Chamaesyce* spp., *Eriogonum inflatum, Dasyochloa pulchella, Aristida* spp., *Cryptantha* spp., *Nama* spp., and *Phacelia* spp. are common. This system can often appear as very open sparse vegetation, with the mostly barren ground surface being the predominant feature.

Description Author: M.S. Reid and K.A. Schulz

CES302.756 CONCEPTUAL MODEL

Environment: *Climate:* Climate is semi-arid to arid with hot summers and warm to cool winters depending on latitude and elevation.

Physiography/landform: This ecological system forms the vegetation matrix in broad valleys, lower bajadas, plains, flats and low hills in the lower Sonoran (Colorado) and Mojave deserts extending into the southeastern Great Basin where it forms the vegetation matrix. Other habitats include minor washes and rills, alluvial fans, and upland slopes. Elevation ranges from -75 to 1200 m. Adjacent ecological systems include ~Mojave Mid-Elevation Mixed Desert Scrub (CES302.742)$$ above and ~Inter-Mountain Basins Playa (CES304.786)$$ below.

Soil/substrate/hydrology: Substrates are typically well-drained, sandy soils derived from colluvium or alluvium, and are often calcareous with a caliche hardpan and/or a pavement surface that is derived from limestone and dolomite (Turner 1982b, Sawyer et al. 2009).

The environmental description is based on several references, including Beatley (1976), Brown (1982a), Turner (1982b), MacMahon (1988), Holland and Keil (1995), Marshall (1995), Reid et al. (1999), Barbour et al. (2007a), Keeler-Wolf (2007), Schoenherr and Burk (2007), and Sawyer et al. (2009).

Key Processes and Interactions: This system covers vast areas of sandy and gravelly alluvial fans and bajadas and rocky slopes in the northwestern Sonoran, Mojave and Colorado deserts (Keeler-Wolf 2007, Sawyer et al. 2009). The dominant shrub, *Larrea tridentata*, is very long-lived, with clones living >10,000 years (Keeler-Wolf 2007) and is very tolerant of drought and high temperatures. It is highly adapted to minimized evapotranspiration both daily and seasonally using stomatal regulation, resinous leaves, and a leaf structure and habit to minimize self-shading and maximize photosynthesis during favorable growing periods (Hamerlynck et al. 2002, Ogle and Reynolds 2002). It may die back during extreme drought but can sprout from the base (Meinzer et al. 1990). It has low recruitment and is slow to re-establish from seed (Keeler-Wolf 2007). *Larrea tridentata* is poorly adapted to fire because of its highly flammable, resinous leaves that burn hot such that fires usually kill the shrub. If the shrub is not killed, it has limited sprouting ability after low-intensity fires (Humphrey 1974, Brown and Minnich 1986, Marshall 1995, Paysen et al. 2000). McLaughlin and Bowers (1982) reported that burned individuals surviving a fire regained their former size in five years.

The main codominant shrub, *Ambrosia dumosa*, is short-lived with a relatively shallow root system, and tends to dominate sandy and rocky sites. It can quickly establish after disturbance or drought (Vasek 1980). Post fire, it also has a limited ability to sprout, but can readily re-establish from seed (Sawyer et al. 2009).

Fire-return interval is long for this open-canopied shrub system with typically discontinuous fuels (Sawyer et al. 2009). Fire occurs under extreme conditions often following a wet year when more fine fuels are available. When it burns, fires are usually of high intensity and moderate severity (Sawyer et al. 2009). Fires in historic creosote-bursage stands were thought to be infrequent except along the margins of the ecological system where it mixed with shrub-steppe containing greater grass fuel loading. Although bunchgrass species can fill in some of the interspaces between shrubs and provide fine fuels, their distribution is generally patchy and rarely provides fuel continuity sufficient to carry fire (Brooks et al. 2007). Periodic drought is occasionally sufficient to thin grass and shrub cover.

LANDFIRE developed a VDDT model for this system which has two classes (LANDFIRE 2007a, BpS 1310870):
A) Early Development 1 Open (15% of type in this stage): Dominant cover is herbaceous, 5-10% canopy cover. Creosotebush scrub is characterized by low cover 5-10%. Little disturbance was considered in class A, except for replacement fire every 300 years on average. Historical condition where invasive annual grasses are absent, the fire-return interval is virtually nonexistent except for areas near the base of mountains experiencing locally higher rainfall and fine fuel buildup from native annuals. After 100 years, class A transitions to class B.

B) Late Development 1 Closed (shrub-dominated - 85% of type in this stage): Greater than 15% shrub cover and 20-40% grass and forb cover; associated with more productive soils. Less fine fuel is associated with this community, therefore the FRIs for replacement fire and mixed-severity fire is 650 years (min-max: 300-1000 years). Wind/weather stress also affected this community on average every 80 years, but did not cause a transition to class A.

LANDFIRE modelers emphasized that pre-settlement fire conditions in warm desert plant communities are not known. However, it is thought that fires in creosotebush scrub were absent to rare events in pre-settlement desert habitats, because fine fuels from winter annual plants were probably sparse, only occurring in large amounts during the spring following exceptionally wet winters (LANDFIRE 2007a).

Threats/Stressors: Primary land uses that alter natural processes of this system directly affect vegetation and soil surface with disturbance and fragmentation, and annual non-native species invasion. Excessive stress to the system occurs through soil disturbance from off-road vehicle (ORV) use, and heavy grazing that alters the species composition by reduction of perennial species and increases native disturbance-driven increaser species as well as non-native annual grasses. Fine fuels from non-native annual grasses, such as *Bromus madritensis, Bromus tectorum*, and *Schismus* spp., currently represents the most important fuel bed component in creosotebush scrub and can substantially increase the fire frequency. In years of good moisture, non-native annual grasses can comprise 66-97% of the total annual biomass in this system (LANDFIRE 2007a, BpS model 1310870). In contrast to native annuals, non-native annual plants produce fine fuel beds that persist throughout the summer and greatly increase the continuity of fuels for much of the fire season (Brooks et al. 2007). Historic year-round livestock grazing has contributed to the deterioration of this system.

Human development has impacted many locations throughout the distribution of this system. High- and low-density urban and industrial developments have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from current and future persistent drought and increased evapotranspiration. Fire in this fire-sensitive ecosystem can also cause ecological collapse especially when fire regimes are altered by increasing fine-fuel accumulations from invasive non-native species such as *Bromus rubens* and *Pennisetum ciliare*.

High-severity environmental degradation appears where occurrences tend to be relatively small (<100 acres) for this matrix type and have evidence of mechanical disturbance from vehicles resulting in obvious soil compaction and sheet and rill erosion. Fire regime is altered due to build up of fine fuels from invasion of non-native grasses and other annuals, especially after a wet winter resulting in loss of fire-sensitive shrubs, especially *Larrea tridentata*, and many other native species.

Moderate-severity environmental degradation appears where occurrences are moderate (100-1000 acres) in size for this matrix type and have evidence of mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Fire regime is altered due to build up of fine fuels from invasion of non-native grasses and other annuals, especially after a wet winter resulting in loss of fire-sensitive shrubs especially *Larrea tridentata* and other native species.

High-severity biotic disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species are abundant (>10% absolute cover to dominant). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring, creating barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are very low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have moderate cover of native species (30-70% relative cover). Invasive non-native species are abundant (3-10% absolute cover). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring creating barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES302.760 Sonoran Granite Outcrop Desert Scrub

CES302.760 CLASSIFICATION

Concept Summary: This ecological system occurs in foothills and mountains of Sonora, Mexico, and extends north across the border into southern Arizona. It is found on low- to mid-elevation granitic outcrops. Tropical genera of *Jatropha* and *Bursera* become codominants in dense to sparse vegetation transitioning upslope from ~Sonoran Paloverde-Mixed Cacti Desert Scrub (CES302.761)$$. Diagnostic species are *Bursera microphylla, Jatropha cuneata, Nolina bigelovii, Parkinsonia microphylla*, or *Rhus kearneyi*.

Related Concepts:

Distribution: Occurs in foothills and mountains of Sonora, Mexico, and extends north across the border into southern Arizona.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES302.760 CONCEPTUAL MODEL

Environment: [from M088] This warm-temperate to subtropical, semi-desert type occurs in the southwestern U.S. and adjacent Sonora and Baja California, Mexico. It forms the vegetation matrix in broad valleys, lower bajadas, plains and low hills in the Mojave, western Sonoran and Lower Colorado deserts. Elevation ranges from -75 to 1200 m. Sites are gentle to moderately sloping. Substrates are typically well-drained, sandy soils derived from colluvium or alluvium, and are often calcareous with a caliche hardpan and/or a pavement surface. Precipitation is markedly unimodal with most falling in the winter months associated with winter storm tracks reaching the desert from the Pacific Ocean. Stands extend north into the broad transition with the Great Basin and at higher elevations on desert mountains above *Larrea tridentata - Ambrosia dumosa* desertscrub and below the lower montane woodlands (700-1800 m elevation) that occurs in the eastern and central Mojave Desert. Stands in the Arizona Sonoran Desert occur on lower slopes of mountains, foothills, hillsides, mesas, upper bajadas, and less commonly in valleys and plains in southern Arizona and extreme southeastern California. Elevations range from 150-1070 m (Shreve and Wiggins 1964). Climate is semi-arid. Summers are hot and winters rarely have freezing temperatures. Freezing winter temperatures limit the elevational and northern extent of these stands. Annual precipitation has bimodal distribution with about half of the rain falling during July to September and a third falling from December to March. Farther west, the proportion of summer precipitation decreases until there is not enough summer moisture to sustain *Carnegiea gigantea* (Barbour and Major 1977). Stands in the subtropical central Gulf of California coast and adjacent portions of the lower Colorado River valley region of the Sonoran Desert occur on gentle to steep, rocky sites. It extends north into the extreme southwestern U.S. and northern Sonora.

At Organ Pipe National Monument, stands typically occur on southerly aspects between 550 and 765 m (1800-2500 feet) elevation. In general, sites have gentle to steep slopes. Sites in northern Baja and southern California occur on isolated maritime coastal bluffs and terraces. Sites in the Vizcaino Region of central Baja California reach several kilometers inland. These areas are frost-free and receive the least annual precipitation of the California and Baja California coastal shrublands, most of which falls in winter. Climate is extremely arid with mean annual precipitation of less than 100 mm, which occurs mostly in the summer-early fall season (monsoon). Precipitation is augmented by summer fog drip. Sonoran stands are extremely arid with mean annual precipitation of less than 100 mm, which occurs mostly in the summer-early fall season (monsoon). Extended drought is common which favors plants with water storage (Turner and Brown 1982). Semi-desert vegetated and sparsely vegetated sandsheets and dunes that are stabilized or partially stabilized are included in this macrogroup. They occur as small to large patches or as a complex of active and stabilized dunes. These sand deposits often form on the leesides of desert playas and basins that serve as a source for the sand. Substrates are variable, but typically shallow, well-drained, rocky or gravelly, coarse-textured soils derived from colluvium or alluvium, except for the sand deposit vegetation included in the macrogroup, which is eolian. Parent material is usually gravelly alluvium and colluvium, derived from basalt and other igneous or metamorphic rocks.

Key Processes and Interactions: [from M088] This type occurs in warm to subtropical semi-arid regions. Most characteristic species are frost-sensitive as only vegetation in the Mojave Desert or at high elevation or in the northern extent of the Sonoran Desert experience frost or extended freezing temperatures.

CES302.035 Sonoran Mid-Elevation Desert Scrub

CES302.035 CLASSIFICATION

Concept Summary: This transitional desert scrub system occurs along the northern edge of the Sonoran Desert in an elevational band along the lower slopes of the Mogollon Rim/Central Highlands region between 750 and 1300 m. Stands occur in the Bradshaw, Hualapai, and Superstition mountains, among other desert ranges, and are found above ~Sonoran Paloverde-Mixed Cacti Desert Scrub (CES302.761)$$ and below ~Mogollon Chaparral (CES302.741)$$. Sites range from a narrow strip on steep slopes to very broad areas such as the Verde Valley. Climate is too dry for chaparral species to be abundant, and freezing temperatures during winter are too frequent and prolonged for many of the frost-sensitive species that are characteristic of ~Sonoran Paloverde-Mixed Cacti Desert Scrub (CES302.761)$$, such as *Carnegiea gigantea, Parkinsonia microphylla, Prosopis* spp., *Olneya tesota, Ferocactus* sp., and *Cylindropuntia bigelovii*. Substrates are generally rocky soils derived from parent materials such as limestone, granitic rocks or rhyolite. The vegetation is typically composed of an open shrub layer of *Larrea tridentata, Ericameria linearifolia*, or *Eriogonum fasciculatum* with taller shrub such as *Canotia holacantha* (limestone or granite) or *Simmondsia chinensis* (rhyolite). The herbaceous layer is generally sparse.

CES302.035 CONCEPTUAL MODEL

Environment: This desert scrub system occurs along the northern edge of the Sonoran Desert and forms an elevational band along the lower slopes of the Mogollon Rim/Central Highlands region between 750 and 1300 m. This system ranges from a narrow strip on steep slopes to very broad areas such as the Verde Valley. Stands also occur in the Bradshaw, Hualapai, and Superstition mountains, among other desert ranges. It is uncommon in the Mojave Desert. This system occurs above ~Sonoran Paloverde-Mixed Cacti Desert

Scrub (CES302.761)$$ and below ~Mogollon Chaparral (CES302.741)$$ where climate is too dry for chaparral species to be abundant, and freezing temperatures during winter are too frequent and prolonged for many of the frost-sensitive species that are characteristic of ~Sonoran Paloverde-Mixed Cacti Desert Scrub (CES302.761)$$. Substrates are generally rocky soils derived from parent materials such as limestone, granitic rocks or rhyolite. The environmental description is based on several references, including Brown (1982), Reid et al. (1999), NatureServe Explorer (2011), and Sawyer et al. (2009).

Key Processes and Interactions: Climate is the main driving ecological variable characterizing this system. Sites are too dry for chaparral species to be abundant, and freezing temperatures during winter are too frequent and prolonged for many of the frost-sensitive species that are characteristic of ~Sonoran Paloverde-Mixed Cacti Desert Scrub (CES302.761)$$, such as *Carnegiea gigantea, Parkinsonia microphylla, Prosopis* spp., *Olneya tesota, Ferocactus* sp., and *Cylindropuntia bigelovii*. Fire appears to be infrequent by the presence of the fire-sensitive dominant shrub *Larrea tridentata*, which is very long-lived with clones living >10,000 years (Keeler-Wolf 2007) and very tolerant of drought and high temperatures with small, evergreen, resinous (highly flammable) leaves reducing evapotranspiration (Hamerlynck et al. 2002). It may die-back during extreme drought, but can sprout from the base (Meinzer et al. 1990). It has low recruitment and is slow to re-establish from seed (Keeler-Wolf 2007).

Simmondsia chinensis is important forage for wildlife species such as mule deer, jackrabbits, desert bighorn sheep (Gentry 1958, Miller and Gaud 1989), and may provide the best browse available within its range (Matthews 1994).

Threats/Stressors: *Simmondsia chinensis* is important forage for livestock such as cattle, goats and sheep (Matthews 1994). Cattle may browse *Simmondsia chinensis* severely enough to prevent any fruit development (Gentry 1958), and often consume it faster than it grows (Brooks 1978). However, in a study in southern Arizona, it appears tolerant of heavy browsing, but moderate browsing was recommended to maintain greater shrub size and forage production (Roundy and Dobrenz 1989).

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES302.761 Sonoran Paloverde-Mixed Cacti Desert Scrub

CES302.761 CLASSIFICATION

Concept Summary: This ecological system occurs on hillsides, mesas and upper bajadas in southern Arizona and extreme southeastern California. The vegetation is characterized by a sparse emergent tree layer of *Carnegiea gigantea* (3-16 m tall) and/or a sparse to moderately dense canopy of xeromorphic deciduous and evergreen tall shrubs codominated by *Parkinsonia microphylla* and *Larrea tridentata*, with *Prosopis* sp., *Olneya tesota*, and *Fouquieria splendens* less prominent. Other common shrubs and dwarf-shrubs include *Acacia greggii, Ambrosia deltoidea, Ambrosia dumosa* (in drier sites), *Calliandra eriophylla, Jatropha cardiophylla, Krameria erecta, Lycium* spp., *Menodora scabra, Simmondsia chinensis*, and many cacti, including *Ferocactus* spp., *Echinocereus* spp., and *Opuntia* spp. (both cholla and prickly-pear). The sparse herbaceous layer is composed of perennial grasses and forbs with annuals seasonally present and occasionally abundant. Outliers of this succulent-dominated ecological system occur as "Cholla Gardens" in transitional areas in the southern and eastern Mojave Desert ecoregion. In this area, the system is characterized by *Cylindropuntia bigelovii, Senna armata*, and other succulents, but it lacks the *Carnegiea gigantea* and *Parkinsonia microphylla* which are typical farther east. *Fouquieria splendens* is present in increasingly diminishing amounts in the system where it occurs further west and north.

Related Concepts:

- Palo Verde - Cactus (507) (Shiflet 1994) =

Distribution: This system is found primarily in southwestern Arizona and western Sonora, Mexico, extending east of the Colorado River in southeastern California where locally there is enough summer precipitation (Whipple Mountains).

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: K.A. Schulz

CES302.761 CONCEPTUAL MODEL

Environment: *Climate:* Climate is arid to semi-arid, continental with mild winters and hot summers (Niering and Lowe 1984). Precipitation has a bimodal distribution with rain in the winter (December-February) and a summer monsoon (July-September). Extended periods of drought or episodes of extreme cold limit this type. Specifically, establishment of dominant species is constrained by decadal or longer periods of below-average precipitation (Turner et al. 1995). Twenty-four hours of below-freezing temperature causes nearly total mortality of the dominant plants. At the southern end of the system's range, competition from more mesic species may constrain distribution of this system (Turner et al. 1995).

Physiography/landform: This succulent desert scrub ecological system occurs on hillsides, mesas and upper bajadas in southern Arizona and extreme southeastern California. Stands are typically found below 1200 m elevation, with rare occurrences up to 1400 m. Landforms range from steep, rocky slopes of desert mountains to upper and lower bajadas extending out on to alluvial flats. With decreasing elevation, the system typically occurs in xeroriparian habitats (edges of channels and washes) and on rock outcrops.

Soil/substrate/hydrology: At higher elevations of bajadas and on steeper surfaces, the system is found on coarse soils that may be associated with poorly developed geomorphic (aka frequently eroded) surfaces; at lower elevations (bottom of bajadas and alluvial fans far from risk of flooding), it is found on very stable geomorphic surfaces. The soils are often underlain by an impervious caliche layer.

Key Processes and Interactions: Complex ecological factors determine the occurrence of characteristic species *Carnegiea gigantea*. Major range-limiting factors are cold winters and dry summers. According to Benson (1982), *Carnegiea gigantea* is killed by extended frosts and does not occur above 1370 m elevation. Its seeds germinate and seedlings and adults grow mostly during the summer monsoon season, so the lack summer moisture further west restricts it from the Mojave Desert. Seedlings require shade from rocks or shrubs called "nurse" plants for seed germination and seedling establishment. The nurse plant protects seedlings from drying out in the intense desert sun, and possibly from frost and predation (Benson 1982, Brown 1982a). As it grows, *Carnegiea gigantea* may inhibit the nurse plant and cause dieback in these shrubs or possibly damage itself significantly (Brown 1982a). In Arizona, north slopes are generally too cold for *Carnegiea gigantea* to germinate; therefore, the best sites are mesic microsites on warm exposures where there is shade and a slight depression to concentrate precipitation. Bats such as lesser long-nosed bat (*Leptonycteris yerbabuenae*) and Mexican long-tongued bat (*Choeronycteris mexicana*) pollinate these large night-blooming cacti. Once the fruit ripens in June, lesser long-nosed bat, white-winged dove (*Zenaida asiatica*), Gila woodpecker (*Melanerpes uropygialis*), and other birds or mammals consume the fleshy red pulp and disperse the seeds, which pass through their guts intact (Pavek 1993b). Seed dispersal beneath nurse plant shrub canopies such as *Parkinsonia microphylla* is primarily done by frugivorous birds and is a major factor in saguaro establishment (McAuliffe 1988, 1993). *Carnegiea gigantea* are vulnerable to fire with smaller individuals (<2-4 m tall) generally killed, especially if large amounts of fuel are present at the plant base, but larger individuals may survive (McLaughlin and Bowers 1982, Pavek 1993b).

This system is not thought to have supported fuel loads to sustain large fires prior to European habitation of the region. Historically, fires in the Sonoran Desert were usually low intensity and uncommon with fire-return interval greater than 250 years because of limited fuel loads (McLaughlin and Bowers 1982, Thomas 1991). Natural fires are associated with dry lightning coincident with monsoonal storms following years when previous winter precipitation was sufficient to create a thick fine-fuel bed of annual plants to carry fire. These fires tend to be patchy due to heavier fuel in microsites, or linear when high winds were associated with convection storms (LANDFIRE 2007a). Replacement fires were very rare or absent (average FRI of 100-1000 years, and perhaps longer) (LANDFIRE 2007a). If they occurred, they did so only during conditions of extreme fire behavior after consecutive years of above-average winter precipitation when necessary fine fuels accumulate. These rare fires - which may or may not have occurred - had tremendous influence on community structure because the dominant overstory plants are extremely susceptible to fires, even those of low intensity (McLaughlin and Bowers 1982, Esque et al. 2004).

LANDFIRE developed a VDDT model for this system which has three classes (LANDFIRE 2007a, BpS 1411090):
A) Early Development 1 Open (5% of type in this stage): Shrub cover is11-50%. Initial post-disturbance community dominated by bursage. Duration 20 years with succession to class B.

B) Mid Development 1 Open (shrub-dominated - 20% of type in this stage): Dominated by bursage and early-seral shrubs such as *Encelia farinosa*. Perennial warm-season grasses are scattered, and dominant succulents and woody plants have established beneath bursage plants. Duration 50-100 years with succession to class C unless infrequent replacement fire or climatic event (drought, frost) returns vegetation to class A. Lethal freeze and drought are listed as Wind/Weather/Stress in model.

C) Late Development 1 Closed (shrub-dominated - 75% of type in this stage): Succulent- and small tree-dominated community. Persists until infrequent replacement fire or climatic event (drought, frost) returns vegetation to class A. Lethal freeze and drought are listed as Wind/Weather/Stress in model.

Prolonged weather-related stress (drought or frost) thinned dominant overstory plants and, in rare cases, led to stand replacement. It is speculated that these events occurred with similar frequency as stand-replacing fires (LANDFIRE 2007a). Cold stress is more common in stands at the northern extent and at higher elevations on desert mountain ranges. Large (presumably old) saguaro plants are also susceptible to windthrow, particularly after rainstorms saturate the soil (LANDFIRE 2007a). LANDFIRE modelers note there is much uncertainty in model parameters, particularly with respect to the return interval of fire, drought and lethal cold temperatures (LANDFIRE 2007a).

Threats/Stressors: Primary land uses that alter natural processes of this system directly affect vegetation and soil surface through disturbance and fragmentation, and annual non-native species invasion. Recent conversion of this type has commonly come from installation of irrigated agriculture near rivers and forage production sites in northern Sonora, Mexico, and southern Arizona where desert is cleared and *Pennisetum ciliare* is planted for forage production.

Altered fire regime from encroachment by invasive non-native grasses such as *Bromus rubens, Schismus barbatus*, and perennial *Pennisetum ciliare* are serious threats and stressors to this ecosystem. Annual invasive non-native grasses such as *Bromus rubens* and *Schismus barbatus* and other annuals can build up enough litter (fine fuels) after a couple wet years to carry fire and cause massive destruction to fire-sensitive desert species. These invasive non-native species have greatly increased the incidence and extent of fires in the Sonoran Desert as these grasses carry fire between shrub interspaces and generally increase fuel loads, fire extent and severity.

Excessive stresses to the system through soil disturbance from off-road vehicle (ORV) use and heavy grazing can alter the composition of perennial species and increase the establishment of native disturbance-increasers and exotic annual grasses. *Pennisetum ciliare*, a fire-adapted perennial forage grass introduced from the African savanna, has gained a foothold in central and southern Arizona and is expanding its range. It can grow in dense stands that crowd out native plants and can fuel devastating fires in the Sonoran Desert. In addition, competition for water can weaken and kill desert plants, even larger trees and cacti, while dense roots and ground shading prevent germination of native seeds. Additional conversion from urban and exurban development near larger metropolitan areas is also significant (LANDFIRE 2007a). Development, including urbanization, suburban, and energy development, continue to convert or degrade existing stands. Losses around large metropolitan areas such as Phoenix and Tucson are significant, especially in northern Phoenix in this mid-elevation ecosystem. Residential development has significantly impacted locations within commuting distance to urban areas (LANDFIRE 2007a). Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Additionally, massive dust from development likely negatively impacts vegetation and habitat quality for wildlife as this dust is a significant health hazard to humans. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Energy development from large-scale solar and, to a lesser extent, wind farms is becoming more common in the desert southwest. These projects span thousands of acres of land. The BLM designated a Solar Energy Zone in California called the "Riverside East Zone" and it contains Sonoran palo verde - mixed cacti scrub. While the BLM and USFWS try to have developers design projects to avoid impacts to the desert dry wash woodland, this results in corridors of washes surrounded by graded and bladed land. Because of these changes in vegetation, landform and soil structure surrounding the corridors, these areas often flood during summer monsoon rains, causing severe erosion and changes their original function in the ecosystem (S. Dashiell pers. comm.). There are some landscape-scale planning processes that attempt to minimize impacts to microphyll woodland: Restoration Design Energy Project in Arizona and BLM's Solar Energy Program and Desert Renewable Energy Conservation Plan (in preparation) (S. Dashiell pers. comm.).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from current and future persistent drought and increased evapo-transpiration. Fire in this fire-sensitive ecosystem can also cause ecological collapse especially when fire regimes are altered by increasing fine fuel accumulations from invasive non-native species such as *Bromus rubens* and *Pennisetum ciliare*.

High-severity environmental degradation appears where occurrences tend to be relatively small (<100 acres) for this matrix type and have evidence of mechanical disturbance from vehicles resulting in obvious soil compaction and sheet and rill erosion. Altered fire regime from build ups of fine fuels from invasion of non-native grasses resulting in loss of shrubs and most native species especially characteristic succulents such as saguaro, cholla, and barrel cacti.

Moderate-severity environmental degradation appears where occurrences are moderate (100-1000 acres) in size for this matrix type and have evidence of mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from build ups of fine fuels from invasion of non-native grasses resulting in reduction of shrubs and all native species especially succulents such as characteristic saguaro, cholla, and barrel cacti.

High-severity biotic disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species are abundant (>10% absolute cover to dominant). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are very low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have moderate cover of native species (30-70% relative cover). Invasive non-native species are abundant (3-10% absolute cover). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

M512. North American Warm Desert Ruderal Scrub & Grassland

CES302.733 Apacherian-Chihuahuan Mesquite Upland Scrub

CES302.733 CLASSIFICATION

Concept Summary: This ecological system often occurs as invasive upland shrublands that are concentrated in the extensive desert grassland in foothills and piedmonts of the Chihuahuan Desert, extending into the Sky Island region to the west. Substrates are typically derived from alluvium, often gravelly without a well-developed argillic or calcic soil horizon that would limit infiltration and storage of winter precipitation in deeper soil layers. *Prosopis* spp. and other deep-rooted shrubs exploit this deep-soil moisture that is unavailable to grasses and cacti. Vegetation is typically dominated by *Prosopis glandulosa* or *Prosopis velutina* and succulents. Other desert scrub species that may codominate include *Acacia neovernicosa, Acacia constricta, Juniperus monosperma*, or *Juniperus coahuilensis*. *Larrea tridentata* is typically absent or has low cover. Grass cover is typically low and composed of desert grasses such as *Dasyochloa pulchella, Muhlenbergia porteri, Muhlenbergia setifolia*, and *Pleuraphis mutica*. During the last century, the area occupied by this system has increased through conversion of desert grasslands as a result of drought, overgrazing by livestock, and/or decreases in fire frequency. It is similar to ~Chihuahuan Mixed Desert and Thornscrub (CES302.734)$$ but is generally found at higher elevations where *Larrea tridentata* and other desert scrub are not codominant. It is also similar to ~Chihuahuan Stabilized Coppice Dune and Sand Flat Scrub (CES302.737)$$ but does not occur on eolian-deposited substrates (sandsheets), although some stands may have evidence of wind erosion and deposition.

- Mesquite (729) (Shiflet 1994) **>**
- Mesquite (western type): 242 (Eyre 1980) **>**

Distribution: This system is found on foothills and piedmont in the Chihuahuan Desert, extending into the Sky Island region and into the lower Mogollon Rim to the west.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: K.A. Schulz

CES302.733 CONCEPTUAL MODEL

Environment: This desert scrub occurs on substrates that are typically derived from alluvium, often gravelly without a well-developed argillic or calcic soil horizon that would limit infiltration and storage of winter precipitation in deeper soil layers. *Prosopis* spp. and other deep-rooted shrubs exploit this deep-soil moisture that is unavailable to grasses and cacti (Burgess 1995).

Key Processes and Interactions: During the last century, the area occupied by this system has increased through conversion of desert grasslands as a result of drought, overgrazing and *Prosopis glandulosa* seed dispersion by livestock, and/or decreases in fire frequency (Buffington and Herbel 1965, Brown and Archer 1987). It is believed that this system formerly occurred in relatively minor amounts and was largely confined to drainages until cattle distributed seed upland from the bosques into desert grasslands (Brown and Archer 1987, 1989). Shrublands dominated by *Prosopis* spp. have replaced large areas of desert grasslands, especially those formerly dominated by *Bouteloua eriopoda*, in Trans Pecos Texas, southern New Mexico and southeastern Arizona (York and Dick-Peddie 1969, Hennessy et al. 1983). Studies on the Jornada Experimental Range suggest that combinations of drought, overgrazing by livestock, wind and water erosion, seed dispersal by livestock, fire suppression, shifting dunes, and changes in the seasonal distribution of precipitation have caused this recent, dramatic shift in vegetation physiognomy (Buffington and Herbel 1965, Herbel et al. 1972, Humphrey 1974, McLaughlin and Bowers 1982, Gibbens et al. 1983, Hennessy et al. 1983, Schlesinger et al. 1990, McPherson 1995).

Historical natural-ignition fires were relatively small, probably 10-15 acres in size. Repeated fire is thought to help maintain a general mosaic pattern between open grassland and shrub-dominated areas (Johnston 1963). Wright et al. (1976) found that *Prosopis glandulosa* is very fire-tolerant when only 3 years old. Most plants resprout after being top-killed by fire. Thus, prior to livestock grazing reducing fire frequency, repeated grassland fires probably maintained lower stature of shrubs and prevented new establishment by killing seedlings.

Drought is a relatively common occurrence in this desert scrub, generally occurring every 10-15 years and lasting 2-3 years with occasional long-term drought periods (10-15 years duration). *Prosopis* spp. and other shrubs have extensive root systems that allow them to exploit deep-soil water that is unavailable to shallower rooted grasses and cacti (Burgess 1995). This strategy works well, especially during drought. However, on sites that have well-developed argillic or calcic soil horizons that limit infiltration and storage of winter moisture in the deeper soil layers, *Prosopis* spp. invasion can be limited to a few, small individuals (McAuliffe 1995). This has implications in plant geography and desert grassland restoration work in the southwestern United States.

M117. North American Warm Semi-Desert Cliff, Scree & Rock Vegetation

CES302.743 North American Warm Desert Badland

CES302.743 CLASSIFICATION

Concept Summary: This ecological system occurs from Arizona to Texas and adjacent Mexico. It is restricted to barren and sparsely vegetated (generally <10% plant cover) substrates typically derived from marine shale or mudstone (badlands and mudhills). The harsh soil properties, high temperatures and evaporation, low precipitation, and high rate of erosion and deposition are driving environmental variables supporting sparse shrubs and dwarf-shrubs, e.g., *Atriplex hymenelytra*, and herbaceous vegetation. These conditions often preclude the development of significant vegetative cover.

Related Concepts:

- Trans-Pecos: Desert Badland (11400) [CES302.743] (Elliott 2012) =

Distribution: This ecological system occurs from Arizona to Texas and adjacent Mexico.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES302.743 CONCEPTUAL MODEL

Environment: This ecological system is restricted to barren and sparsely vegetated substrates typically derived from marine shales or mudstones (badlands and mudhills). The harsh soil properties, such as high salinity and alkalinity, and high rates of erosion and deposition are driving environmental variables that maintain the barren to sparse vegetation character. Substrates are generally shallow, fine-textured silty and clayey soils. In Texas, these sites are highly erosional and occupy rolling landscapes frequently cut by drainages. Adjacent systems include ~Sonora-Mojave Creosotebush-White Bursage Desert Scrub (CES302.756)$$, ~Sonora-Mojave Mixed Salt Desert Scrub (CES302.749)$$, and ~North American Warm Desert Playa (CES302.751)$$. The environmental description is based on several references, including Reid et al. (1999), Comer et al. (2003), Thomas et al. (2004), Sawyer et al. (2009), and NatureServe Explorer (2011).

Key Processes and Interactions: Geomorphic and fluvial processes disturb this system more than fire. Harsh soil properties, such as high salinity and alkalinity, and high rates of erosion and deposition are driving environmental variables supporting the characteristic vegetation pattern (Sawyer et al. 2009). Fire is extremely rare and is only possible after very high winter precipitation produces an abundance of annual vegetation (fine fuels) that can carry a fire. *Atriplex hymenelytra* has low flammability and is fire-hardy, and *Ephedra californica* is adapted to fire and will vigorously sprout from underground rhizomes after top-killed from burning (Sawyer et al. 2009).

Threats/Stressors: Invasion by introduced annuals such as *Brassica tournefortii* and *Bromus rubens* increases the risk of fire (Sawyer et al. 2009).

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds:

CES302.745 North American Warm Desert Bedrock Cliff and Outcrop

CES302.745 CLASSIFICATION

Concept Summary: This ecological system occurs from California to Texas and adjacent Mexico. It is found from subalpine to foothill elevations and includes barren and sparsely vegetated landscapes (generally <10% plant cover) of steep cliff faces, narrow canyons, and smaller rock outcrops of various igneous, sedimentary, and metamorphic bedrock types. Also included are unstable scree and talus slopes that typically occur bellow cliff faces. Species present are diverse and may include *Bursera microphylla, Fouquieria splendens, Nolina bigelovii, Cylindropuntia bigelovii*, and other desert species, especially succulents. Lichens are predominant lifeforms in some areas. May include a variety of desert shrublands less than 2 ha (5 acres) in size from adjacent areas. In the Trans-Pecos of Texas, this system is well-developed on rock faces (some of which are 100s of feet tall with slopes greater than 80%) on massive Cretaceous and Permian limestones, but also occupies igneous and sandstone formations. Vegetation is typically restricted to crevices, although crustose lichens may be well-represented.

Related Concepts:
- Trans-Pecos: Cliff and Outcrop (10100) [CES.302.745.1] (Elliott 2012) =

Distribution: This ecological system occurs from California to Texas and adjacent Mexico.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES302.745 CONCEPTUAL MODEL

Environment: This ecological system occurs across the southwestern U.S. in the Chihuahuan, Sonoran and Mojave deserts. It is restricted to barren and sparsely vegetated sites (generally < 10% plant cover) from smaller rock outcrops in low-elevation desert hills, on cliff faces in canyons including unstable scree and talus slopes, to higher-elevation rock outcrops in the foothill and lower montane zones in desert mountain ranges. Substrates are various igneous, sedimentary, and metamorphic bedrock types. Adjacent systems include ~Chihuahuan Mixed Desert and Thornscrub (CES302.734)$$, ~Sonoran Paloverde-Mixed Cacti Desert Scrub (CES302.761)$$, ~Sonoran Mid-Elevation Desert Scrub (CES302.035)$$, ~Mojave Mid-Elevation Mixed Desert Scrub (CES302.742)$$, and at higher elevation ~Sonora-Mojave Semi-Desert Chaparral (CES302.757)$$ and ~Great Basin Pinyon-Juniper Woodland (CES304.773)$$. The environmental description is based on several references, including Shreve and Wiggins (1964), MacMahon and Wagner (1985), Barbour and Major (1988), MacMahon (1988), Dick-Peddie (1993), Reid et al. (1999), Comer et al. (2003), Thomas et al. (2004), Barbour et al. (2007), Sawyer et al. (2009), and NatureServe Explorer (2011).

Key Processes and Interactions: In this system growing sites are often limited with plants restricted to cracks in rocks where moisture accumulates.

Threats/Stressors: Introduced annuals may invade the limited growing sites and deplete soil moisture from native species.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES302.750 North American Warm Desert Pavement

CES302.750 CLASSIFICATION

Concept Summary: This ecological system occurs throughout much of the warm deserts of North America and is composed of unvegetated to very sparsely vegetated (<2% plant cover) landscapes, typically flat basins where extreme temperature and wind develop ground surfaces of fine to medium gravel coated with "desert varnish." This sparsely vegetated system may surround playas in valley bottoms or near washes and, less commonly, on dissected, eroding alluvial fans. Very low cover of desert scrub species such as *Larrea tridentata* or *Eriogonum fasciculatum* is usually present. However, ephemeral herbaceous species may have high cover in response to seasonal precipitation, including *Chorizanthe rigida, Eriogonum inflatum*, and *Geraea canescens*.

Related Concepts:

- Trans-Pecos: Desert Pavement (11800) [CES302.750] (Elliott 2012) **<**

Distribution: Occurs throughout much of the warm deserts of North America.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES302.750 CONCEPTUAL MODEL

Environment: This ecological system occurs throughout much of the warm deserts of North America on flat basins and lower bajadas. Elevations range from 1600 m to below sea level. Climate is semi-arid to arid with hot summers. Potential for freezing winter temperatures depends on latitude and elevation. Desert precipitation varies greatly from year to year with drought not uncommon. In the Mojave Desert, mean annual precipitation is typically <150 mm falling in the winter months (Barbour and Major 1988). In the Sonoran and Chihuahuan deserts, annual precipitation is 230 mm occurring bi-modally during winter and late-summer monsoons (Barbour and Major 1988). Substrates are typically gravelly alluvium. In the typically flat intermountain basin sites, extreme temperature and wind develop ground surfaces of fine to medium gravel coated with "desert varnish." This sparsely vegetated system may surround playas or be near washes in valley bottoms, and, less commonly, on dissected, eroding alluvial fans. Adjacent systems include ~Sonora-Mojave Creosotebush-White Bursage Desert Scrub (CES302.756)$$, ~Sonora-Mojave Mixed Salt Desert Scrub (CES302.749)$$, and ~North American Warm Desert Playa (CES302.751)$$. The environmental description is based on several references, including Brown (1982a), MacMahon and Wagner (1985), Barbour and Major (1988), MacMahon (1988), Holland

and Keil (1995), Reid et al. (1999), Comer et al. (2003), Thomas et al. (2004), Barbour et al. (2007), Sawyer et al. (2009), and NatureServe Explorer (2011).

Key Processes and Interactions: There are several theories about the formation of desert pavement. The more common theory is that pavements are created by the removal of the fine soil particles by the wind and intermittent rain leaving only the larger fragments behind, forming a pebble pavement (McFadden et al. 1987). This pavement acts as a barrier to reduce further erosion. The pavement also reduces water infiltration which reduces soil moisture and increases runoff and concentration of moisture in drainages. The reduced soil moisture likely contributes to sparse cover of *Larrea tridentata* and other deeper-rooted shrubs (Hamerlynck et al. 2002). Pavement affects the shallower-rooted *Ambrosia dumosa* and annual plants less (Hamerlynck et al. 2002).

Fire is extremely rare and is only possible after very high winter precipitation produces an abundance of annual vegetation (fine fuels) that can carry a fire. Although very long-lived, *Larrea tridentata* shrubs are poorly adapted to fire because of highly flammable, resinous foliage and limited ability to sprout after burning (Sawyer et al. 2009).

Threats/Stressors: Mechanical disturbance of pavement exposes subsurface layers and likely results in increased soil erosion. After extremely wet winters/springs, flushes of introduced annuals such as *Bromus rubens* may increase the risk of fire.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES302.754 North American Warm Desert Volcanic Rockland

CES302.754 CLASSIFICATION

Concept Summary: This ecological system occurs across the warm deserts of North America and is restricted to barren and sparsely vegetated (<10% plant cover) volcanic substrates such as basalt lava (malpais) and tuff. Vegetation is variable and includes a variety of species depending on local environmental conditions, e.g., elevation, age and type of substrate. Typically scattered *Larrea tridentata, Atriplex hymenelytra*, or other desert shrubs are present. In Texas, this system occurs on rocky or boulder-strewn slopes and flats where the rock material is volcanic in origin.

Related Concepts:

- Trans-Pecos: Desert Volcanic Rockland (12100) [CES302.754] (Elliott 2012) =

Distribution: Occurs across the warm deserts of North America.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: L. Elliott and J. Teague

CES302.754 CONCEPTUAL MODEL

Environment: This system occurs on volcanic substrates such as basalt lava (malpais), tuff, and rhyolite. In Texas landforms supporting this system are usually talus slopes, but also relatively level rocky and boulder sites. Soil is generally lacking or reduced to small pockets within the rock matrix.

Key Processes and Interactions: [from M117] These sparsely vegetated plant communities often represent primary succession on parent materials such as bare rock outcrops or disturbance-maintained communities such as scree and talus slopes that are frequently disturbed and constantly re-establishing themselves. Biological soil crusts can improve soil stability and soil fertility, and disturbances such as grazing and non-native species invasion can negatively impact these crusts (Belnap and Eldridge 2003, Belnap et al. 2006).

Threats/Stressors: [from M117] Invasion by introduced annual vegetation such as *Bromus rubens* and *Salsola tragus* can alter dune processes by stabilizing dunes and depleting soil moisture.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

M092. North American Warm-Desert Xeric-Riparian Scrub

CES302.755 North American Warm Desert Wash

CES302.755 CLASSIFICATION

Concept Summary: This ecological system is restricted to intermittently flooded washes or arroyos that dissect bajadas, mesas, plains and basin floors throughout the warm deserts of North America. Although often dry, the intermittent fluvial processes define this system, which are often associated with rapid sheet and gully flow. This system occurs as linear or braided strips within desert scrub-or desert grassland-dominated landscapes. The vegetation of desert washes is quite variable, ranging from sparse and patchy to moderately dense, and typically occurs along the banks, but may occur within the channel. The woody layer is typically intermittent to open and may be dominated by shrubs and small trees such as *Acacia greggii, Brickellia laciniata, Baccharis sarothroides, Chilopsis linearis, Fallugia paradoxa, Hymenoclea salsola, Hymenoclea monogyra, Juglans microcarpa, Olneya tesota, Parkinsonia florida, Prosopis* spp., *Psorothamnus spinosus, Prunus fasciculata, Rhus microphylla, Salazaria mexicana*, or *Sarcobatus vermiculatus*. Common upland shrubs such as *Larrea tridentata* and *Ambrosia dumosa* are often present along the edges of these washes. In Texas, woody species found in and adjacent to these washes include *Acacia greggii, Baccharis salicifolia, Brickellia laciniata, Celtis laevigata var. reticulata, Chilopsis linearis, Dasylirion leiophyllum, Fallugia paradoxa, Fraxinus greggii, Juglans microcarpa, Juglans microcarpa, Leucaena retusa, Prosopis glandulosa, Rhus microphylla*, and *Salix gooddingii*. Taller species may form a sparse canopy over the shorter shrubs. In addition, shrubs from the adjacent upland, such as *Larrea tridentata, Viguiera stenoloba, Flourensia cernua*, and *Juniperus pinchotii* may be commonly encountered.

M130. Tamaulipan Scrub & Grassland

CES301.713 Central Mexican Mixed Desert Scrub

CES301.713 CLASSIFICATION

Concept Summary: Tipo de vegetación dominada fisonómicamente por cactáceas grandes con tallos aplanados o cilíndricos que se desarrollan principalmente en las zonas áridas y semiáridas del centro y norte del país. Algunas especies comunes son: *Opuntia* spp., *Carnegiea gigantea, Pachycereus pringlei, Stenocereus thurberi*. Se incluyen las asociaciones conocidas como Nopaleras, Chollales, Cardonales, Tetecheras, etc.

El Central Mexican Mixed Desert Scrub que se establece en la parte central de Zacatecas y algunas zonas adyacentes de Durango, Aguascalientes, Jalisco, Guanajuato y San Luis Potosí presentan como cubierta vegetal de *Opuntia*, siendo las principales especies dominantes de estas "nopaleras" *Opuntia streptacantha* y *Opuntia leucotricha*.

Esta comunidad se desarrolla preferentemente sobre suelos someros de laderas de cerros de naturaleza volcánica, aunque también desciende a suelos aluviales contiguos. La precipitación media anual varía entre 300 y 600 mm y la temperatura es de 16° a 22°C en promedio anual. En algunas partes de San Luis Potosí y de Guanajuato se le asocia *Myrtillocactus geometrizans* y a veces también *Stenocereus* spp. Por otro lado *Yucca decipiens* puede formar un estrato emergente, mientras que a niveles inferiores conviven muchos arbustos micrófilos, como por ejemplo, especies de *Mimosa, Acacia, Dalea, Prosopis, Rhus, Larrea, Brickelia, Eupatorium, Buddleia, Celtis*, etc.

La altura de este matorral alcanza generalmente de 2 a 4 m, su densidad es variable, pudiendo alcanzar casi 100% de cobertura, y el matorral puede admitir la presencia la numerosa presencia de planta herbáceas.

Generalmente existe ganadería a base de caprinos y bovinos; es igualmente importante la recolección de frutos comestibles, y en el caso de los nopales, de los tallos.

CES301.713 CONCEPTUAL MODEL

Environment: [from M130] This vegetation is found in semi-arid and subtropical southern Texas over a variety of soil depths and textures. Rainfall is highly variable both spatially and temporally and can range from 38 to 76 cm (15-30 inches) annually in a given locality, but all areas are prone to drought and water deficits (Bray 1901, Gilbert 1982, Jahrsdoerfer and Leslie 1988).

Key Processes and Interactions:

Threats/Stressors: [from M130] Threats from development, including overgrazing by livestock, mining, and energy development, continue to convert or degrade existing stands. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Persistent drought may result in loss of key species. Conversion of this type has commonly come from effective brush eradication using mechanical, chemical or prescribed burning method. Common and threats include fragmentation from roads, non-native species invasion (Landfire 2007a), and development, mining, agriculture. Other and threats include overgrazing/browsing by livestock, and possibly loss of pollinators.

According to Climate Wizard (TNC 2013) in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5 degrees F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion.

CES301.714 Central Mexican Submontane Mixed Desert Scrub

CES301.714 CLASSIFICATION

Concept Summary: Comunidad arbustiva a veces muy densa, formado por especies inermes o a veces espinosas, caducifolias por un breve período del año, se desarrolla entre los matorrales áridos y los bosques de Encino y la Selva Baja Caducifolia a altitudes de 1500 a 1700 msnm, principalmente en las laderas bajas de ambas vertientes de la Sierra Madre Oriental, desde Querétaro e Hidalgo hacia el norte, penetrando más allá de la frontera política con los Estados Unidos de Norteamérica.

Para el noreste de México se describe la siguiente comunidad de Central Mexican Submontane Mixed Desert Scrub: la fisonomía de esta comunidad la proporciona el estrato arbustivo superior, cuya altura varía entre 2.5 a 5 m y alcanza una cobertura hasta de un 70%. Lo caracteriza *Helietta parvifolia* (Barreta), rutácea inerme que le da a la vegetación una estructura relativamente uniforme, pues normalmente es la única dominante, aunque en ocasiones *Acacia berlandieri* (Huajillo) es igual de importante. Las plantas prevalecientes del estrato arbustivo medio (0.5 a 2 m de alto) son *Leucophyllum frutescens* y *Acacia rigidula*. Su cobertura varía de 50 a 80%. El estrato inferior, menor a 0.5 m de altura, es diverso tanto en especies como en cobertura; es notable en los claros de la vegetación, donde *Agave lechuguilla, Euphorbia antisyphilitica* (Candelilla) y las gramíneas amacolladas de los géneros *Bouteloua, Tridens* y *Aristida* son los elementos más importantes. El terreno es pedregoso y es común encontrar plantas creciendo sobre rocas.

Este tipo de vegetación se encuentra en laderas, cañadas y partes altas, sean planas o con pendiente, de las mesetas y lomeríos. Crece sobre suelos someros que a veces presentan una capa superficial de hojarasca y son comunes los afloramientos de la roca madre.

Francisco González Medrano en el trabajo denominado Vegetación al Noreste de Tamaulipas cita al Central Mexican Submontane Mixed Desert Scrub como Matorral Alto Subinerme en el cual cita que este tipo de vegetación es muy complejo y variable, ocupando los suelos pedregosos de cerros escarpados y lomeríos con buen drenaje por su inclinación y abundancia de partículas gruesas del suelo. La caracteriza gran número de arbustos a veces subarbóreos, inermes en su gran mayoría, aunque cierto número de especies espinosas se entremezclan con los dominantes. Algunas son caducifolias, pero la mayoría son perennifolias. El elemento característico y dominante de este matorral es *Helietta parvifolia*, asociada con *Gochnatia hypoleuca*. Su límite superior oscila entre 1.800 y 2000 m Crece dentro de una zona con clima BS. La precipitación es inferior a 700 mm anuales, con una temperatura media anual superior a los 23°C.

La dominancia de *Helietta parvifolia* y *Gochnatia hypoleuca* es notoria, forman un matorral denso de 3 a 4 m de altura; aquí se encuentran especies propias del estrato arbustivo del Matorral Espinoso Tamaulipeco con el cual colinda.

Sus principales componentes pueden ser los siguientes: *Helieta parvifolia* (Barreta), *Neopringlea integrifolia* (Corva de gallina), *Cordia boissieri* (Anacahuita), *Havardia pallens (= Pithecellobium pallens)* (Tenaza), *Acacia rigidula* (Gavia), *Gochnatia hypoleuca* (Ocotillo, Olivo), *Karwinskia* spp. (Limoncillo), *Capparis incana* (Vara blanca), *Rhus virens* (Lantrisco), *Flourensia lauriforia, Mimosa leucaeneoides, Mortonia greggii* (Afinador) *Zanthoxylum fagara*, etc.

Su área de distribución ha sido ocupada por la agricultura, ganadería y la explotación forestal.

CES301.538 South Texas Sand Sheet Grassland

CES301.538 CLASSIFICATION

Concept Summary: This system occurs on the ridge-and-swale topography within 100 km of the Texas coast on the Holocene-aged eolian sand deposits of the South Texas Sand Sheet (primarily Kenedy and Brooks counties and extending into adjacent Jim Hogg, Hidalgo, and Willacy counties). While the vegetation of the ridges and swales is somewhat distinct, they are not separated here. In general, ridges are dominated by *Schizachyrium littorale* and a mixture of forbs, and swales are dominated by *Paspalum monostachyum, Andropogon gerardii, Muhlenbergia capillaris*, and *Sorghastrum nutans*. *Paspalum plicatulum* may be important in both environments. In addition to the dominants, common herbaceous components include *Eragrostis* spp., *Acalypha radians, Argythamnia mercurialina var. pilosissima, Chamaecrista flexuosa var. texana, Cnidoscolus texanus, Croton argyranthemus, Dalea phleoides, Froelichia floridana, Galactia canescens, Gaura mckelveyae, Helianthemum georgianum, Monarda fruticulosa (= Monarda punctata var. fruticulosa), Phlox cuspidata, Rhynchosia americana, Stillingia sylvatica*, and *Thelesperma nuecense*. These grasslands occur intermixed with woodlands dominated by *Quercus fusiformis* and/or *Prosopis glandulosa var. glandulosa*.

Related Concepts:

Distribution: This system is endemic to Texas. It is found within 100 km of the coast on the Holocene-aged eolian sand deposits of the South Texas Sand Sheet primarily Kenedy and Brooks counties and extending into adjacent Jim Hogg, Hidalgo, and Willacy counties.

Nations: US

Description Author: J. Teague

CES301.538 CONCEPTUAL MODEL

Environment: This system occurs on deep sands of the Pleistocene-aged Ingleside barrier-strandplain and the Holocene-aged eolian sand deposits of the South Texas Sand Sheet. Topography varies from larger dunes to smaller ridges and swales.

Key Processes and Interactions: Fire, climate, and edaphic factors all likely played a role historically in maintaining a more open structure in this vegetation. Historically, fire likely limited the development of woody cover. Likewise, edaphic conditions limited this system to deep sandy soils. Loss of these natural processes often results in a shift toward a more closed canopy and decrease in native grass cover. Threats to this system include fire suppression, invasive exotics, and damage by vehicles.

CES301.986 Tamaulipan Calcareous Thornscrub

CES301.986 CLASSIFICATION

Concept Summary: This xeric thornscrub ecological system is restricted to limestone and calcareous sandstone hills and caliche substrates such as along the Bordas Scarp in southern Texas and northeastern Mexico. Soils are shallow, alkaline, strongly calcareous and underlain by bedrock or a caliche layer. It has a shorter, more open shrub canopy (usually less than 2 m) when compared to more typical thornscrub growing on more favorable sites. However, shrub cover is generally greater than 70% and often greater than 85%. Dominant species include *Leucophyllum frutescens, Acacia berlandieri*, and *Acacia farnesiana* with many other shrub species that may be locally dominant. The sparse to moderately dense herbaceous layer is dominated by perennial graminoids.

Distribution: Restricted to limestone and calcareous sandstone hills and caliche substrates such as along the Bordas Scarp in southern Texas and northeastern Mexico.
Nations: MX, US
Concept Source: K.A. Schulz
Description Author: J. Teague and L. Elliott

CES301.986 CONCEPTUAL MODEL

Environment: This system is restricted to xeric, rocky hills, rolling or level plateaus, and ridges composed of limestone and calcareous sandstone, as well as caliche substrates such as of the Goliad Formation or Uvalde gravel along the Bordas Scarp in southern Texas and northeastern Mexico. Soils are thin, alkaline, strongly calcareous and underlain by bedrock or a caliche layer. These are Shallow, Shallow Ridge or Gravelly Ridge Ecological Sites.
Key Processes and Interactions: Erosion occurs on these sites, creating gullies, but not causing a shift in the community. Fire played little to no role in this system, though may have spread into the margins of stands during drought and high wind conditions (Landfire 2007a).

This system was modeled by Landfire (2007a) using a single class. Dense shrubland, generally 40-90% cover with sparse cover from emergent overstory species. Little natural disturbance affects this shrubland. Low fine fuel loadings make fire spread minimal except under extreme windy and dry conditions when fire may spread into it from surrounding sites. Species are drought-resistant. However, this system occurs in large patch to matrix scale and marginal fires likely spread little into the interior portions of occurrences.
Threats/Stressors: Threats from development, including overgrazing by livestock, mining, and energy development, continue to convert or degrade existing stands. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Persistent drought may result in loss of key species. Conversion of this type has commonly come from effective brush eradication using mechanical, chemical or prescribed burning method. Common stressors and threats include fragmentation from roads, non-native species invasion (Landfire 2007a), and development, mining, agriculture. Other stressors and threats include overgrazing/browsing by livestock, and possibly loss of pollinators.

According to Climate Wizard in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5°F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion.
Ecosystem Collapse Thresholds: Ecological collapse tends to result from persistent drought and extreme erosion that remove what little soil is left and make it unsuitable for characteristic scrub species *Leucophyllum frutescens, Acacia berlandieri*, and *Acacia farnesiana*.

High-severity environmental degradation appears where occurrences tend to be relatively small (<100 acres) for this large-patch type and have evidence of mechanical disturbance from vehicles resulting in obvious soil compaction and sheet and rill erosion. Moderate-severity environmental degradation appears where occurrences are moderate (100-1000 acres) in size for this large-patch type and have evidence of mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion.

High-severity disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species are abundant (>10% absolute cover to dominant). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are very low when compared to an intact ecosystem. Moderate-severity disruption appears where occurrences have moderate cover of native species (30-70% relative cover). Invasive non-native species are abundant (3-10% absolute cover). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES301.989 Tamaulipan Caliche Grassland

CES301.989 CLASSIFICATION

Concept Summary: This ecological system is restricted to the Loreto Plain in Tamaulipas, Mexico. It occurs on shallow sandy loam soils with a caliche hardpan subhorizon. These small-patch grasslands are less than 40 ha in area and are dominated by perennial grasses often with sparse low shrubs within a mosaic of thornscrub. Dominant grasses may include *Aristida purpurea, Bouteloua hirsuta, Bouteloua radicosa, Cenchrus spinifex, Paspalum setaceum*, and *Tridens muticus*. Perennial forbs may be abundant such as *Boerhavia coccinea, Chamaecrista flexuosa, Heliotropium confertifolium*, or *Rhynchosia americana*. Low shrubs are *Calliandra conferta* and *Krameria ramosissima*.

Related Concepts:

- South Texas: Caliche Grassland (6707) [CES301.989] (Elliott 2011) =

Distribution: This system is restricted to the Loreto Plain in Tamaulipas, Mexico. It may also be present in Texas on the edge of the sandsheet where it passes over the Goliad Formation in northern Hidalgo and Starr counties (Elliott 2011).

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: L. Elliott and K.A. Schulz

CES301.989 CONCEPTUAL MODEL

Environment: This system is described from the vicinity of Loreto in Tamaulipas, Mexico, but the conditions of sand veneer over caliche outcrop may also be present on the edge of the sandsheet where it passes over the Goliad Formation in northern Hidalgo and Starr counties (Elliott 2011). Soils are a reddish sandy loam about 0.3 m in depth or less. These grasslands occur on relatively level sites atop the Goliad Formation. These are areas that have a relatively thin veneer of eolian sand over caliche substrate. Such sites occur on the edge of the South Texas Sand Sheet where it overlies caliche of the Goliad Formation. Soils are shallow sands and sandy loams, sometimes red sandy loams, over caliche substrate. This Tamaulipan ecological system occurs on clay prairies near the Gulf Coast and drier sites further inland. Substrates are fine calcareous clays and clay loam. Occasional fires and root-pruning from montmorillonitic clay limit shrub invasion, if the grassland is not overgrazed. If overgrazed, the land will convert to stable thornscrub dominated by *Prosopis glandulosa* and *Celtis ehrenbergiana*.

Key Processes and Interactions: Occurrences are naturally small with the larger brush-free stands only 50-100 acres in extent. Larger areas occur as mosaics of grassland mixed with brush mottes (Johnston 1963). Fire is a key process that limits invasion by brush (Landfire 2007a). Fire occurs on a frequent 2- to 5-year return interval. The fire regime has frequent replacement fires, both lightning and anthropogenic in origin (Stewart 1951, Lehmann 1965, Drawe 1980, Stewart 2002, Jurney et al. 2004). Fire was dependent on the availability of dry fine fuel sufficient to carry a fire. Both native grazing and wet/dry periods would have dictated whether sufficient dry fine fuels were present to carry a burn and strongly influenced the probable size of burns. Drought may shift composition and cause minor changes in herbaceous cover (Landfire 2007a).

Threats/Stressors: The keys threats are conversion to agriculture and brush encroachment. Brush invasion is caused by altered fire regime from active fire suppression and passive suppression from heavy grazing by livestock that removes fine fuels that carry fire. Other threats from development, invasive species, and energy development continue to convert or degrade existing stands. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Persistent drought may result in loss of key species. Conversion of this type has commonly come from agriculture (Johnston 1955) and invasion by brush (Landfire 2007a). Common stressors and threats include conversion to cropland, invasion by brush, altered fire regime, overgrazing by livestock (Landfire 2007a), and development. Other stressors and threats include fragmentation from roads and invasion non-native species.

According to Climate Wizard in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5°F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from brush invasion or conversion non-native species. High-severity environmental degradation appears where occurrences tend to be relatively small (<10 acres) for this small-patch type and have evidence of mechanical disturbance from vehicles resulting in obvious soil compaction and sheet and rill erosion. Altered fire regime from prescribed burning reduces cover key species. Moderate-severity environmental degradation appears where occurrences are moderate (50 acres) in size for this small-patch type and have evidence of mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from prescribed burning reduces cover key species.

High-severity disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species are abundant (>10% absolute cover to dominant). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring such as fire, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are very low when compared to an intact ecosystem. Moderate-severity disruption appears where occurrences have moderate cover of native species (30-70% relative cover. Invasive non-native species are abundant (3-10% absolute cover). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring such as fire, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES301.987 Tamaulipan Clay Grassland

CES301.987 CLASSIFICATION

Concept Summary: This Tamaulipan ecological system occurs on clay prairies near the Gulf Coast and drier sites further inland. Substrates are fine calcareous clays and clay loam. Occasional fires and root pruning from montmorillonitic clay limit shrub invasion, if the grassland is not overgrazed. If overgrazed the land will convert to stable thornscrub dominated by *Prosopis glandulosa* and *Celtis ehrenbergiana (= Celtis pallida)*. Vegetation is dominated by perennial mid and short grasses such as *Schizachyrium scoparium, Paspalum* spp., *Trichloris pluriflora (= Chloris pluriflora), Bouteloua dactyloides (= Buchloe dactyloides)*, with other grasses such as *Bothriochloa saccharoides, Bouteloua curtipendula, Chloris andropogonoides, Nassella leucotricha, Schedonnardus paniculatus, Setaria leucopila*, and clumps of *Andropogon gerardii* on less clayey sites. *Prosopis glandulosa* or *Quercus fusiformis* are often present as scattered mottes or are restricted to drainages. *Opuntia engelmannii var. lindheimeri* is often present.

Concept Source: NatureServe Western Ecology Team

Description Author: NatureServe Western Ecology Team

CES301.987 CONCEPTUAL MODEL

Environment: [from M130] This vegetation is found in semi-arid and subtropical southern Texas over a variety of soil depths and textures. Rainfall is highly variable both spatially and temporally and can range from 38 to 76 cm (15-30 inches) annually in a given locality, but all areas are prone to drought and water deficits (Bray 1901, Gilbert 1982, Jahrsdoerfer and Leslie 1988).

Key Processes and Interactions:

Threats/Stressors: [from M130] Threats from development, including overgrazing by livestock, mining, and energy development, continue to convert or degrade existing stands. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Persistent drought may result in loss of key species. Conversion of this type has commonly come from effective brush eradication using mechanical, chemical or prescribed burning method. Common and threats include fragmentation from roads, non-native species invasion (Landfire 2007a), and development, mining, agriculture. Other and threats include overgrazing/browsing by livestock, and possibly loss of pollinators.

According to Climate Wizard (TNC 2013) in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5 degrees F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion.

CES301.462 Tamaulipan Lomas

CES301.462 CLASSIFICATION

Concept Summary: This ecological system occurs on well-drained portions of clay dunes (lomas) rising above surrounding coastal tidal flats. It is a xeric, subtropical shrubland dominated by thorny evergreen shrubs, generally 2-4 m tall. Composition of this system is extremely variable, and there is usually no clear dominant, except locally. Local dominants may include *Citharexylum berlandieri, Leucophyllum frutescens, Havardia pallens (= Pithecellobium pallens)*, and *Ebenopsis ebano*. While there is often no clear dominant, *Yucca treculeana* is a constant and conspicuous emergent in many occurrences. Some lomas may be flooded by the sea during severe storm events. Vegetation in this system is sometimes influenced by salt spray, high winds, limited rooting depth, saline water table, and extreme xeric conditions.

- South Texas: Loma Grassland (7307) [CES301.462.7] (Elliott 2011) **<**

Distribution: This coastal system is known from Aransas County, Texas, south into Mexico.
Nations: US
Concept Source: J. Teague
Description Author: J. Teague and L. Elliott

CES301.462 CONCEPTUAL MODEL

Environment: This system occupies well-drained portions of clay dunes (lomas) along the lower Texas coast (and somewhat inland) and adjacent Mexico. These rise above surrounding coastal tidal flats and often develop from deposition of windblown fine sediments, resulting in elevated landforms within a matrix of tidal flats (Elliott 2011). At the time of formation, lomas were located on the leeward side of irregularly flooded lagoons and tidal flats that when dry provided the source for the windblown clayey sediments. The geology consists of Quaternary windblown deposits identified as clay dunes (Qcd). Landforms are round, elliptic, or crescent-shaped topographic highs, often within a matrix of low flats influenced by wind-driven tides. Soils include Point Isabel clay loam and Lalinda fine sandy loam, which are often associated with the Coastal Ridge Ecological Site. Lomas are characterized as wind-formed clay dunes on or near the coast, often surrounded by flats containing halophytic vegetation, coastal grasslands, or unvegetated wind-tidal flats. They usually occur as topographic highs in the surrounding level landscape, sometimes to 10 m above the surrounding plain and are a small-patch occurrence.
Key Processes and Interactions: From Landfire (2007a): Hurricanes and tropical storms can affect these sites through tidal surge causing influx of saline waters. Saltwater inundation would be restricted temporally to the period during storm surge and would not likely significantly affect shrub mortality. Also, high-intensity storms may completely eliminate these sites through erosion. Erosional processes would tend to completely eliminate sites rather than causing changes in the system structure. Fire is not a process important to this system and does not or rarely occurs. Tidal flat islands are important for wildlife such as migratory birds, mollusks and fish (USACE 2013).

This system occurs as small-patch sites ranging from 10s to a few 100 acres. Disturbances tend to have local effects or completely eliminate a site. This BpS occurs as a stable system.
Threats/Stressors: Key threats are potential changes in weather patterns that would increase the number and power of high-intensity storms such as hurricanes that can completely eliminate these sites through erosion of these islands in the tidal flats where they occur. Rising sea level may cause long-term influx of saline water that would cause mortality of shrubs that stabilize these tidal flat islands (lomas). Other threats from poor coastal management, including land development, dredging, levee construction, invasive species, chemical pollution and other human impacts, continue to degrade existing stands. Persistent drought may result in loss of key species. Conversion of this type has commonly come from land development and dredging. Common stressors and threats include coastal management actions such as levee construction and maintenance, development and invasion of non-native species.

According to Climate Wizard in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5°F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion.
Ecosystem Collapse Thresholds: Ecological collapse tends to result from land development and dredging or conversion non-native species. High-severity environmental degradation appears where occurrences tend to be relatively small for this small-patch type and have evidence of mechanical disturbance resulting in erosion. Moderate-severity environmental degradation appears where occurrences are moderate in size for this small-patch type and have evidence of mechanical disturbance resulting in erosion. Altered fire regime from prescribed burning reduces cover key species.

High-severity disruption appears where occurrences have low cover of native woody species (<30% relative cover). Invasive non-native species are abundant (>10% absolute cover to dominant). Connectivity is severely hampered by fragmentation from development that prevents natural ecological processes from occurring and creates barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are very low when compared to an intact ecosystem.

CES301.984 Tamaulipan Mesquite Upland Scrub

CES301.984 CLASSIFICATION

Concept Summary: This ecological system occurs in the Tamaulipan region of northeastern Mexico. Its current concept is dominated by thornscrub that was limited to rocky, broken uplands and drainages that has become widespread in the last 100-150 years as the result of disturbance to adjacent mesquite savanna grasslands. Severe overgrazing in the mid-1800s, with subsequent shifts in fire processes and changes in edaphic conditions, has allowed this thornscrub ecological system to be the new steady-state. The vegetation is characterized by an open to dense tall-shrub layer dominated by *Prosopis glandulosa* with many other species present to codominant such as *Acacia berlandieri, Vachellia farnesiana, Acacia rigidula, Amyris madrensis, Amyris texana, Celtis ehrenbergiana, Leucophyllum frutescens, Opuntia* spp., *Parkinsonia texana, Yucca* spp., and *Zanthoxylum fagara*. The herbaceous layer is generally sparse, but dense graminoids may dominate the herbaceous layer of stands with open shrub canopies or remnant patches of savanna.

CES301.983 Tamaulipan Mixed Deciduous Thornscrub

CES301.983 CLASSIFICATION

Concept Summary: This thornscrub ecological system occurs throughout much of northeastern Mexico and southern Texas. It occurs on a variety of substrates and landforms. Dominant species include *Acacia roemeriana, Leucophyllum frutescens*, and *Prosopis glandulosa*. Other species present to codominant include *Acacia berlandieri, Vachellia farnesiana, Amyris madrensis, Amyris texana, Celtis ehrenbergiana, Parkinsonia texana*, and cacti such as *Opuntia engelmannii var. lindheimeri*. The herbaceous layer is not well-developed but *Trichloris pluriflora, Setaria* spp., and *Malpighia glabra* are present. This system generally occurs as a closed shrubland or low woodland, usually lacking a purely open herbaceous component. Soils are clays, clay loams, and clay flats and are often calcareous or alkaline to varying degrees. Some sites are highly saline, and these sites are occupied by ~Tamaulipan Saline Thornscrub (CES301.711)$$, but transitions between the systems may be subtle.

Distribution: Occurs throughout much of northeastern Mexico and southern Texas.
Nations: MX, US
Concept Source: K.A. Schulz
Description Author: L. Elliott and K.A. Schulz

CES301.983 CONCEPTUAL MODEL

Environment: This system is well-represented on the Eocene Claiborne and Jackson groups and the Pleistocene Beaumont Formation, but is also found on various other formations. Its landforms are gently rolling to nearly level sites, sometimes interdigitated with calcareous ridges and low-lying drainages and bottomlands. Found on upland sites on tight soils deposited through alluvial processes associated with the Rio Grande, also occurs on uplands away from the delta on deeper soils. Clay, Clay Flat, and Clay Loam Ecological Sites are the typical soils for this system.

Key Processes and Interactions: Fire plays a role in this system, occurring in situations adjacent to grasslands during dry conditions when fire would jump to the canopy and carry during wind events. Drought would influence fire occurring in the woodland and shrubland classes (Landfire 2007a).

This system was modeled by Landfire (2007a) using three classes: early-, mid- and late-seral. The early-seral (0-5 years) class is dominated by perennial grasses. This class was maintained on higher topographic positions somewhat longer because of slower shrub growth in more xeric situations. Frequent replacement fire (MFRI = 7 years) is the dominant disturbance type in this class (Landfire 2007a). Mid-seral class is dominated by shrubs (40-70% cover). In this class, mesquite is a component of the shrub layer along with the other shrubs. Drought is incorporated into the MFRI in that dry conditions would be required for fire to be carried in the canopy. Replacement fire (MFRI = 20 years) is the dominant disturbance type in this class (Landfire 2007a). The late-seral class has a shrub layer at a height of 2-4 m and 70-100% cover. Mesquite canopy is well-developed in this class. Shrub layer development is extensive forming an almost continuous layer. Replacement fire (MFRI = 30 years) is the dominant disturbance type in this class (Landfire 2007a).

Threats/Stressors: Much of this system was decimated by development for agriculture early in the twentieth century (Crosswhite 1980). Grazing pressure removing native grasses, increase in invasive (introduced) grasses, and lack of fire threaten this system. Currently the non-native grasses *Pennisetum ciliare* and *Urochloa maxima* can serve as ladder fuel which increases the potential for fire in this system. Threats from development, including development for agriculture, overgrazing by livestock, and possibly energy development, continue to convert or degrade existing stands. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Persistent drought may result in loss of key species. Conversion of this type has commonly come from agricultural practices. Common stressors and threats include fragmentation from roads, agriculture and development, and non-native species invasion. Other stressors and threats include overgrazing/browsing by livestock, and possibly loss of pollinators.

According to Climate Wizard in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5°F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from major disturbances such as development or brush removal using herbicides or mechanical treatments resulting in conversion to agriculture.

High-severity environmental degradation appears where occurrences tend to be relatively small (<100 acres) for this large-patch type and have evidence of mechanical disturbance from vehicles resulting in obvious soil compaction and sheet and rill erosion. Altered fire regime. Moderate-severity environmental degradation appears where occurrences are moderate (100-1000 acres) in size for this large-patch type and have evidence of mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from prescribed burning reduces cover key species.

High-severity disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species are abundant (>10% absolute cover to dominant). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring such as fire, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are very low when compared to an intact ecosystem. Moderate-severity disruption appears where occurrences have moderate cover of native species (30-70% relative cover). Invasive non-native species are abundant (3-10% absolute cover). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring such as fire, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES301.992 Tamaulipan Ramadero

CES301.992 CLASSIFICATION

Concept Summary: This Tamaulipan riparian shrubland system is restricted to drainages in upland areas or ramaderos of southern Texas and adjacent Mexico that are intermittently flooded. Typical stands have a closed canopy (relative to the surrounding landscape) from 5 to 10 m in height. The overstory canopy is typically dominated by species such as *Prosopis glandulosa, Vachellia farnesiana, Celtis ehrenbergiana*, and/or *Parkinsonia aculeata*. In addition, *Celtis laevigata* and/or *Ebenopsis ebano* may also be present in the canopy. Some sites have a relatively open subcanopy, but more commonly the shrub layer is thick, sometimes impenetrable, and varies in height from 1 to 5 m. Species commonly encountered in the shrub layer include *Aloysia gratissima, Phaulothamnus spinescens, Celtis ehrenbergiana, Condalia hookeri, Forestiera angustifolia, Diospyros texana, Ziziphus obtusifolia, Koeberlinia spinosa, Malpighia glabra, Zanthoxylum fagara, Opuntia engelmannii var. lindheimeri, Guaiacum angustifolium, Colubrina texensis*, and *Amyris texana*. Ground cover can be sparse or, in more open stands, may have a fairly continuous grassy cover.

Description Author: L. Elliott

CES301.992 CONCEPTUAL MODEL

Environment: This Tamaulipan riparian shrubland system is restricted to drainages in upland areas or ramaderos (isolated strips of dense brush associated with arroyos) that are intermittently flooded. This is a widespread system on various geologic strata. It is typically found in upland drainages in various landscapes. Drainages are extremely flashy from runoff from surrounding landscape. These sites are infrequently flooded during local rainfall events, but because they accumulate runoff, they tend to be slightly more mesic in this otherwise xeric landscape. Soils are various upland soils (but not Bottomland ecological site types). These are sometimes mapped specifically as Ramadero Ecological Site. These woodlands are found along drainages (locally known as ramaderos) that are extremely flashy and are infrequently and briefly flooded during local rain events. The soils are typically clay loams or sandy clay loams

Key Processes and Interactions: Intermittent fluvial processes define this system, which are often associated with rapid sheet and gully flow that scours the channel bottoms.

Threats/Stressors: [from M130] Threats from development, including overgrazing by livestock, mining, and energy development, continue to convert or degrade existing stands. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Persistent drought may result in loss of key species. Conversion of this type has commonly come from effective brush eradication using mechanical, chemical or prescribed burning method. Common and threats include fragmentation from roads, non-native species invasion (Landfire 2007a), and development, mining, agriculture. Other and threats include overgrazing/browsing by livestock, and possibly loss of pollinators.

According to Climate Wizard (TNC 2013) in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5 degrees F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion.

CES301.711 Tamaulipan Saline Thornscrub

CES301.711 CLASSIFICATION

Concept Summary: This system is an open shrubland on gently rolling to level sites where soil salinity is particularly high on saline clays. It occurs in the Tamaulipan region of southern Texas and possibly ranges into Mexico. Scattered *Prosopis glandulosa* usually form an emergent canopy less than 5 m in height, creating an overstory canopy cover of around 10%. A variety of shrubs and subshrubs form the dominant layer with a cover of 20-70% interspersed in a mosaic with patchy grasses.

Related Concepts:

- South Texas: Salty Thornscrub (6806) (Elliott 2011) =

Distribution: This system occurs in the Tamaulipan region of southern Texas and possibly ranges into Mexico.

Nations: MX?, US

Concept Source: L. Elliott, D. Diamond, A. Treuer-kuehn, D. German, J. Teague

Description Author: L. Elliott, J. Teague and K.A. Schulz

CES301.711 CONCEPTUAL MODEL

Environment: This ecological system occurs on gently rolling to low flats, sometimes dissected by minor drainages. It is frequently associated with the Yegua Formation or the Jackson Group and within the Saline Clay and Saline Clay Loam Ecological Sites. Soils are typically saline clays such as Montell, Maverick, and Catarina soils and may have a veneer of gravel over the clay.

Key Processes and Interactions: Regular fire plays a limited role in this system because of the relatively low cover of fine fuel. During dry conditions it may burn when fire would jump to the shrub layer and canopy and carry during wind events spreading from adjacent grasslands that have more frequent fires. Saline substrates are the driving environmental variable that limits plant growth and species diversity. Substrates are highly erodible saline clay and saline clay loam soils.

Threats/Stressors: Threats from development, including overgrazing by livestock, mining, and energy development, continue to convert or degrade existing stands. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Persistent drought may result in loss of key species. Conversion of this type has commonly come from effective brush eradication using mechanical or herbicide method. Common stressors and threats include fragmentation from roads, agriculture development, and non-native species invasion. Other stressors and threats include overgrazing/browsing by livestock.

According to Climate Wizard (TNC 2013), in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5°F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from major disturbances such as development or from severe soil erosion after overgrazing by livestock or drought followed by high intensity rainfall events.

High-severity environmental degradation appears where occurrences tend to be relatively small (<100 acres) for this large-patch type and have evidence of mechanical disturbance from vehicles resulting in obvious soil compaction and sheet and rill erosion. Moderate-severity environmental degradation appears where occurrences are moderate (100-1000 acres) in size for this large-patch type and have evidence of mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion.

High-severity disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species are abundant (>10% absolute cover to dominant). Connectivity is severely hampered by fragmentation from roads and/or agriculture development that restrict or prevent natural ecological processes from occurring and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are very low when compared to an intact ecosystem. Moderate-severity disruption appears where occurrences have moderate cover of native species (30-70% relative cover). Invasive non-native species are abundant (3-10% absolute cover). Connectivity is severely hampered by fragmentation from roads and/or agriculture development that restrict or prevent natural ecological processes from occurring and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES301.985 Tamaulipan Savanna Grassland

CES301.985 CLASSIFICATION

Concept Summary: This Tamaulipan ecological system is dominated by perennial grasses with sparse overstory of mesquite or oak trees and thornscrub. Stands of the system are typically dominated by *Prosopis glandulosa* in the overstory, which may be sparse, giving the aspect of an open grassland with scattered trees and shrubs. Or, more commonly, the system occurs as shrub-dominated patches within a grassy matrix. There will typically be an emergent canopy ranging to about 6 or more meters in height, composed of *Prosopis glandulosa* sometimes with *Ebenopsis ebano* and/or *Celtis ehrenbergiana*. Sometimes the overstory canopy is well-developed and would be considered woodland. These patches often coalesce to form significant expanses of shrubland. Dominant grasses are *Cynodon* spp. This system was once a common matrix system, but has largely been converted to desert scrub and exists as remnant patches. Degraded subtropical forests and woodlands may have similar structure but are not included in this system because different ecological processes maintain them.

Distribution: Examples of the system are found on thinner eolian sands on the western side of the South Texas Sand Sheet in Texas and related areas of Mexico.
Nations: MX, US
Concept Source: K.A. Schulz
Description Author: L. Elliott and K.A. Schulz

CES301.985 CONCEPTUAL MODEL

Environment: Examples of the system are found on thinner eolian sands on the western side of the South Texas Sand Sheet, as well as other sandy sites such as those of the Eocene sands of the Carrizo, Queen City, and Sparta formations. It may also be found associated with other formations, such as Oakville sandstone and other formations producing sandy residuum. Typical sites are level to gently rolling. This system occurs on sandy soils, including sandy, sandy loam, and loamy sands. Ecological Sites include sandy to sandy loam sites, such as those of the Sandy, Loamy Sand and Sandy Loam Ecological Sites (Elliott 2011).

Key Processes and Interactions: Fire and drought are key ecological processes in this system. This system was modeled by Landfire (2007a) using three classes: early-, mid- and late-seral. The early-seral class (1-20 years) is dominated by perennial grasses. This class was maintained by frequent replacement fire (MFRI = 5 years) as the dominant disturbance type in this class. Droughts slow progression of this class to mid-seral class. This class is modeled to last 20 years; this duration is extended due to limited mesquite seed dispersal mechanisms historically (prior to livestock introduction) (Landfire 2007a).

Mid-seral class (21-50 years) is the early development of shrub patches, often surrounding a mesquite trees. Tree canopy is sparse, but shrub cover is dense. Herbaceous cover is declining due to increased shrub and overstory canopy. Replacement fire is modeled to occur with a 20-year return interval. A mixed fire is modeled to occur with a 7-year return interval. Twenty-year drought is modeled to slow successional progression to late-seral class. The mechanism for drought effect may be an enhanced effect of fire. This class is modeled to last 30 years (Landfire 2007a).

The late-seral class (51+ years) is a closed-canopy, late-development stage that represents the continued development of shrub patches as they coalesce into more well-developed woodlands of *Prosopis glandulosa* (Archer 1989). In these late stages other species begin to colonize into woodlands and shrublands. Species present in mid-seral class are still present in late-seral class, but other species begin to colonize, such as *Mahonia trifoliolata, Schaefferia cuneifolia*, and *Lycium berlandieri*. Replacement fire is modeled to occur with a 200-year return interval. A mixed fire is modeled to occur with a 20-year return interval. Twenty-year drought is modeled and may slow increase in patch size but does not cause transition (Landfire 2007a).

Threats/Stressors: The natural range of variation in disturbance within this vegetation is difficult to assess currently, because of dramatic changes resulting from severe overgrazing and the resultant changes in vegetation dynamics in the region which occurred in the early to mid-1800s. While most experts agree that this was a major habitat type of the region, the historic extent of mesquite savanna is arguable. Periodic fire, probably resulting from human sources of ignition, likely maintained the habitats as an open savanna. The average fire-return interval is 6 years. Periods of overgrazing apparently led to an alternative stable state in which fire does not play a significant role, and the habitat has become a closed shrubland community with little to no opportunity for reverting to mesquite savanna (Landfire 2007a). Many sites are currently occupied by denser shrub cover than historical condition (Landfire 2007a).

Threats from development, including development for agriculture and overgrazing by livestock, continue to convert or degrade existing stands. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species. Persistent drought may result in loss of key species. Conversion of this type has commonly come from agricultural practices. Common stressors and threats include fragmentation from roads, agriculture and development, and non-native species invasion. Other stressors and threats include overgrazing/browsing by livestock, and possibly loss of pollinators.

According to Climate Wizard (TNC 2013), in 2050 global climate change model (using Medium A1B emission scenario and Ensemble Average general circulation model), the average annual temperature is predicted to rise approximately 5°F and average annual precipitation will not significantly change (TNC 2013). Seasonal shifts in precipitation predict increased fall (monsoon) moisture with similar levels of precipitation to current in the rest of the year (TNC 2013). Potential climate change effects on vegetation could include a shift to species adapted to a hotter, generally drier environment. While average precipitation amounts may remain similar or slightly decrease during the winter, spring and summer months, that, along with increased temperatures, may cause vegetation to experience less effective precipitation and more soil moisture deficit during much of the growing season reducing plant growth and increasing mortality from extreme events including exceptional drought. If the increased fall precipitation is from intense storms such as hurricanes, we can expect more disturbances from flooding and water erosion.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from major disturbances such as development or brush removal using herbicides or mechanical treatments resulting in conversion to agriculture.

High-severity environmental degradation appears where occurrences tend to be relatively small (<100 acres) for this large-patch type and have evidence of mechanical disturbance from vehicles resulting in obvious soil compaction and sheet and rill erosion. Altered fire regime. Moderate-severity environmental degradation appears where occurrences are moderate (100-1000 acres) in size for this large-patch type and have evidence of mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from prescribed burning reduces cover key species.

High-severity disruption appears where occurrences have low cover of native species (<30% relative cover). Invasive non-native species are abundant (>10% absolute cover to dominant). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring such as fire, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are very low when compared to an intact ecosystem. Moderate-severity disruption appears where occurrences have moderate cover of native species (30-70% relative cover). Invasive non-native species are abundant (3-10% absolute cover). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring such as fire, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

M089. Viscaino-Baja California Desert Scrub

CES302.013 Gulf of California Coast Torchwood-Cardon Desert Scrub

CES302.013 CLASSIFICATION

Concept Summary: This desert scrub system is found in disjunct areas along the eastern side of central Baja California south from uplands that divide the peninsula to the Gulf of California, and on the west coast of Sonora inland 20-40 km from Punta Lobos south to Guaymas, including the major islands. Climate is extremely arid with mean annual precipitation of less than 100 mm in the north increasing to 300 mm in southern Baja. Precipitation occurs mostly in the summer-early fall season (monsoon). Extended drought is common which favors plants with water storage. This system occurs on coarse substrates such as deep granitic soils and a'a lava flows in broad valley bottoms, alluvial fans and on lower mountain slopes. The vegetation is characterized by an open layer of xeromorphic trees and tall shrubs and tall cacti without a low-shrub layer common elsewhere in the Sonoran Desert. Species such as *Bursera hindsiana, Bursera microphylla, Parkinsonia microphylla, Fouquieria diguetii, Fouquieria splendens, Pachycereus schottii, Pachycereus pringlei*, and *Stenocereus thurberi* dominate with other scattered shrubs and cacti that include *Ambrosia dumosa, Encelia farinosa, Jatropha cinerea, Jatropha cuneata, Hyptis emoryi, Justicia californica, Cylindropuntia bigelovii*, and *Solanum hindsianum*. Isolated *Fouquieria columnaris*, a species typical of Baja, may occur in this system in Sonora.

Related Concepts:

CES302.740 Magdalena Plain Desert Scrub

CES302.740 CLASSIFICATION

Concept Summary: This southern Baja California desert scrub is found in the southern part of the Magdalena region along the Pacific Ocean where the narrow coastal strip widens into a broad plain. Climate is arid with less than 200 mm mean annual precipitation (less than 100 mm near the coast) occurring mostly in the summer-early fall season (monsoon). However, cool coastal sea breezes and fog help ameliorate some of the aridity. Substrates are generally clayey soils with low infiltration that are derived from volcanic rock. Vegetation in this plain is more open than ~Magdalena Barrancas Desert Scrub (CES302.739)$$ but is composed of similar species with the addition of halophytic species that occur on the many playas (both large and small) in this plain. The lack of *Fouquieria columnaris, Pachycormus discolor*, and low frequency of *Agave* and *Yucca* species separate this vegetation from the Vizcaino region. Common species may include *Jatropha cuneata, Larrea tridentata, Lysiloma candida, Opuntia cholla, Pachycereus pringlei, Parkinsonia microphylla, Prosopis glandulosa var. torreyana, Stenocereus thurberi*, and halophytes such as species of *Lycium* and *Suaeda*.

CES302.740 CONCEPTUAL MODEL

Environment: [from M089] This desert scrub type comprises most of the Baja California peninsula and occurs in diverse environments from the coastal and inland plains to alluvial fans, foothills, and mountains. Climate is extremely arid with mean annual precipitation of less than 100 mm in the north increasing to 300 mm in southern Baja. Precipitation occurs mostly in the summer-early fall season (monsoon). Extended drought is common and favors plants with water storage. Coastal stands west of the mountain divide may benefit from cool sea breezes and fog that help ameliorate some of the aridity. Some vegetation types, such as *Frankenia-Ocotillo-Datilillo* desert scrub are limited to the fog belt in the coastal plain of southern Viscaino. Substrates vary from coarse-textured, deep granitic soils and a'a lava flows in broad valley bottoms, alluvial fans and on lower mountain slopes to finer-textured, alkaline, sometimes saline, clayey soils with low infiltration that are derived from marine deposit, basalt or other volcanic rock. Some stands occur in narrow valleys and rocky slopes below generally sparsely vegetated volcanic mesas. Soil is present and moisture is available locally in seeps from these mesas. Larger valleys or barrancas are typically drier and have more open vegetation than smaller ones. An exception to the extremely arid environments is the tropical San Lucan thornscrub, which is limited in distribution to central and southern Baja California. These areas receive more precipitation (316-482 mm) per year, with a dry season from late October through July. Mean monthly temperatures range from 21.5-23.6°C. Pacific slopes receive greater rainfall and experience generally lower temperatures than the gulf side of the Cape region.

Key Processes and Interactions: [from M089] Periodic severe drought is common in Baja California which favors plants that can store water during the unfavorable times.

Threats/Stressors:

CES302.006 Northern Viscaino Coastal Plain Maguey-Boojum Desert Scrub

CES302.006 CLASSIFICATION

Concept Summary: This desert scrub system is found near the Pacific Coast on the plains and rolling hills of the northern Vizcaino region in central Baja California. Climate is extremely arid with less than 100 mm mean annual precipitation occurring mostly in the fall-winter. However, cool coastal sea breezes and spring and summer fog help ameliorate the aridity. Substrates are clayey soils with low infiltration that are derived from volcanic rock. Vegetation is an open desert scrub dominated by *Agave shawii* and *Fouquieria columnaris* with abundant low shrubs such as *Ambrosia camphorata, Ambrosia chenopodiifolia, Echinocereus maritimus, Eriogonum fasciculatum*, and *Cylindropuntia prolifera (= Opuntia prolifera)*.

CES302.007 Northern Viscaino White Bursage-Agave Inland Low Desert Scrub

CES302.007 CLASSIFICATION

Concept Summary: This desert scrub system is found on rolling hills and plains of the northern Vizcaino region in central Baja California from the Pacific Ocean to the crest of the uplands that divide the peninsula. Climate is extremely arid with less than 100 mm mean annual precipitation occurring mostly in the fall-winter. However, cool coastal sea breezes help ameliorate some of the aridity, but it occurs too far inland for the fog to influence the vegetation. The vegetation is dominated by low shrubs *Ambrosia dumosa* and *Agave cerulata* with *Encelia californica, Ambrosia camphorata, Eriogonum fasciculatum*, and *Krascheninnikovia lanata*. *Larrea tridentata* is uncommon, but always present. There are only widely scattered taller plants of *Fouquieria columnaris, Fouquieria splendens, Pachycereus pringlei, Pachycormus discolor*, and *Yucca schidigera* because of the aridity. Other common species include *Simmondsia chinensis, Viguiera laciniata, Krameria* spp., and the cacti *Pachycereus schottii (= Lophocereus schottii), Opuntia molesta*, and *Ferocactus* spp.

Related Concepts:

CES401.301 San Lucan Thornscrub

CES401.301 CLASSIFICATION

Concept Summary: This tropical thornscrub system is limited in distribution to central and southern Baja California. These are found along low foothills, bajada, and arroyos with sandy alluvial soils derived from granitic rocks. This forms a transition between succulent-rich Sonoran Desert scrub types and ~San Lucan Dry Deciduous Forest (CES401.299)$$. The following list of species is diagnostic for this system: *Pachycereus pringlei, Machaerocereus gummosus, Solanum hindsianum, Jatropha cinerea, Bursera microphylla*.

Nations: MX

Concept Source: C. Josse

Description Author: C. Josse

CES401.301 CONCEPTUAL MODEL

Environment: These are found along low foothills, bajadas, and arroyos with sandy, alluvial soils derived from granitic rocks. These areas receive 316-482 mm of precipitation per year, with a dry season from late October through July. Mean monthly temperatures range from 21.5-23.6°C. Pacific slopes reveive greater rainfall and experience generally lower temperatures than the Gulf side of the Cape region.

Key Processes and Interactions: Successional dynamics exist between Sonoran desert scrub, thornscrub and dry deciduous forest. Natural fire regimes are not documented.

Threats/Stressors:

Ecosystem Collapse Thresholds:

3.B.1.Ne. Western North American Cool Semi-Desert Scrub & Grassland

M093. Great Basin Saltbush Scrub

CES304.783 Inter-Mountain Basins Mat Saltbush Shrubland

CES304.783 CLASSIFICATION

Concept Summary: This ecological system occurs on gentle slopes and rolling plains in the northern Colorado Plateau and Uinta Basin on Mancos shale and arid, windswept basins and plains across parts of Wyoming. It is also found in eastern Wyoming in Great Plains areas and may extend north into Montana and Canada. These landscapes typically support dwarf-shrublands composed of relatively pure stands of *Atriplex* spp., such as *Atriplex corrugata* (in Colorado and Utah), *Atriplex gardneri* (Wyoming and Montana into Canada), or *Atriplex falcata* (Columbia Plateau and northern Great Basin). Other dominant or codominant dwarf-shrubs may include *Artemisia longifolia, Artemisia pedatifida* (very important in Wyoming, rare in Colorado stands), or *Picrothamnus desertorum*, sometimes with other low shrubs, such as *Krascheninnikovia lanata* or *Tetradymia spinosa*. *Atriplex confertifolia* or *Atriplex canescens* may be present but do not codominate. *Artemisia tridentata ssp. wyomingensis* can occur in local patches within this system. The herbaceous layer is typically sparse. Scattered perennial forbs occur, such as *Oenothera* spp., *Phacelia* spp., *Sphaeralcea grossulariifolia, Stanleya pinnata*, and *Xylorhiza glabriuscula*; perennial grasses *Achnatherum hymenoides, Bouteloua gracilis* (not in Wyoming), *Distichlis spicata, Elymus elymoides, Elymus lanceolatus ssp. lanceolatus, Pascopyrum smithii, Pleuraphis jamesii, Poa secunda*, or *Sporobolus airoides* may comprise the herbaceous layer. In less saline areas, there may be inclusions of grassland patches dominated by *Hesperostipa comata, Leymus salinus, Pascopyrum smithii*, or *Pseudoroegneria spicata*. Substrates are shallow, typically saline, alkaline, fine-textured soils developed from shale or alluvium and may be associated with shale badlands. Infiltration rate is typically low. In Wyoming and possibly elsewhere, inclusions of non-saline, gravelly barrens or rock outcrops dominated by cushion plants such as *Arenaria hookeri* and *Phlox hoodii* without dwarf-shrubs may be present (these are not restricted to this system). Annuals are seasonally present and may include *Eriogonum inflatum, Monolepis nuttalliana, Plantago tweedyi*, and the introduced annual grass *Bromus tectorum*. In Montana, *Atriplex gardneri* also occurs associated with Great Plains badlands, and determining which system it falls into may be difficult.

Distribution: This system occurs on gentle slopes and rolling plains in the northern Colorado Plateau and Uinta Basin on Mancos shale and arid, windswept basins and plains across parts of Wyoming, and possibly into Montana and Canada.

Nations: US

Concept Source: K.A. Schulz

Description Author: K.A. Schulz

CES304.783 CONCEPTUAL MODEL

Environment: *Climate:* Climate is temperate and semi-arid. Summers are generally hot, and freezing temperatures are common in the winter. Mean annual precipitation ranges from 13-33 cm. In Montana and Wyoming, approximately two-thirds of the annual precipitation falls in spring and early summer. In Colorado and Utah, over half the precipitation occurs in the late summer monsoons as high-intensity thunderstorms.

Physiography/landform: This ecological system occurs in the intermountain western U.S. on gentle slopes and rolling plains on semi-arid, windswept plains and basins. Elevation ranges from 1150-2200 m. Stands occur on shale outcrops and plains and are nearly flat to moderately steep.

Soils/substrate/hydrology: Substrates are shallow to moderately deep, typically saline, alkaline, poorly developed, fine-textured soils but range from sandy loam to clay and may be gravelly. Soil are developed from shale, alluvium, and bentonite and may be associated with shale badlands. Infiltration rate is typically low and erosion rates are high because of poor infiltration and high runoff. In Wyoming and possibly elsewhere, inclusions of non-saline, gravelly barrens or rock outcrops may be present.

Key Processes and Interactions: These are highly saline-tolerant and drought-tolerant shrublands. *Atriplex corrugata*- and *Atriplex gardneri*-dominated shrublands are the most saline-tolerant of the Mancos shale plant communities studied by Branson et al. (1976). Gardner's saltbush has an extensive, highly branched root system, and tolerates poor site conditions (Reed 1993b). Stands are characterized by bare ground and young to mature shrubs that have re-sprouted or established from nearby seed. Although very slow-growing, these shrubs can completely dominate these extremely saline sites (Branson et al. 1976). They are true evergreen dwarf-shrubs retaining leaves for several years. This plant utilizes winter soil moisture, beginning new growth in March when the soils are relatively warm and moist. It flowers in April and by mid-July fruits are shattered (Branson et al. 1976). If the soils dry out in midsummer, it can go dormant until the late summer monsoon rains begin. Disturbance is characterized by very wet periods that contribute to high shrub mortality every 100 years on average.

Shrub cover may be patchy and discontinuous, but cover is higher than ~Inter-Mountain Basin Shale Badland (CES304.789)$$. These shrublands typically occur on flatter slopes with less severe erosion than those occupied by badland communities. This system does not have a fire regime due to discontinuous fuel (LANDFIRE 2007a). Fire can occur in conjunction with wet years possibly once every 100 years on average. Most species of *Atriplex* sprout after fire, recovering fully within 2 to 3 years from root sprouts (Wright 1980).

LANDFIRE developed a VDDT model for this system which has two classes (LANDFIRE 2007a, BpS 2310660):
A) Early Development 1 All Structures (10% of type in this stage): Shrub cover is 0-5%. Characterized by bare ground and young shrubs that have re-sprouted or established from nearby seed. May find some ephemeral forbs or grasses at this stage. Disturbance is characterized by very wet periods that contribute to high shrub mortality every 100 years on average. Succession to class B after 12 years.

B) Late Development 1 All Structures (90% of type in this stage): Characterized by mature shrubs (10-20% cover). Typically lacks understory vegetation. Sites at this stage are very patchy with discontinuous shrubs. Same disturbance as in class A.

Threats/Stressors: The naturally sparse plant cover along with fine-grained salt soils make these shrublands particularly vulnerable to water and wind erosion, especially where vegetation has been depleted by grazing or disturbances (CNHP 2010). The dwarf-shrub *Atriplex gardneri* is very resilient and has been used to stabilize soils and to reclaim disturbed sites. It had one of the highest survival rates of all shrubs planted on processed oil shale in the Uinta Basin in Utah and was one of only two species to establish on coal mine spoils in Wyoming (Reed 1993b). Sites are arid and harsh with high winds and substrates that are typically highly erodible, saline, alkaline clays and silty clay soils low in phosphorous, nitrogen, and potassium. Sites are susceptible to accelerated erosion and soil loss. Sites are harsh and few other species can grow on them.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing or mechanical disturbance where perennial plant cover is reduced enough to allow removal of topsoil by wind or sheet and rill erosion. Continued surface disturbances cause loss of native species and allows for invasive non-native species to become established, and outcompete and replace native perennial species. Alteration of vegetation is extensive and no restoration potential. System remains fundamentally compromised despite restoration of some processes (CNHP 2010).

High-severity environmental degradation appears where occurrences tend to be relatively small in size (<100 acres) (CNHP 2010). Area is highly disturbed from roads or human development (e.g., oil and gas) that is frequent enough to cause an increase in non-native plants (CNHP 2010). Unnatural erosion, compaction, and altered species composition are noticeable (CNHP 2010). Surficial disturbances occur on more than 30% of the area (CNHP 2010). Biological soil crusts are >75% removed, occurring only in small pockets naturally protected from livestock and off-road vehicle use. Area around the occurrence is entirely, or almost entirely, surrounded by agricultural or urban land use and is at best buffered on one side by natural communities (CNHP 2010).

Moderate-severity environmental degradation appears where occurrences tend to be relatively small in size (100-1000 acres) (CNHP 2010). Disturbance from roads or human development (e.g., oil and gas) are frequent enough to cause an increase in non-native plants (CNHP 2010). Unnatural erosion, compaction, and altered species composition are usually noticeable (CNHP 2010). Surficial disturbances occur on more than 10% of the area (CNHP 2010). Biological soil crusts are >30% removed, occurring only in areas naturally protected from livestock and off-road vehicle use. The surrounding landscape is largely a combination of cultural and natural vegetation (CNHP 2010).

High-severity disruption of biotic processes appears where alteration of vegetation is extensive and restoration potential is low and system remains fundamentally compromised despite restoration of some processes (CNHP 2010), Remnant native plants may be present in the occurrence. Non-native annuals such as *Bassia hyssopifolia, Bassia scoparia, Bromus tectorum, Halogeton glomeratus, Salsola kali*, and *Salsola tragus* are present and abundant. Area is highly fragmented with barriers between species interactions and natural processes across natural communities (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity disruption of biotic processes appears where alteration of vegetation is extensive but potentially restorable over several decades (CNHP 2010). Native plants are present in the occurrence although cover is low. Non-native annuals such as *Bassia hyssopifolia, Bassia scoparia, Bromus tectorum, Halogeton glomeratus, Salsola kali*, and *Salsola tragus* are usually present, but not dominant; area is moderately fragmented with some barriers between species interactions and natural processes across natural communities (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.784 Inter-Mountain Basins Mixed Salt Desert Scrub

CES304.784 CLASSIFICATION

Concept Summary: This extensive ecological system includes open-canopied shrublands of typically saline basins, alluvial slopes and plains across the Intermountain western U.S. This type also extends in limited distribution into the southern Great Plains. Substrates are often saline and calcareous, medium- to fine-textured, alkaline soils, but include some coarser-textured soils. The vegetation is characterized by a typically open to moderately dense shrubland composed of one or more *Atriplex* species, such as *Atriplex confertifolia, Atriplex canescens, Atriplex obovata, Atriplex polycarpa*, or *Atriplex spinifera*. Other shrubs present to codominant may include *Artemisia tridentata ssp. wyomingensis, Chrysothamnus viscidiflorus, Ericameria nauseosa, Ephedra nevadensis, Grayia spinosa, Krascheninnikovia lanata, Lycium* spp., *Picrothamnus desertorum*, or *Tetradymia* spp. Northern occurrences may lack *Atriplex* species and are typically dominated by *Grayia spinosa, Krascheninnikovia lanata*, and/or *Picrothamnus desertorum*. In Wyoming, occurrences are typically a mix of *Atriplex confertifolia, Grayia spinosa, Artemisia tridentata ssp. wyomingensis, Sarcobatus vermiculatus, Krascheninnikovia lanata*, and various *Ericameria* or *Chrysothamnus* species. Some places are a mix of *Atriplex confertifolia* and *Artemisia tridentata ssp. wyomingensis*. In the Great Basin, *Sarcobatus vermiculatus* is generally absent but, if present, does not codominate. The herbaceous layer varies from sparse to moderately dense and is dominated by perennial graminoids such as *Achnatherum hymenoides, Bouteloua gracilis, Elymus lanceolatus ssp. lanceolatus, Pascopyrum smithii, Pleuraphis jamesii, Pleuraphis rigida, Poa secunda*, or *Sporobolus airoides*. Various forbs are also present.

Concept Source: K.A. Schulz

Description Author: R. Crawford, M.S. Reid and K.A. Schulz

CES304.784 CONCEPTUAL MODEL

Environment: *Climate:* This is a semi-arid system of extreme climatic conditions, with warm to hot summers and cold winters. Annual precipitation ranges from approximately 13-33 cm. In much of this shrubland's distribution the season of greatest moisture is mid to late summer, although in the more northern areas a moist period is to be expected in the winter and spring. Precipitation is extremely irregular in the southern part of its distribution, such that long-term seasonal or monthly averages do not convey the full story (Blaisdell and Holmgren 1984).

Physiography/landform: This salt desert shrubland system is a matrix system in the Intermountain West. This system occurs on lowland and upland sites usually at elevations between 1520 and 2200 m (4987-7218 feet). Sites can be found on all aspects and include valley bottoms, alluvial and alkaline flats, mesas and plateaus, playas, drainage terraces, washes and interdune basins, bluffs, and gentle to moderately steep sandy or rocky slopes. Slopes are typically gentle to moderately steep but are sometimes unstable and prone to surface movement. Many areas within this system are degraded due to erosion and may resemble "badlands." Soil surface is often very barren in occurrences of this system. The interspaces between the characteristic plant clusters are commonly covered by a biological soil crust (West 1982).

Soils/substrates/hydrology: Soils are shallow to moderately deep, poorly-developed, and often alkaline or saline. The soils of much of the area are poorly-developed Entisols, a product of an arid climate. Vegetation within this system is tolerant of these soil conditions but not restricted to it. Other sites include level pediment remnants where coarse-textured and well-developed soil profiles have been derived from sandstone gravel and are alkaline, or on Mancos shale badlands, where soil profiles are typically fine-textured and non-alkaline throughout (West and Ibrahim 1968). They can also occur in alluvial basins where parent materials from the other habitats have been deposited over Mancos shale and the soils are heavy-textured and saline-alkaline throughout the profile (West and Ibrahim 1968). The environmental description is based on several other references, including Branson et al. (1967, 1976), Beatley (1976), Campbell (1977), Brown (1982), West (1983b), Knight et al. (1987), Knight (1994), Shiflet (1994), Holland and Keil (1995), Reid et al. (1999), Ostler et al. (2000), Barbour et al. (2007), and Sawyer et al. (2009).

Key Processes and Interactions: West (1982) stated that "salt desert shrub vegetation occurs mostly in two kinds of situations that promote soil salinity, alkalinity, or both. These are either at the bottom of drainages in enclosed basins or where marine shales outcrop." However, salt-desert shrub vegetation may also occur in climatically extremely dry, non-saline sites, as well as physiologically dry (saline) soils (Blaisdell and Holmgren 1984). Not all salt desert shrub soils are saline, and their hydrologic characteristics may often be responsible for the associated vegetation (Naphan 1966). That is, they are flooded or wetted enough to mobilize but not flush soil salt content, and therefore the ephemeral hydrology precipitates and concentrates salts. Species of the salt desert shrub complex have different degrees of tolerance to salinity and aridity, and they tend to sort themselves out along a moisture/salinity gradient (West 1982). Thus these saltbush shrublands are dependent on a certain amount of ephemeral flooding and warm temperatures causing evaporation. The effects of these physical, chemical, moisture, and topographic gradients on species and communities occur through complex relations that are not well understood and are in need of further study (Blaisdell and Holmgren 1984). In northern, cool desert locations of this system, soil moisture accumulation and storage within this system typically occur in the winter months. There is generally at least one good snowstorm per season that will provide sufficient moisture to the vegetation. The winter moisture accumulation amounts will affect spring plant growth. Plants may grow as little as a few inches to 1 m. Unless more rains come in the spring, the soil moisture will be depleted in a few weeks, growth will slow and ultimately cease, and the perennial plants will assume their various forms of dormancy (Blaisdell and Holmgren 1984). If effective rain comes later in the warm season, some of the species will renew their growth from the stage at which it had stopped. Others, having died back, will start over as if emerging from winter dormancy (Blaisdell and Holmgren 1984). *Atriplex confertifolia* shrubs often develop large leaves in the spring, which increase the rate of photosynthesis. As soil moisture decreases, the leaves are lost, and the plant takes on a dead appearance. During late fall, very small overwintering leaves appear which provide some photosynthetic capability through the remainder of the year (Reid et al. 1999).

The variation of plant communities found within this ecological system is maintained by intra- or inter-annual cycles of flooding followed by extended drought, which favor accumulation of transported salts. The moisture supporting these intermittently flooded communities is usually derived off-site, and they are dependent upon natural watershed function for persistence (Reid et al. 1999). As a result, these desert communities of perennial plants are dynamic and changing. The composition within this system may change dramatically and may be both cyclic and unidirectional. Superimposed on the compositional change is great variation from year to year in growth of all the vegetation, the sum of varying growth responses of individual species to specific conditions of different years (Blaisdell and Holmgren 1984). Desert plants grow when temperature is satisfactory, but only if soil moisture is available at the same time. Because the amount of moisture is variable from year to year and because different species flourish under different seasons of soil moisture, seldom do all components of the vegetation thrive in the same year (Blaisdell and Holmgren 1984).

Insects are an important component of many shrub steppe and grassland systems. Mormon crickets and grasshoppers are natural components of many rangeland systems (USDA-APHIS 2003, 2010). There are almost 400 species of grasshoppers that inhabit the western United States with 15-45 species occurring in a given rangeland system (USDA-APHIS 2003). Mormon crickets are also present in many western rangelands and, although flightless, are highly mobile and can migrate large distances consuming much of the forage while travelling in wide bands (USDA-APHIS 2010). Following a high population year for grasshoppers or Mormon crickets and under relatively warm dry spring environmental conditions that favor egg hatching and grasshopper and Mormon cricket survival, there may be large population outbreaks that can utilize 80% or more of the forage in areas as large as 2000 square mile. Conversely, relatively cool and wet spring weather can limit the potential for outbreaks. These outbreaks are naturally occurring cycles and, especially during drought, can denude an area of vegetation leaving it exposed to increased erosion rates from wind and water (USDA-APHIS 2003).

Disturbance scale was variable during presettlement. Droughts and extended wet periods could be region-wide, or more local. A series of high water years or drought could affect whole basins. Mormon cricket disturbances could affect hundreds to perhaps thousands of acres for a few years to 1-2 decades (LANDFIRE 2007a).

LANDFIRE developed a VDDT model for this system which has three classes (LANDFIRE 2007a, BpS 2310810):
A) Early Development 1 All Structures (25% of type in this stage): Shrub cover is 0-5%. Dominated by continuous grass with widely scattered shrubs and relatively younger shrubs than in classes B and C. Over 10 years, vegetation moves to class B as the primary succession pathway. Replacement fire occurs every 300 years on average, and will set back succession to year zero. Extended wet periods (every 35 years) will also have a stand-replacing effect. During a drought (mean return interval of 35 years), vegetation will follow an alternative succession pathway to class C.

B) Mid Development 1 Open (45% of type in this stage): Characterized by mature shrubs (5-20% cover). Discontinuous grass patches and higher shrub canopy cover than in class A. Extended wet periods (every 35 years on average) will cause a stand-replacing transition to class A. During extended drought periods (every 35 years), vegetation will shift to class C. Replacement fire is rare (mean FRI of 500 years). Class B will be maintained in the absence of disturbance.

C) Mid Development 2 Open (30% of type in this stage): Characterized by mature shrubs (21-30% cover). Grass is lacking and shrub canopy cover is even higher than class B. During extended wet periods (35 years), vegetation will transition to class A. After 20 years, vegetation moves back to class B through succession. Drought (mean return interval of 35 years) will maintain vegetation in class C. Fire would not carry in this class and is not modeled.

Under reference conditions disturbances were unpredictable, but flooding, drought, insects and fire may all occur in this system. Extended wet periods were modeled as occurring every 35 years, and drought periods every 35 years. Extended wet periods tended to favor perennial grass development, while extended drought tended to favor shrub development. Fire was rare and limited to more mesic sites (and moist periods) with high grass productivity. Mixed-severity fire was modeled as occurring with a mean FRI of 500-1000 years (LANDFIRE 2007a).

In summary, desert communities of perennial plants are dynamic and changing. The composition within this system may change dramatically over time and may be both cyclic and unidirectional. Superimposed on the compositional change is great variation from year to year in growth of all the vegetation - the sum of varying growth responses of individual species to specific conditions of different years (Blaisdell and Holmgren 1984). Desert plants grow when temperature is satisfactory, but only if soil moisture is available at the same time. Because amount of moisture is variable from year to year and because different species flourish under different seasons of soil moisture, seldom do all components of the vegetation thrive in the same year (Blaisdell and Holmgren 1984).

Threats/Stressors: Conversion of this type has commonly come from invasive annual plant species, which displace natural composition and provide fine fuels that significantly increase spread of catastrophic fire. The primary land uses that alter the natural processes of this system are associated with livestock grazing and introduction of exotic annual grasses. Some of the salt desert shrub species are more palatable; *Atriplex canescens, Kochia americana, Krascheninnikovia lanata*, and *Picrothamnus desertorum* are at greater risk of overuse by livestock (West 1983b). There is evidence that palatable grasses such as *Achnatherum hymenoides, Elymus elymoides, Pleuraphis jamesii*, and *Sporobolus cryptandrus* may have been more abundant before grazing (West 1983). Excessive grazing stresses the system through soil disturbance, diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and annual species, particularly *Bromus madritensis, Bromus tectorum, Schismus* spp., and other exotic annual grasses. The introduction of exotic annual grasses has altered many stands by increasing the amount of fine fuels present that can substantially increase fire frequency and intensity which reduces the cover of shrubs (Sawyer et al. 2009).

When grasshopper and Mormon cricket populations reach outbreak levels, they cause significant economic losses for ranchers and livestock producers, especially when accompanied by a drought (USDA-APHIS 2003, 2010). Both rangeland forage and cultivated crops can be consumed by grasshoppers. The U.S. Department of Agriculture's (USDA) Animal and Plant Health Inspection Service (APHIS) is the Federal agency responsible for controlling economic infestations of grasshoppers on western rangelands with a cooperative suppression program. They work with federal land managing agencies to conduct grasshopper suppression. The goal of APHIS's grasshopper program is not to eradicate them but to reduce outbreak populations to less economically damaging levels (USDA-APHIS 2003). This APHIS effort dampens the natural ecological outbreak cycles of grasshoppers and Mormon crickets, but does not eradicate the species.

Human development has impacted many locations throughout the range of this type. High- and low-density urban and industrial developments have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances allow invasive non-native species to become established and outcompete and replace the dominant native perennial species. Invasive annual plant species displace natural composition and provide fine fuels that significantly increase spread of catastrophic fire. Altered fire regime further stresses livestock-altered vegetation by increasing exposure of bare ground and consequently dominance of exotic species and loss of perennial bunchgrass and sagebrush. Alteration of vegetation is extensive with low restoration potential. System remains fundamentally compromised despite restoration of some processes (CNHP 2010).

High-severity environmental degradation appears where occurrences tend to be relatively small in size (<5000 acres or <30 acres in Great Plain) and are too small to remain viable with altered natural geomorphic processes and contain insufficient area to maintain a diversity of plant associations and are vulnerable to invasive exotics. Surficial disturbances occur on more than 50% of the area (e.g., mines, energy development, or ranch activities and buildings; off-road vehicle use). Many roads are found within the occurrence (CNHP 2010). Biological soil crusts are >75% removed, remaining only in naturally protected small pockets from livestock and off-road vehicle use. The occurrence is highly fragmented and isolated (CNHP 2010). The area around the occurrence is entirely, or almost entirely, converted to agricultural or urban land use and occurrence is at best buffered on one side by natural communities (CNHP 2010). The surrounding landscape is primarily intensive agriculture or urban development (CNHP 2010).

Moderate-severity environmental degradation appears where occurrences tend to be relatively small in size (5000-10,000 acres or 30-100 acres in Great Plain) (CNHP 2010). Surficial disturbances occur on more than 20% of the area (e.g., mines, energy development, or ranch activities and buildings; off-road vehicle use). There are more than a few roads found within the occurrence (CNHP 2010). Biological soil crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence (CNHP 2010). The occurrence is moderately fragmented and isolated, and the surrounding landscape is a mosaic of agricultural or semi-developed areas with natural or semi-natural vegetation (CNHP 2010). Adjacent systems surrounding occurrence are fragmented by alteration (20-70% natural) with limited connectivity to other characteristic natural communities (CNHP 2010).

High-severity disruption of biotic processes appears where alteration of vegetation is extensive and restoration potential is low and system remains fundamentally compromised despite restoration of some processes (CNHP 2010). Vegetation within the occurrence has little or no structural diversity and is likely to have low native species diversity (CNHP 2010). Invasive exotics with major potential to alter structure and composition, such as *Acroptilon repens, Cardaria draba, Centaurea diffusa, Centaurea stoebe, Euphorbia esula, Lepidium latifolium*, and *Linaria vulgaris*, may be dominant over significant portions of the area, with little potential for control (CNHP 2010). Other non-native annuals such as *Bassia hyssopifolia, Bassia scoparia, Bromus tectorum, Halogeton glomeratus, Salsola kali*, and *Salsola tragus* are present and abundant (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity disruption of biotic processes appears where alteration of vegetation is extensive but potentially restorable over several decades (CNHP 2010). Much of the occurrence is dominated by a single structural stage, and may be lacking in vegetative species diversity (CNHP 2010). Invasive exotics with major potential to alter structure and composition, such as *Acroptilon repens, Cardaria draba, Centaurea diffusa, Centaurea stoebe, Euphorbia esula, Lepidium latifolium*, and *Linaria vulgaris*, may be widespread (3-7% of the occurrence with some patches larger than 1 acre) but potentially manageable with restoration of most natural processes (CNHP 2010). Other non-native annuals such as *Bassia hyssopifolia, Bassia scoparia, Bromus tectorum, Halogeton glomeratus, Salsola kali*, and *Salsola tragus* can be present and abundant in small patches (CNHP 2010). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES302.749 Sonora-Mojave Mixed Salt Desert Scrub

CES302.749 CLASSIFICATION

Concept Summary: This ecological system includes extensive open-canopied shrublands of typically saline basins in the Mojave and Sonoran deserts. Stands most often occur around playas and in valley bottoms or basins where evapotranspiration results in saline soils. Substrates are generally fine-textured, saline soils. Vegetation is typically composed of one or more *Atriplex* species, such as *Atriplex canescens* or *Atriplex polycarpa*, along with other species of *Atriplex*. Species of *Allenrolfea, Salicornia, Suaeda, Krascheninnikovia lanata*, or other halophytic plants are often present to codominant. In some locations, scattered *Yucca brevifolia* may occur, but other Mojavean taxa are typically not present. Graminoid species may include *Sporobolus airoides* or *Distichlis spicata* at varying densities.

Related Concepts:

- Saltbush - Greasewood (501) (Shiflet 1994) **><**

Distribution: This system is found in saline basins of the Mojave and Sonoran deserts.

Nations: MX, US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES302.749 CONCEPTUAL MODEL

Environment: This ecological system includes extensive open-canopied shrublands in saline basins, near and around washes, lower bajadas and alluvial fans in the Mojave and Sonoran deserts. Stands most often occur around playas and in valley bottoms or basins where evapotranspiration results in saline soils. Substrates are generally fine-textured, saline soils. Adjacent systems include ~Sonora-Mojave Creosotebush-White Bursage Desert Scrub (CES302.756)$$ and ~Sonoran Paloverde-Mixed Cacti Desert Scrub (CES302.761)$$ above and ~North American Warm Desert Playa (CES302.751)$$ below. The environmental description is based on several references, including Brown (1982), MacMahon and Wagner (1985), Barbour and Major (1988), MacMahon (1988), Holland and Keil (1995), Reid et al. (1999), Comer et al. (2003), Thomas et al. (2004), Barbour et al. (2007), Keeler-Wolf (2007), Sawyer et al. (2009), and NatureServe Explorer (2011).

Key Processes and Interactions: West (1982) stated that "salt desert shrub vegetation occurs mostly in two kinds of situations that promote soil salinity, alkalinity, or both. These are either at the bottom of drainages in enclosed basins or where marine shales outcrop." Species and communities are apparently sorted out along physical, chemical, moisture, and topographic gradients with *Atriplex lentiformis* being the most salt-tolerant, often occurring where the water table is close to the soil surface. It is followed by *Atriplex polycarpa* which has the broadest tolerance (5% salinity to non-saline soils). *Atriplex canescens* is the least salt-tolerant and often occurs on well-drained, sandy soil (Keeler-Wolf 2007). *Atriplex confertifolia* occurs on both saline bottomland and dry uplands.

Threats/Stressors: The primary land uses that alter the natural processes of this system are associated with livestock grazing and introduction of exotic annual grasses. Excessive grazing stresses the system through soil disturbance, diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and annual grasses, particularly *Bromus rubens, Bromus madritensis, Bromus tectorum, Schismus* spp., and other exotic annual grasses. The introduction of exotic annual grasses has altered many stands by increasing the amount of fine fuels present that can substantially increasing fire frequency and intensity, reducing the cover of fire-sensitive shrubs (Sawyer et al. 2009).

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds:

M171. Great Basin-Intermountain Dry Shrubland & Grassland

CES304.763 Colorado Plateau Blackbrush-Mormon-tea Shrubland

CES304.763 CLASSIFICATION

Concept Summary: This ecological system occurs in the Colorado Plateau on benchlands, colluvial slopes, pediments or bajadas. Elevation ranges from 560-1650 m. Substrates are shallow, typically calcareous, non-saline and gravelly or sandy soils over sandstone or limestone bedrock, caliche or limestone alluvium. It also occurs in deeper soils on sandy plains where it may have invaded desert grasslands. This is an evergreen, microphyllous scrub with succulents, half-shrubs, and scattered deciduous shrubs. The vegetation is characterized by extensive open shrublands dominated by *Coleogyne ramosissima* often with *Ephedra viridis, Ephedra torreyana*, or *Grayia spinosa*. Sandy portions may include *Artemisia filifolia, Eriogonum leptocladon, Poliomintha incana*, or *Quercus havardii var. tuckeri* (relict populations) as codominant. The herbaceous layer is sparse and composed of graminoids such as *Achnatherum hymenoides, Pleuraphis jamesii*, or *Sporobolus cryptandrus*.

Related Concepts:

- Blackbush (212) (Shiflet 1994) **>**

Distribution: Occurs in the Colorado Plateau on benchlands, colluvial slopes, pediments or bajadas. Elevation ranges from 560-1600 m.

Nations: US

Concept Source: K.A. Schulz

Description Author: K.A. Schulz

CES304.763 CONCEPTUAL MODEL

Environment: This shrubland ecological system occurs in the Colorado Plateau at elevations ranging from 580 to 1650 m (1903-5413 feet) (Bowns and West 1976). *Climate:* This shrubland system occurs in an arid to semi-arid climate with annual precipitation in the form of summer monsoons and winter storms is generally less than 30 cm, averaging approximately 20 cm.

Physiography/landform: Stands occur on gentle to steep, bouldery or rocky colluvial and alluvial slopes of mountains, plateaus, canyons, washes, valley bottoms, and mesas with varying aspects (Anderson 2001a).

Soils/substrates/hydrology: Substrates are shallow, well-drained, typically calcareous, non-saline and gravelly or sandy soils over sandstone or limestone bedrock, caliche or limestone alluvium, but may include other parent materials such as shale, gneiss, quartzites, and igneous rocks (Anderson 2001a). Effective soil moisture appears to be primarily controlled by regolith depth and position in relation to the water table. This brushland system occupies most sites where regolith is uniformly shallow. In association with blackbrush (*Coleogyne ramosissima*) sites, the soil moisture is concentrated on top of impermeable bedrock at a shallow depth. This perching effect allows for gradual uptake of moisture by the plants roots (Loope and West 1979). This permits growth of plants with more mesic habitat requirements (Warren et al. 1982). On sites with deep soil, blackbrush may occur in almost pure occurrences with only a few associated species (Warren et al. 1982). Dark-colored biological soil crusts, composed of lichens, mosses, fungi, and algae, are often present in this system in fairly undisturbed areas. Sandy soils may have more biological soil crusts than clayish or silty soil surfaces.

Key Processes and Interactions: Blackbrush is a slow-growing, long-lived, drought-tolerant, evergreen shrub with a diffuse and shallow root system (Bowns 1973, Anderson 2001a). It may lose older leaves during the dry summer season (drought-deciduous) to reduce water stress and become dormant during dry periods. Unlike many rosaceous species, *Coleogyne ramosissima* is wind-pollinated and largely self-incompatible (Pendleton et al. 1995, Pendleton and Pendleton 1998). Blackbrush is a mast species. The resulting fruit crop is a function of available stored energy, producing abundant crops of seeds every few to several years (Pendleton and Meyer 2004).

In general, seed germination and establishment are rare as seedings are uncommon (Anderson 2001a). The germination rate is low, except after a wet spring when soils remain moist for two weeks (Lei 1997). Seeds also require cold stratification (6 weeks) without light to break dormancy (Lei 1997, Meyer and Pendleton 1990). Seeds appear to remain viable for a long time in seed bank. Meyer and Pendleton (2005) observed 80% germination from 15-year-old seeds. Abundant seedlings have been observed in clumps from rodent caches (Bowns and West 1976, Lei 1997) or after heavy spring rains, which suggests adaptions to seed caching by small mammals or large runoff events that bury seeds. Kangaroo rats are the main seed dispersers, caching large numbers during mast years (Meyer and Pendleton 2005). Fruits are large and require small mammals or large storm runoff for dispersal (Anderson 2001a).

Blackbrush also provides fair forage for desert bighorn sheep (*Ovis canadensis nelsoni*) and mule deer (*Odocoileus hemionus*) during the winter, and it can tolerate heavy browsing (USFS 1937, Mozingo 1986, Anderson 2001a). Herbaceous forage from understory is generally low.

Fire does not appear to play a role in maintenance of shrublands within this system. Topographic breaks dissect the landscape, and isolated pockets of vegetation are separated by rock walls or steep canyons that protect it from spreading fire. Blackbrush is fire-intolerant (Loope and West 1979). It does not sprout after fire and is slow to re-colonized burned sites (Wright 1972). In shallow regolith situations, secondary succession, in the sense of site preparation by seral plants, may not occur at all (Loope and West 1979). In *Coleogyne ramosissima* mixed shrub stands, fire will favor more fire-tolerant shrubs such as *Artemisia filifolia, Ephedra viridis, Grayia spinosa, Quercus havardii var. tuckeri*, or ruderal species (Tirmenstein 1999j, Anderson 2001a, 2001b, Gucker 2006d).

Biological soil crusts associated with the system are negatively affected by fire, as burning reduced biological soil crusts from 9% cover to less than 1% of total cover, and there was little evidence of recovery postburn after 19 years (Callison et al. 1985). Biological soil crusts are critically important for soil fertility, soil moisture, and soil stability in the many semi-arid ecosystems in the western U.S. (Belnap and Lange 2003). Biological soil crusts fix large amounts of soil nitrogen (mostly by cyanobacteria) and soil carbon, they protect soils from wind erosion, and rough surface texture slows runoff and allows for more infiltration (Evans and Belnap 1999, Belnap et al. 2001, Belnap and Lange 2003, Johansen 2001). Fires in desert scrub are typically patchy and vary in severity, leaving patches of biological crust organisms to recolonize. Recover rates for biological soil crust organisms vary, e.g., green algae (~2 years), cyanobacteria (2-6 years), mosses (3-8 years); however, lichens may take decades (Johansen 2001).

Burning blackbrush stands should be minimized because of the unpredictability of successive vegetation, accelerated soil erosion, long-term or permanent removal of blackbrush, and damage to biological soil crusts (Wright 1980, West 1983d, 1988, Callison et al. 1985).

LANDFIRE (2007a) VDDT model for this system (BpS 2310780) has three classes:

A) Early Development 1 Open (5% of type in this stage): Shrub cover is 0-5%. Dominated by grasses, shrub seedlings and post-fire associated forbs. This type typically occurs where fires burn relatively hot in classes B and C. Shrubs (*Coleogyne ramosissima, Ephedra viridis, Ephedra torreyana*, and *Grayia spinosa*) will generally be re-established after 20-30 years.

B) Late Development 2 Closed (shrub-dominated - 30% of type in this stage): Shrub cover (*Coleogyne ramosissima, Ephedra viridis, Ephedra torreyana*, and *Grayia spinosa*) 21-100%. Greater than 15% shrub cover and 10-20% herb cover; generally associated with more productive soils. Effects of cumulative drought can cause a shift from this class to class C.

C) Late Development 1 Closed (shrub-dominated - 65% of type in this stage): Shrubs (*Coleogyne ramosissima, Ephedra viridis, Ephedra torreyana*, and *Grayia spinosa*) are the dominant lifeform with canopy cover of 10-20%. Less than 15% shrub cover and <10% herb cover generally associated with less productive cobbly and gravelly soils. Effects of cumulative drought can cause a shift from class B to this class.

LANDFIRE modelers emphasized that blackbrush is fire-intolerant, may be slow to re-establish following fire such that grasses may dominate immediately following fire. Invasion of non-native annual grasses following fire is likely under current conditions (LANDFIRE 2007a). LANDFIRE modelers state that generally, the mean fire interval is approximately 75 years with high variability due to annual variation in drying of shrub foliage, shrub mortality and grass and forb production related to drought and moisture cycles (LANDFIRE 2007a). There is also high variation in ignitions and associated fire weather (LANDFIRE 2007a). Fire years are typically correlated with wet years that produce high herbaceous biomass/fine fuel amounts. In areas with high summer moisture from monsoon season rains there are many chances for lightning strikes (LANDFIRE 2007a). Fire-return intervals would have been much longer in drier geographic areas with return intervals over 200 years (LANDFIRE 2007a). Fire size would have been small because of the discontinuous fuel; frequent topographic breaks that dissect the landscape creating isolated pockets of vegetation are separated by rock walls or steep canyons (LANDFIRE 2007a).

Threats/Stressors: Altered fire regime and invasive species are the biggest threats to this system. These are brought on by activities that disturb vegetation and biological soil crusts and include livestock grazing, mining, utility rights-of-way, ORVs and other dispersed recreation. Conversion of this type has commonly come from burning. Burning blackbrush stands is not recommended due to the unpredictability of successive vegetation, accelerated soil erosion, long-term or permanent removal of blackbrush, and damage to biological soil crusts (Wright 1980, West 1983d, 1988, Callison et al. 1985). Following fires, these communities are often colonized by non-native grasses, such as *Bromus rubens* and *Bromus tectorum* which serve to encourage recurrent fires and delay shrub regeneration. Where non-native annual grasses have invaded, fire may be much more frequent than the reference condition and can cause a rapid decline in ecological function (and a higher Fire Regime Condition Class) (LANDFIRE 2007a).

Human development and land use have impacted many areas. Fragmentation from transportation infrastructure (roads, railways, pipelines and transmission lines) leads to dispersal of invasive non-native species and altered hydrological processes such as surface flow when excessive runoff from roads creates gullies. Additionally, increased mortality from road kill affects wildlife populations. Other developments that have large impacts include high- and low-density urban and industrial such as energy (renewable wind/solar, oil/gas), mining and landfills. Human land-use impacts from recreation (ORVs, mountain biking, hiking) and agriculture (livestock grazing/browsing) can also be significant (West 1983d).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from burning, loss of shrub cover, soil erosion from wind and conversion to active dune and sandsheet systems or to exotic annual grasses (West 1983d, 1988). Widespread burning to reduce blackbrush in the 1940s and 1950s converted vast areas dominated by the ruderal half-shrub *Gutierrezia sarothrae* and exotic annual grasses (West 1983d).

High-severity environmental degradation appears where occurrences have been fragmented into relatively small (<25 acres) sizes for this large-patch type and have evidence of burning; excessive livestock grazing and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion and stands remain fundamentally compromised despite restoration of some processes (Rondeau 1999). Soil compaction and continued disturbance is extensive throughout the occurrence. Heavy invasion of non-native annual grasses will eventually result in a stand-replacing fire and conversion from native shrubland to invasive annual grassland post-burn. The resulting altered fire regime will eliminate potential for restoration because of extensive non-native degradation and frequent fire. Biological soil crust, if present, is found only in small protected areas.

Moderate-severity environmental degradation appears where occurrences are moderate (<100 acres) in size for this large-patch type and have evidence of heavy livestock grazing and/or mechanical disturbance from vehicles resulting in soil compaction and erosion (Rondeau 1999). Invasion of non-native annual grasses degrades stands and increases risk of stand-replacing fire that will eliminate shrubs and reduce all native species. Stands have potential for restoration over several decades. Biological soil crust is present in protected areas and with a minor component elsewhere.

High-severity biotic disruption appears where non-native herbaceous species are dominant (Rondeau 1999). Alteration of vegetation is extensive and restoration potential is low. Connectivity is severely hampered by fragmentation from roads that restrict or prevent natural ecological processes from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where herbaceous species are codominated by native and non-native species. Alteration of vegetation is extensive but potentially restorable over several decades. Fragmentation is less than 15% of the occurrence. Invasive woody species may be present but still controllable. Connectivity is severely hampered by fragmentation from roads that restrict or prevent natural ecological processes from occurring, and create barriers to natural movement of animal and plant populations. Some non-natural barriers are present. Significant disturbance has occurred but damage is easily restorable. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.993 Columbia Basin Foothill and Canyon Dry Grassland

CES304.993 CLASSIFICATION

Concept Summary: These grasslands are similar floristically to ~Columbia Basin Palouse Prairie (CES304.792)$$ but are distinguished by landform, soil, and process characteristics. They occur in the canyons and valleys of the Columbia Basin, particularly along the Snake River canyon, the lower foothill slopes of the Blue Mountains, and along the main stem of the Columbia River in eastern Washington. Occurrences are found on steep open slopes, from 90 to 1525 m (300-5000 feet) elevation. Annual precipitation is low, ranging from 10 to 25 cm (4-10 inches). Settings are primarily long, steep slopes of 100 m to well over 400 m, with soils derived from residuum and having patchy, thin, wind-blown surface deposits. Slope failures are a common process. Fire frequency is presumed to be less than 20 years. The vegetation is dominated by patchy graminoid cover, cacti, and some forbs. *Pseudoroegneria spicata, Festuca idahoensis*, and *Opuntia polyacantha* are common species. Deciduous shrubs *Symphoricarpos* spp., *Physocarpus malvaceus, Holodiscus discolor*, and *Ribes* spp. are infrequent native species that may increase with fire exclusion.

CES304.993 CONCEPTUAL MODEL

Environment: These dry grasslands are distinguished by landform, soil, and process characteristics. Annual precipitation is low, ranging from 12-25 cm (5-10 inches) that occurs mostly in the winter, primarily as rain. They occur in the canyons and valleys of the Columbia Basin, particularly along the Snake River canyon, the lower foothill slopes of the Blue Mountains, and along the main stem of the Columbia River in eastern Washington. Occurrences are found on steep open slopes, from 90 to 1525 m (300-5000 feet) elevation. Landform settings of this grassland are primarily long, steep slopes of 100 m to well over 400 m in length, with colluvial soils derived from residuum and having patchy, thin, wind-blown surface deposits. Bare ground, gravel and rock between bunches are common features due to frequent soil movement and sun exposure. Biological soil crust cover is usually present but generally decreases with increasing vascular plant cover, elevation, loose surface rock, and coarseness of soil. Elk, deer and bighorn sheep are native large grazers in the canyon who used these grasslands, particularly in winter and spring (Tisdale 1986).

Key Processes and Interactions: This grassland primarily occurs on long, steep slopes. Surface disturbances from slope failure are a common process. Most slips result from saturated soil layers over frozen ground (Tisdale 1986). Fire is the primary disturbance factor. Historically, fire resulted in top-kill and some mortality, although the overall grassland was not changed. Fires were low intensity due to limited fuel and significant internal spacing between fuel patches. Currently, cheatgrass and other introduced grasses often invade these habitats after fire. The historic frequency was 5-20 years. Fire frequency is presumed to be less than 20 years; the return interval may have been as low as 5-10 years (Landfire 2007a).

Biological soil crust cover diminishing or eliminated alters the composition of perennial species and increases the establishment of native disturbance-increasers and annual grasses, particularly *Bromus tectorum* and other exotic annual bromes (WNHP 2011). Crust cover and diversity are greatest where not impacted by trampling, other soil surface disturbance and fragmentation (Belnap et al. 2001, Rosentreter and Eldridge 2002, Tyler 2006).

Threats/Stressors: In the early 1900s, heavy sheep and cattle grazing led to an increase of shrubs into much of the area, although shrubs generally don't occur in the canyon grassland (Landfire 2007a). Currently, the primary land uses that alter the natural processes of this system are associated with livestock practices, annual non-native species invasion, fire regime alteration, direct soil surface disturbance, and fragmentation (WNHP 2011). Excessive grazing stresses the system through soil disturbance, diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increases the establishment of native disturbance-increasers and annual grasses particularly *Bromus tectorum* and exotics forbs such as *Centaurea solstitialis*. Persistent grazing will further diminish perennial cover, expose bare ground, and increase exotic annuals. Darambazar et al. (2007) cite Johnston (1962) that when bare ground is approximately 15% reduced infiltration and increased runoff occur in fescue grassland ecosystems. Fire further stresses livestock-altered vegetation by increasing exposure of bare ground and consequent increases in exotic annuals and decrease in perennial bunchgrass. Due to steepness of terrain, grazing effects are usually concentrated in less steep slopes, although grazing does create contour trail networks that can lead to addition slope failures.

In more mesic canyon steppe, fire suppression leads to deciduous shrubs (*Symphoricarpos* spp., *Physocarpus malvaceus, Holodiscus discolor*, and *Ribes* spp.) and in some areas trees (*Pinus ponderosa* or *Pseudotsuga menziesii*) to increase (WNHP 2011). Additional disturbances, such as vehicle tracks, will increase the probability of alteration of vegetation structure and composition and response to fire as discussed above. Invasive perennial exotics such as *Hypericum perforatum, Poa pratensis*, and *Prunus cerasifera* are major site stressors. Davies et al. (2009) conclude that sites with heavy litter accumulation (e.g., ungrazed *Artemisia tridentata ssp. wyomingensis / Festuca idahoensis - Achnatherum thurberianum* community) are more susceptible to exotic annual invasion following fire than those with less litter accumulation. They note that introduced species and changes in climate can change ecosystem response to natural disturbance regimes.

Tisdale (1986) notes that canyon grasslands are "highly stable, with boundaries that are unlikely to change without a sizeable shift in climate." And that "grassland community changes caused by heavy grazing do not appear to have altered their pattern of distribution."

Conversion of this type has commonly come from agriculture (wheat farming) in less steep foothill sites, historically (Landfire 2007a). Currently, conversion is to invasive non-native species such as *Bromus tectorum, Centaurea solstitialis, Hypericum perforatum, Poa pratensis*, and *Prunus cerasifera*. These invasive species increase post disturbance including excessive grazing by livestock, or direct soil disturbance from severe trampling by livestock and roads. Altered fire regimes, including frequent fires, result in annual, non-native brome-dominated sites. On mesic sites, fire suppression has allowed succession and conversion to deciduous shrublands (*Symphoricarpos* spp., *Physocarpus malvaceus, Holodiscus discolor*, and *Ribes* spp.) and in some areas trees (*Pinus ponderosa* or *Pseudotsuga menziesii*) to increase (Landfire 2007a, WNHP 2011). Common stressors and threats include fragmentation from agriculture and roads, altered fire regime from fire suppression and indirectly from livestock grazing and fragmentation, introduction of invasive non-native species (WNHP 2011).

Potential climate change effects could include a shift to species more common on hotter, drier southern aspects, if climate change has the predicted effect of less effective moisture with increasing mean temperature (TNC 2013).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances that allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<25 acres) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval to >20 years (Landfire 2007a) resulting in regeneration of trees and shrubs (5-10 % cover). Biological soil crust, if present, is found only in protected areas (WNHP 2011). Moderate-severity environmental degradation appears where occurrences are moderate (25-1250 acres) in size and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion. Altered fire regime from fire suppression and reduction of fine fuels by grazing increased the fire-return interval from >20 years (Landfire 2007a) resulting in regeneration of trees and shrubs (5-10 % cover). Biological soil crust is present in protected areas and with a minor component elsewhere (WNHP 2011).

High-severity disruption appears where occurrences have low cover of native grassland species (<50% relative cover) (WNHP 2011). There may be significant cover of shrubs and/or trees (>10%) because of fire suppression. Invasive non-native species are abundant (>10% absolute cover) (WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Moderate-severity disruption appears where occurrences have low cover of native grassland species (50-85% relative cover) (WNHP 2011). There may be significant cover of shrubs and/or trees (5-10%) because of fire suppression. Invasive non-native species are abundant (3-10% absolute cover) (WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.775 Inter-Mountain Basins Active and Stabilized Dune

CES304.775 CLASSIFICATION

Concept Summary: This ecological system occurs in the Intermountain western U.S. on basins, valleys and plains. Often it is composed of a mosaic of migrating, bare dunes; anchored dunes with sparse to moderately dense vegetation (<10-30% canopy cover); and stabilized dunes. The system is defined by the presence of migrating dunes or, where the dunes are entirely anchored or stabilized, evidence that the substrate is eolian and not residual, that the vegetation is early- or mid-seral, and that the substrate is likely to become actively migrating again with disturbance or increased aridity. In the Colorado Plateau, there are many small active and partially vegetated dunes along some of the larger washes and playas (where sand is blown out of wash and forms dunes) and some larger dunes such as Coral Pink Dunes in southwestern Utah. Substrates are usually eolian sand, but small dunes composed of silt and clay downwind from playas in the Wyoming Basins (which usually support greasewood vegetation) also are included here. Species occupying these environments are often adapted to shifting, coarse-textured substrates (usually quartz sand) and form patchy or open grasslands, shrublands or steppe, and occasionally woodlands. Vegetation varies and may be composed of *Achnatherum hymenoides, Artemisia filifolia, Artemisia tridentata ssp. tridentata, Atriplex canescens, Ephedra* spp., *Chrysothamnus viscidiflorus, Coleogyne ramosissima, Ericameria nauseosa, Hesperostipa comata, Leymus flavescens, Muhlenbergia pungens, Psoralidium lanceolatum, Purshia tridentata, Redfieldia flexuosa, Sporobolus airoides, Sarcobatus vermiculatus, Tetradymia tetrameres*, or *Tiquilia* spp. Herbaceous species such as *Achnatherum hymenoides, Redfieldia flexuosa*, and *Psoralidium lanceolatum* are characteristic of early-seral vegetation through much of this system's range. Shrubs are commonly dominant on mid- to late-seral stands, and *Ericameria nauseosa* can be found at any stage.

Related Concepts:

Distribution: This system occurs in intermountain basins of the western U.S. including southwestern Montana in the Centennial Valley.

CES304.775 CONCEPTUAL MODEL

Environment: This ecological system occurs in the intermountain western U.S. on basins, valleys and plains. Often it is composed of a mosaic of migrating, bare dunes; anchored dunes with sparse to moderately dense vegetation (<10-30% canopy cover); and stabilized dunes. The system is defined by the presence of migrating dunes or, where the dunes are entirely anchored or stabilized, evidence that the substrate is eolian and not residual, that the vegetation is early- or mid-seral, and that the substrate is likely to become actively migrating again with disturbance or increased aridity. In the Colorado Plateau and Great Basin, there are many small, active and partially vegetated dunes along some of the larger washes and on sides of playas and basins (where sand is blown out of a wash or basin and forms dunes) and some larger dunes, including Coral Pink Dunes in southwestern Utah, Great Sand Dunes in south-central Colorado, Alkali Lake Dunes in southern Oregon, and many in Nevada, such as Clayton Valley Dunes, Crescent Dunes, Fish Lake Dunes, Sand Mountain, Silver State Dunes, Teel Mountain and Winnemucca Dunes. Substrates are usually eolian sand, but small dunes composed of silt and clay downwind from playas in the Wyoming Basins (which usually support greasewood vegetation) also are included here. Species occupying these environments are often adapted to shifting, coarse-textured substrates (usually quartz sand) and form patchy or open grasslands, shrublands or steppe, and occasionally woodlands. The environmental description is based on several other references, including Chadwick and Dalke (1965), Bowers (1982), Caicco and Wellner (1983e), Pavlik (1985, 1989), Fryberger et al. (1990), Knight (1994), Pineada et al. (1999), Reid et al. (1999), Marin et al. (2005), Forman et al. (2006), Jones (2006), Hallock et al. (2007), Sawyer et al. (2009).

Key Processes and Interactions: Periodic drought influences dune migration rates by reducing vegetation cover that anchors dunes (Marin et al. 2005, Forman et al. 2006). Disturbances by fire, heavy grazing, and burrowing are important processes influencing successional dynamics (Lesica and Cooper 1998). A typical primary successional sere on sands appears to be as follows: bare sand or sparse herbaceous vegetation on migrating sand; denser herbaceous vegetation or shrub stands of *Ericameria nauseosa* on anchored or recently stabilized sand; and shrub vegetation of *Artemisia tridentata, Atriplex canescens, Purshia tridentata, Sarcobatus vermiculatus*, and other long-lived shrub and tree species on longer-stabilized sands. Vegetation growing on stabilized sandsheets and dunes may be dense enough to carry fire, especially when there is strong wind. Fire reduces vegetation cover and, when stabilized dunes burn followed by wind or drought, local blowouts may occur or stabilized dunes may become active. This creates bare areas capable of supporting early-successional species.

Threats/Stressors: Invasive annual herbaceous species especially *Salsola tragus*, have colonized and stabilized large areas of formally active dunes at Petrified Forest National Park, Arizona, interfering with natural dune processes (Thomas et al. 2009a).

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES304.787 Inter-Mountain Basins Semi-Desert Grassland

CES304.787 CLASSIFICATION

Concept Summary: This widespread ecological system includes the driest grasslands throughout the intermountain western U.S. It occurs on xeric sites over an elevation range of approximately 1450 to 2320 m (4750-7610 feet) on a variety of landforms, including swales, playas, mesas, alluvial flats, and plains. This system may constitute the matrix over large areas of intermountain basins, and also may occur as large patches in mosaics with shrubland systems dominated by *Artemisia tridentata ssp. tridentata, Artemisia tridentata ssp. wyomingensis, Atriplex* spp., *Coleogyne* spp., *Ephedra* spp., *Gutierrezia sarothrae*, or *Krascheninnikovia lanata*. Grasslands in areas of higher precipitation, at higher elevation, typically belong to other systems. Substrates are often well-drained sandy or loam soils derived from sedimentary parent materials but are quite variable and may include fine-textured soils derived from igneous and metamorphic rocks. The dominant perennial bunchgrasses and shrubs within this system are all drought-resistant plants. Dominant or codominant species are *Achnatherum hymenoides, Aristida* spp., *Bouteloua gracilis, Hesperostipa comata, Muhlenbergia* spp., *Pleuraphis jamesii*, or *Sporobolus* spp. Scattered shrubs and dwarf-shrubs often are present, especially *Artemisia tridentata ssp. tridentata, Artemisia tridentata ssp. wyomingensis, Atriplex* spp., *Coleogyne* spp., *Ephedra* spp., *Ericameria* spp., *Gutierrezia sarothrae*, and *Krascheninnikovia lanata*. This system is typically composed of cool-season grasses in the western portion of its range where winter precipitation dominates, and a mix of cool- and warm-season grasses where precipitation occurs during both winter and summer seasons (Colorado Plateau). Grasslands in the basins of south-central and southwestern Wyoming, dominated by *Pseudoroegneria spicata* and *Poa secunda* and containing cushion-form forbs and other species typical of dry basins, are included in this system.

- Grama - Galleta (502) (Shiflet 1994) **<**

Distribution: This system occurs throughout the intermountain western U.S. on dry plains and mesas, at approximately 1450 to 2320 m (4750-7610 feet) elevation. In the Bighorn Basin of north-central Wyoming, there may be some desert grasslands, but this is uncertain.

CES304.787 CONCEPTUAL MODEL

Environment: This widespread semi-arid ecological system consists of lower-elevation dry grasslands found on plains, mesas and foothills throughout the intermountain western U.S. Elevation ranges from approximately 1450 to 2320 m (4750-7610 feet).

Climate: Climate usually includes hot summers and cold winters with freezing temperatures and snow common. Annual precipitation is usually from 20-40 cm (7.9-15.7 inches). A significant portion of the precipitation falls in July through October during the summer monsoon storms, with the rest falling as snow during the winter and early spring months (bimodal precipitation). However, precipitation in the western portion of this system's range occurs primarily in the winter.

Physiography/landform: These grasslands occur on a variety of aspects, slopes and landforms, including swales, playas, mesas, alluvial flats, plains and hillslopes. Stands are found in lowland and upland areas usually on xeric sites. Grasslands in areas of higher precipitation, at higher elevation, typically belong to other systems.

Soil/substrate/hydrology: Substrates range from deep to shallow, frequently well-drained sandy or loam soils derived from sandstone or shale parent materials but are quite variable and may include fine-textured soils derived from igneous and metamorphic rocks. Some occurrences on sandy soils have a high cover of cryptogams on the soil surface. These cryptogams tend to increase the stability of the highly erodible sandy soils of these grasslands during torrential summer rains and heavy wind storms (Kleiner and Harper 1977). *Muhlenbergia*-dominated grasslands which flood temporarily, combined with high evaporation rates in this dry system, can have accumulations of soluble salts in the soil. Soil salinity depends on the nature of the parent material and on the amount and timing of precipitation and flooding. Growth-inhibiting salt concentrations are diluted when the soil is saturated, allowing the growth of less salt-tolerant species. As the saturated soils dry, the salt concentrates until it precipitates out on the soil surface (Dodd and Coupland 1966, Ungar 1968). The environmental description is based on several other references, including Barbour and Major (1977), Brown (1982), West (1983e), Knight (1994), Reid et al. (1999), West and Young (2000), Tuhy et al. (2002), Barbour et al. (2007), and Sawyer et al. (2009).

Key Processes and Interactions: Disturbance dynamics in this semi-arid grassland system are variable because of variation in the composition; however, most are dominated by perennial bunchgrasses that are adapted to low- to medium-frequency (<30 to <100 years) and low- to medium-intensity fires (Howard 1997a, b, Tirmenstein 1999e, Zlatnik 1999a, b, Johnson 2000c, Simonin 2000a, b, c, Anderson 2003a, Sawyer et al. 2009). Most of the species are classified as resistant or tolerant of fire, with the exception of *Bouteloua eriopoda*, which is classified as sensitive, but will recover quickly if there is adequate summer moisture (Simonin 2000a). Season of burn is also important for predicting post-burn recovery.

The majority of characteristic grass species, such as *Achnatherum hymenoides, Aristida* spp., *Bouteloua eriopoda, Bouteloua gracilis, Hesperostipa comata, Pleuraphis jamesii, Poa secunda, Pseudoroegneria spicata, Sporobolus airoides*, and *Sporobolus cryptandrus*, will be top-killed after burning, then resprout from rootcrowns unless the fire was very severe (Howard 1997a, b, Tirmenstein 1999e, Zlatnik 1999a, b, Johnson 2000c, Simonin 2000a, b, c, Anderson 2003a, Sawyer et al. 2009). This grassland system is maintained by fires that kill or reduce cover of the more fire-sensitive shrub species.

The dominant perennial grass species are well-adapted to the semi-arid conditions. *Achnatherum hymenoides* is one of the most drought-tolerant, cool-season grasses in the western U.S. (USFS 1937, Tirmenstein 1999e). It is also a valuable forage grass in arid and semi-arid regions. *Hesperostipa comata* is a deep-rooted, cool-season grass that uses soil moisture below 0.5 m depth during the dry summers. It is prone to litter accumulations at plant bases, which can increase intensity of fire, making it more susceptible to mortality (Zlatnik 1999a). *Bouteloua gracilis* is a drought- and very grazing-tolerant warm-season grass that generally forms a short sod. *Pleuraphis jamesii*, also a warm-season grass, is only moderately palatable to grazers, but decreases when heavily utilized during drought and in the more arid portions of its range where it is the dominant grass (West et al. 1972). This grass reproduces extensively from scaly rhizomes, which make the plant resistant to trampling by large wildlife or livestock and have good soil-binding properties (Weaver and Albertson 1956, West 1972).

Insects are an important component of many shrub-steppe and grassland systems. Mormon crickets and grasshoppers are natural components of many rangeland systems (USDA-APHIS 2003, 2010). There are almost 400 species of grasshoppers that inhabit the western United States with 15-45 species occurring in a given rangeland system (USDA-APHIS 2003). Mormon crickets are also present in many western rangelands and, although flightless, are highly mobile and can migrate large distances consuming much of the forage while travelling in wide bands (USDA-APHIS 2010). Following a high population year for grasshoppers or Mormon crickets and under relatively warm dry spring environmental conditions that favor egg hatching and grasshopper and Mormon cricket survival, there may be large population outbreaks that can utilize 80% or more of the forage in areas as large as 2,000 square miles. Conversely, relatively cool and wet spring weather can limit the potential for outbreaks. These outbreaks are naturally occurring cycles and, especially during drought, can denude an area of vegetation leaving it exposed to increased erosion rates from wind and water (USDA-APHIS 2003).

LANDFIRE developed this VDDT model for this system for the Great Basin using two classes (LANDFIRE 2007a, BpS 1211350).

A) Early Development 1 Open (grass-dominated - 20% of type in this stage): Dominated by grasses (*Achnatherum hymenoides, Hesperostipa comata*) and post-fire-associated forbs, and remnant *Artemisia tridentata*. Perennial grasses and forbs dominate (generally 25-40% cover) where woody shrub canopy has been top-killed/removed by wildfire. Shrub cover is less than 5%. Replacement fire occurs every 120 years on average. Succession to class B after 20 years.

B) Mid Development 1 Open (grass with shrubs - 80% of type in this stage): Dominated by grasses (*Achnatherum hymenoides, Hesperostipa comata*) and *Artemisia tridentata*. Shrubs compose the upper layer lifeform (5-25% cover) with diverse perennial grass and forb understory dominant. Mean fire-return interval (FRI) is 75 years with 80% replacement fire (mean FRI of 94 years) and 20% mixed-severity fire (mean FRI of 375 years). Mixed-severity fire, insect/disease (return interval of 75 years), and weather-related stress (return interval of 100 years) maintain vegetation in class B.

Threats/Stressors: Conversion of this type has commonly come from the combination of heavy livestock use and drought, which can push these grassland communities over thresholds that are often irreversible because of soil loss and arroyo formation. Relatively intact sites will have both native perennial grasses and intact biological soil crusts. Conversions occur as biological soil crusts decrease, shrubs increase, and non-native species begin to invade, such as *Bromus rubens, Bromus tectorum, Centaurea solstitialis, Hypericum perforatum*, and *Poa pratensis*. The final endpoint on severely altered sites is non-native grasses and severe soil loss. This has been well established on both the Colorado Plateau and Great Basin.

The primary land uses that alter the natural processes of this system are associated with livestock practices, invasive annual plant invasion, fire regime alteration, direct soil surface disturbance, and fragmentation (WNHP 2011). Excessive grazing stresses the system through soil disturbance, diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers including *Aristida* spp., *Ericameria* spp., and *Gutierrezia sarothrae*, and annual grasses, particularly *Bromus tectorum* and other exotic annual bromes. Persistent grazing will further diminish perennial grass cover, expose bare ground, increase exotic annuals, and may lead to higher density of *Ericameria* spp. or *Gutierrezia sarothrae*. Fire further stresses livestock-altered vegetation by increasing exposure of bare ground to erosion and consequent increases in exotic annuals and decrease in perennial bunchgrasses. The introduction of *Bromus tectorum* into these communities has altered fuel loads and fuel distribution. More frequent fire favors cool-season annuals that complete their life cycles in early spring, leaving abundant fine fuels that burn hot and damage and kill perennial grasses. Fragmentation of grasslands by agriculture also increases cover of annual grass, annual/biennial forbs, bare ground, decreases cover of perennial forbs and biological soil crusts, and reduces obligate insects (Quinn 2004), obligate birds and small mammals (Vander Haegen et al. 2001).

When grasshopper and Mormon cricket populations reach outbreak levels, they cause significant economic losses for ranchers and livestock producers, especially when accompanied by a drought (USDA-APHIS 2003, 2010). Both rangeland forage and cultivated crops can be consumed by grasshoppers. The U.S. Department of Agriculture's (USDA) Animal and Plant Health Inspection Service (APHIS) is the federal agency responsible for controlling economic infestations of grasshoppers on western rangelands with a cooperative suppression program. They work with federal land managing agencies to conduct grasshopper suppression. The goal of APHIS's grasshopper program is not to eradicate them but to reduce outbreak populations to less economically damaging levels (USDA-APHIS 2003). This APHIS effort dampens the natural ecological outbreak cycles of grasshoppers and Mormon crickets but does not eradicate the species.

Human development has impacted many locations throughout the range of this system. High- and low-density urban and industrial developments can have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Common stressors and threats include fragmentation from roads, ORV use (LANDFIRE 2007a, WNHP 2011), altered fire regime from too frequent fires caused by build ups of fine fuels from invasion of non-native annual grasses (Pellant 1990, 1996), altered fire regime from active fire suppression and indirect fire suppression from livestock grazing and fragmentation, and introduction of

invasive non-native species (WNHP 2011). The most serious current threat is from the interaction between livestock grazing and long-term drought, which together exceed the resilience of system and leads to degradation and conversion.
Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing often combined with drought where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<50 acres) (WNHP 2011) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from too frequent fires caused by build ups of fine fuels from invasion of non-native annual grasses resulting in loss of shrubs and reduction of all native species especially dominant native grasses to <50% total cover (WNHP 2011). Altered fire regime from historic and ongoing fire suppression and reduction of fine fuels by grazing has increased the estimated mean fire-return interval for all fires from 75-94 years to >100 years (Landfire 2007a) resulting in regeneration of shrubs (>20% cover). Biological soil crust, if present, is found only in protected areas (WNHP 2011).

Moderate-severity environmental degradation appears where occurrences are moderate (50-500 acres) (WNHP 2011) and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion. Altered fire regime from too frequent fires caused by build ups of fine fuels from invasion of non-native annual grasses resulting in reduction of shrubs and reduction of all native species especially dominant native grasses to 50-79% total cover WNHP 2011. Altered fire regime from fire suppression and reduction of fine fuels by grazing has increased the estimated mean fire-return interval for all fires from 75-94 to >100 years (Landfire 2007a) resulting in regeneration of shrub (>20% cover). Biological soil crust is present in protected areas and with a minor component elsewhere (WNHP 2011).

High-severity disruption appears where occurrences have low cover of native grassland species (<50% relative cover) (WNHP 2011). There may be significant cover of shrubs (well >20%) because of fire suppression that is suppressing native perennial grasses (WNHP 2011). Invasive non-native species are abundant (>10% absolute cover to dominant) (CNHP 2010, WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. The change in plant composition often has negative consequences for invertebrate guilds such as pollinators or herbivorous species that rely on annual or perennial forbs or perennial grasses to complete life cycles.

Moderate-severity disruption appears where occurrences have low cover of native grassland species (50-85% relative cover) (WNHP 2011). There may be significant cover of shrubs (>20%) because of fire suppression that is beginning to suppress native grasses (WNHP 2011). Invasive non-native species are abundant (3-10% absolute cover) (CNHP 2010, WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. The change in plant composition often has negative consequences for invertebrate guilds such as pollinators or herbivorous species that rely on annual or perennial forbs or perennial grasses to complete life cycles.

CES304.788 Inter-Mountain Basins Semi-Desert Shrub-Steppe

CES304.788 CLASSIFICATION

Concept Summary: This ecological system occurs throughout the intermountain western U.S., typically at lower elevations on alluvial fans and flats with moderate to deep soils, and extends into south-central Montana between the Pryor and Beartooth ranges where a distinct rainshadow effect occurs. This semi-arid shrub-steppe is typically dominated by graminoids (>25% cover) with an open shrub to moderately dense woody layer with a typically strong graminoid layer. The most widespread (but not dominant) species is *Pseudoroegneria spicata*, which occurs from the Columbia Basin to the Northern Rockies. Characteristic grasses include *Achnatherum hymenoides, Bouteloua gracilis, Distichlis spicata, Poa secunda, Poa fendleriana, Sporobolus airoides, Hesperostipa comata, Pleuraphis jamesii*, and *Leymus salinus*. The woody layer is often a mixture of shrubs and dwarf-shrubs, although it may be dominated by a single species. Characteristic species include *Atriplex canescens, Artemisia tridentata, Chrysothamnus greenei, Chrysothamnus viscidiflorus, Ephedra* spp., *Ericameria nauseosa, Gutierrezia sarothrae*, and *Krascheninnikovia lanata*. *Artemisia tridentata* or *Atriplex canescens* may be present but does not dominate. Annual grasses, especially the exotics *Bromus arvensis* and *Bromus tectorum*, may be present to abundant. Forbs are generally of low importance and are highly variable across the range but may be diverse in some occurrences. The general aspect of occurrences may be either open shrubland with patchy grasses or patchy open herbaceous layers. Disturbance may be important in maintaining the woody component. Microphytic crust is very important in some stands.

Related Concepts:
- Sagebrush - Grass (612) (Shiflet 1994) **><**

Distribution: This system occurs throughout the intermountain western U.S., typically at lower elevations, and extends into Wyoming and Montana across the Great Divide Basin. It barely gets as far north into north-central Montana (mapzone 20) but is unlikely to be mapped.

CES304.788 CONCEPTUAL MODEL

Environment: This ecological system occurs throughout the intermountain western U.S., from the western Great Basin to the northern Rocky Mountains and Colorado Plateau and extends into south-central Montana between the Pryor and Beartooth ranges where a distinct rainshadow effect occurs. Elevation ranges from 300 m up to 2500 m. The climate where this system occurs is generally hot in summers and cold in winters with low annual precipitation, ranging from 18-40 cm and high inter-annual variation. Much of the precipitation falls as snow, and growing-season drought is characteristic. Temperatures are continental with large annual and diurnal variations. Sites are generally alluvial fans and flats with moderate to deep soils. Some sites can be flat, poorly drained and intermittently flooded with a shallow or perched water table often within 1 m depth (West 1983e). Substrates are generally shallow, calcareous, fine-textured soils (clays to silt loams), derived from alluvium; or deep, fine to medium-textured alluvial soils with some source of subirrigation during the summer season. Soils may be alkaline and typically moderately saline (West 1983e). Some occurrences are found on deep, sandy loam soils, or soils that are highly calcareous, but not deep sand with active dune fields (Hironaka et al. 1983). The environmental description is based on several references, including Hanson (1929), Branson et al. (1976), Barbour and Major (1977), Brown (1982), Hironaka et al. (1983), West (1983e), Knight (1994), Holland and Keil (1995), Reid et al. (1999), West and Young (2000), Tuhy et al. (2002), Barbour et al. (2007), Sawyer et al. (2009), and NatureServe Explorer (2011).

Key Processes and Interactions: Disturbance dynamics in this system are variable because of variation in the compositions; however, most are dominated by short- to long-lived, deciduous shrubs that are adapted to low- to medium-frequency, medium- to large-sized and low- to medium-intensity fire (Carey 1995, Tirmenstein 1999b, 1999f, 1999g, Anderson 2001b, 2004b, Scher 2001, Sawyer et al. 2009). Some shrubs, such as *Chrysothamnus viscidiflorus, Ephedra torreyana, Ephedra viridis, Ericameria nauseosa, Sarcobatus vermiculatus*, and *Tetradymia canescens*, are generally top-killed in burns, but then vigorously resprout from rootcrowns unless the fire was very severe (Tirmenstein 1999b, 1999f, 1999g, Anderson 2001b, 2004b, Scher 2001, Sawyer et al. 2009). Other shrubs, such a *Gutierrezia sarothrae* and *Krascheninnikovia lanata*, are more typically killed by fire and only weakly sprout post-fire, if at all (Carey 1995, Tirmenstein 1999g). However, in most cases, reestablishment generally proceeds rapidly through light wind-dispersed seeds from adjacent unburned areas, and in some case, these shrub species aggressively invade disturbed open sites, then decline after 15 years to be replaced by longer-lived species such as *Artemisia tridentata* or *Sarcobatus vermiculatus* (Carey 1995, Tirmenstein 1999b, 1999f, 1999g, Anderson 2001b, 2004b, Scher 2001, Sawyer et al. 2009). Some stands, such as those dominated by *Ericameria parryi*, are too sparse to carry fire (Sawyer et al. 2009). Many stands have a lush herbaceous layer that dries to fine fuels that readily carry fire regardless of shrub density.

Insects are an important component of many shrub-steppe and grassland systems. Mormon crickets and grasshoppers are natural components of many rangeland systems (USDA-APHIS 2003, 2010). There are almost 400 species of grasshoppers that inhabit the western United States, with 15-45 species occurring in a given rangeland system (USDA-APHIS 2003). Mormon crickets are also present in many western rangelands and, although flightless, are highly mobile and can migrate large distances consuming much of the forage while travelling in wide bands (USDA-APHIS 2010). Following a high population year for grasshoppers or Mormon crickets and under relatively warm dry spring environmental conditions that favor egg hatching and grasshopper and Mormon cricket survival, there may be large population outbreaks that can utilize 80% or more of the forage in areas as large as 2000 square miles. Conversely, relatively cool and wet spring weather can limit the potential for outbreaks. These outbreaks are naturally occurring cycles and, especially during drought, can denude an area of vegetation leaving it exposed to increased erosion rates from wind and water (USDA 2003).

Chrysothamnus viscidiflorus plants are relatively short-lived (approximately 12-13 years). Infestation in some densely populated stands by larvae of the beetle *Acamaeodera pulchella* is related to senescence and death. In shrubland stands were *Chrysothamnus viscidiflorus* is scattered, there are lower levels of infestation (Young and Evans 1974).

Threats/Stressors: The primary land uses that alter the natural processes of this system are associated with livestock grazing and introduction of exotic annual grasses. Increases in fine fuels from alien annual grasses, such as *Bromus madritensis, Bromus tectorum*, and *Schismus* spp., can substantially increase the fire frequency. Shrubs species, such as *Chrysothamnus viscidiflorus, Ephedra torreyana, Ephedra viridis, Ericameria nauseosa, Sarcobatus vermiculatus*, and *Tetradymia canescens*, that vigorously resprout from rootcrowns after burning become more common and replace longer-lived and more fire-sensitive species such as *Artemisia tridentata, Artemisia bigelovii, Artemisia nova*, and *Coleogyne ramosissima* (Tirmenstein 1999a, 1999b, Sawyer et al. 2009). This system is expected to increase in range with increased fire-return interval (FRI) (Tirmenstein 1999a, 1999b, Sawyer et al. 2009).

Both *Chrysothamnus viscidiflorus* and *Ericameria nauseosa* are considered important forage for livestock on depleted ranges (Tirmenstein 1999a, 1999b). Palatability of these shrubs to both livestock and wildlife is variable depending subspecies, with *Chrysothamnus viscidiflorus ssp. lanceolatus, Chrysothamnus viscidiflorus ssp. puberulus, Ericameria nauseosa var. speciosa (= Chrysothamnus nauseosus ssp. albicaulis), Ericameria nauseosa var. hololeuca*, and *Ericameria nauseosa var. salicifolia* noted as favored subspecies (Tirmenstein 1999a, 1999b). Over time, heavy grazing by livestock will decrease abundance of desirable perennial grasses such as *Achnatherum hymenoides, Bouteloua gracilis, Hesperostipa comata, Pleuraphis jamesii*, or *Pseudoroegneria spicata*.

When grasshopper and Mormon cricket populations reach outbreak levels, they cause significant economic losses for ranchers and livestock producers, especially when accompanied by a drought (USDA-APHIS 2003, 2010). Both rangeland forage and cultivated crops can be consumed by grasshoppers. The U.S. Department of Agriculture's (USDA) Animal and Plant Health Inspection Service (APHIS) is the Federal agency responsible for controlling economic infestations of grasshoppers on western rangelands with a cooperative suppression program. They work with federal land managing agencies to conduct grasshopper suppression. The goal of the APHIS's grasshopper program is not to eradicate them but to reduce outbreak populations to less economically damaging levels (USDA-APHIS 2003). This APHIS effort dampens the natural ecological outbreak cycles of grasshoppers and Mormon crickets, but does not eradicate the species.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES302.742 Mojave Mid-Elevation Mixed Desert Scrub

CES302.742 CLASSIFICATION

Concept Summary: This ecological system is an extensive desert scrub dominated by *Yucca brevifolia* and/or *Coleogyne ramosissima*. It is found in the transition zone between *Larrea tridentata - Ambrosia dumosa* desert scrub and lower montane woodlands (700-1800 m elevations) that occur in the eastern and central Mojave Desert, and in southern Great Basin. The vegetation in this ecological system is quite variable. Major communities include *Yucca brevifolia* and *Coleogyne ramosissima* scrub. Dominant and diagnostic species include *Coleogyne ramosissima, Ericameria parryi, Ericameria teretifolia, Eriogonum fasciculatum, Ephedra nevadensis, Grayia spinosa, Lycium* spp., *Menodora spinescens, Nolina* spp., *Cylindropuntia acanthocarpa, Salazaria mexicana, Viguiera parishii, Yucca brevifolia*, or *Yucca schidigera*. Less common are stands with scattered Joshua trees and a saltbush short-shrub layer dominated by *Atriplex canescens, Atriplex confertifolia*, or *Atriplex polycarpa*, or occasionally *Hymenoclea salsola*. In some areas in the western Mojave, *Juniperus californica* is common with the yuccas. Desert grasses, including *Achnatherum hymenoides, Achnatherum speciosum, Muhlenbergia porteri, Pleuraphis jamesii, Pleuraphis rigida*, or *Poa secunda*, may form an herbaceous layer. Scattered *Juniperus osteosperma* or desert scrub species may also be present.

Description Author: M.S. Reid and K.A. Schulz

CES302.742 CONCEPTUAL MODEL

Environment: This ecological system is found in the Mojave Desert and in the transition zone into the southern Great Basin. It represents the extensive mid-elevation desert scrub in the transition zone above the lower elevation creosotebush desert scrub and generally below the foothill and lower montane woodlands (700-1850 m elevations (Sawyer et al. 2009). Adjacent ecological systems include ~Great Basin Pinyon-Juniper Woodland (CES304.773)$$ and ~Inter-Mountain Basins Big Sagebrush Shrubland (CES304.777)$$ above and ~Sonora-Mojave Creosotebush-White Bursage Desert Scrub (CES302.756)$$ below.

Climate: Climate is semi-arid with hot summers and cool winters. Annual precipitation is low, averaging between 4 and 25 cm. However, year-to-year precipitation variability can be quite large with drought common and rare wet years producing a bloom of desert annuals.

Physiography/landform: Stands occur on upper bajada and lower piedmont slopes with smaller patches occurring on rocky ridges and outcrops. Slopes are gentle to moderate. Aspect is variable with higher elevation stands found on warmer south- to west-facing slopes.

Soil/substrate/hydrology: Substrates are a mixture of alluvium and colluvium and are variable, ranging from silt to loam to coarse sand, but often shallow, well-drained, sandy and rocky. Many stands occur on alkaline, calcareous substrates and often have biological crusts and a shallow caliche layer (Sawyer et al. 2009). The environmental description is based on several references, including Beatley (1976), Brown (1982a), Turner (1982b), MacMahon (1988), Holland and Keil (1995), Reid et al. (1999), Ostler et al. (2000), Anderson (2001c), Gucker (2006a, 2006b), Barbour et al. (2007a), Keeler-Wolf (2007), and Sawyer et al. (2009).

Key Processes and Interactions: This system occurs on extremely xeric sites and is well-adapted to prolonged drought and heat stress. Growth slows or stops in winter due to cold and is inhibited at other times by heat. Winter rains are sometimes sufficient to allow ephemeral herbs to flower in the spring. Late summer thunderstorms also contribute moisture.

Disturbance dynamics in this system are variable because of variation in structure and composition, being dominated by open- to closed-canopy scrub to desert grasslands dominated by *Pleuraphis rigida* (<1400 m elevation) and *Pleuraphis jamesii* (>1400 m elevation) sometimes with a *Yucca brevifolia* overstory (Sawyer et al. 2009). Except for the relatively few stands with an herbaceous layer, fire-return intervals (FRI) also tend to be long because the open stands only burn under extreme conditions. Older *Yucca brevifolia* individuals can tolerate low-severity fires due to fire-resistant bark, and both *Yucca brevifolia* and *Yucca schidigera* can sprout if burned (Gucker 2006a, b).

LANDFIRE developed a VDDT model for this system which has two classes (LANDFIRE 2007a, BpS 1410820):
A) Early Development 1 Open (25% of type in this stage): Shrub cover is 0-50%. Historically, fire was relatively uncommon in this vegetation. The average FRI for replacement fire was 400 years. When burned, the fire-tolerant/crown-sprouting shrubs such as spiny menodora, horsebrush and snakeweed will dominate the site. At higher elevations of mesic blackbrush, a big sagebrush-desert bitterbrush community typically replaces blackbrush for a protracted period. This class can express itself for over a hundred years with varying amounts of blackbrush gradually establishing after decades and eventually succeeding to class B. A few examples of this that have been observed in the field are believed to be over 60+ years. The ground cover varies by elevation and moisture regime with mesic sites being generally 10-35% with some sites only capable of 10% cover. The thermic sites are generally 10-15% ground cover with exception going as high as 35%.

B) Late Development 2 Closed (shrub-dominated - 30% of type in this stage): This community class seems to be stable and occurs after a threshold is crossed. Composition is 50-70% blackbrush-dominated. Other species are perennial grasses of desert needlegrass, Indian ricegrass, galleta grass, fluff grass, and threeawn. Lesser shrub composition includes Nevada ephedra, turbinella oak, desert bitterbrush, fourwing saltbush, and Anderson's wolfberry in mesic sites and Nevada ephedra, creosotebush, Mojave buckwheat, snakeweed, prickly pear, white bursage, and spiny menodora in thermic sites. There are other shrubs also. The FRI for replacement fire is 400 years, which causes a rare transition to class A.

Fire-sensitive shrub species such as the long-lived *Coleogyne ramosissima, Menodora spinescens, Nolina bigelovii*, or *Nolina parryi* will convert to early-seral and intermediate shrublands dominated by *Hymenoclea salsola, Grayia spinosa, Gutierrezia sarothrae, Ericameria teretifolia, Ephedra nevadensis, Menodora spinescens, Cylindropuntia acanthocarpa, Salazaria mexicana, Tetradymia* spp., or *Yucca schidigera* which have shorter FRIs (Anderson 2001c, Keeler-Wolf 2007, Sawyer et al. 2009). LANDFIRE modelers emphasized that blackbrush is fire-intolerant, may be slow to re-establish following fire, and grasses may dominate immediately following fire. Invasion of non-native annual grasses following fire is likely under current conditions (LANDFIRE 2007a).

Some species such as yucca moths (*Tegeticula* spp.) and *Yucca* species have obligate mutualistic relationships (Baker 1986b, Althoff et al. 2006). *Yucca* sp. are typically dependent on one or sometimes two species of *Tegeticula* for pollination, which is usually dependent on one to several *Yucca* host plant species for habitat and food for larvae; for example, *Tegeticula mojavella* and *Tegeticula californica* pollinate *Yucca schidigera*, and *Tegeticula antithetica* and *Tegeticula synthetica* pollinate *Yucca brevifolia*. More study and review are needed to fully understand the many functional roles animals have within this ecosystem.

Threats/Stressors: The primary land uses that alter the natural processes of this system are associated with livestock practices, annual exotic species introduction, fire regime alteration, direct soil surface disturbance, and fragmentation. Excessive grazing stresses the system through soil disturbance (also from ORV use), diminishing or eliminating the biological soil crust, altering the plant species composition by loss of perennial species, and increasing the establishment of native disturbance-increasers and annual grasses, particularly *Bromus madritensis* and other non-native annual bromes.

Natural fire regimes may have been altered because of grazing by livestock and fire suppression over the last 100 years. This may allow the presence of relatively fire-intolerant species such as *Artemisia tridentata, Coleogyne ramosissima*, or *Larrea tridentata* in stands of this system in relatively mesic sites (Keeler-Wolf and Thomas 2000). In sites throughout the range of this system, annual grass invasion has also substantially altered the fire frequency. Fine fuel adjacency from alien annual grasses, such as *Bromus madritensis, Bromus tectorum*, and *Schismus* spp., currently represents the most important fuel bed component in desert scrub and can substantially increase the fire frequency. After a year of moderate to high rainfall, the annual vegetation converts into fine fuels that can carry fire through these open scrub stands, killing fire-sensitive species with moderate to long fire-return intervals and converting to exotic annual grasslands (Keeler-Wolf et al. 1998).

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from burning, loss of shrubs, soil erosion from wind and water conversion to exotic annual grasses (West 1983d, 1988). Widespread burning to reduce blackbrush in the 1940s and 1950s converted vast areas to the ruderal half-shrub *Gutierrezia sarothrae* and exotic annual grasses (West 1983d).

High-severity environmental degradation appears where occurrences tend to be relatively small (<25 acres) for this large-patch type and have evidence of burning, excessive livestock grazing and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. System remains fundamentally compromised despite restoration of some processes. Soil compaction and continued disturbance are extensive throughout the occurrence. Heavy invasion of non-native annual grasses will eventually result in a stand-replacing fire and conversion from native shrubland to invasive annual grassland post-burn. The resulting altered fire regime will eliminate potential for restoration because of extensive non-native degradation and frequent fire. Biological soil crust, if present, is found only in protected areas.

Moderate-severity environmental degradation appears where occurrences are moderate (<100 acres) in size for this large-patch type and have evidence of heavy livestock grazing and/or mechanical disturbance from vehicles resulting in soil compaction and erosion. Invasion of non-native annual grasses degrades stands and increases risk of stand-replacing fire that will eliminate shrubs and reduce all native species. Stands have potential for restoration over several decades. Biological soil crust is present in protected areas and with a minor component elsewhere.

High-severity biotic disruption appears where non-native herbaceous species are dominant (Rondeau 1999). Alteration of vegetation is extensive and restoration potential is low. Connectivity is severely hampered by fragmentation from roads that restrict or prevent natural ecological processes from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where herbaceous species are codominated by native and non-native species. Alteration of vegetation is extensive but potentially restorable over several decades. Fragmentation is limited to less than 15% of the occurrence. Invasive woody species may present but still controllable. Connectivity is severely hampered by fragmentation from roads that restrict or prevent natural ecological processes from occurring, and create barriers to natural movement of animal and plant populations. Some non-natural barriers are present. Significant disturbance, but easily restorable. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.793 Southern Colorado Plateau Sand Shrubland

CES304.793 CLASSIFICATION

Concept Summary: This large-patch ecological system is found on the south-central Colorado Plateau in northeastern Arizona extending into southern and central Utah. It occurs on windswept mesas, broad basins and plains at low to moderate elevations (1300-1800 m). Substrates are stabilized sandsheets or shallow to moderately deep sandy soils that may form small hummocks or small coppice dunes. This semi-arid, open shrubland is typically dominated by short shrubs (10-30 % cover) with a sparse graminoid layer. The woody layer is often a mixture of shrubs and dwarf-shrubs. Characteristic species include *Ephedra cutleri, Ephedra torreyana, Ephedra viridis*, and *Artemisia filifolia*. *Coleogyne ramosissima* is typically not present. *Poliomintha incana, Parryella filifolia, Quercus havardii var. tuckeri*, or *Ericameria nauseosa* may be present to dominant locally. *Ephedra cutleri* and *Ephedra viridis* often assume a distinctive matty growth form. Characteristic grasses include *Achnatherum hymenoides, Bouteloua gracilis, Hesperostipa comata*, and *Pleuraphis jamesii*. The general aspect of occurrences is an open low shrubland but may include small blowouts and dunes. Occasionally grasses may be moderately abundant locally and form a distinct layer. Disturbance may be important in maintaining the woody component. Eolian processes are evident, such as pediceled plants, occasional blowouts or small dunes, but the generally higher vegetative cover and less prominent geomorphic features distinguish this system from ~Inter-Mountain Basins Active and Stabilized Dune (CES304.775)$$.

Related Concepts:

Distribution: This system occurs in sandy plains and mesas on the south-central Colorado Plateau in northeastern Arizona extending into southern and central Utah.

M170. Great Basin-Intermountain Dwarf Sagebrush Steppe & Shrubland

CES304.762 Colorado Plateau Mixed Low Sagebrush Shrubland

CES304.762 CLASSIFICATION

Concept Summary: This ecological system occurs in the Colorado Plateau, Tavaputs Plateau and Uinta Basin in canyons, gravelly draws, hilltops, and dry flats at elevations generally below 1800 m. Soils are often rocky, shallow, and alkaline. This type extends across northern New Mexico into the southern Great Plains on limestone hills. It includes open shrublands and steppe dominated by *Artemisia nova* or *Artemisia bigelovii* sometimes with *Artemisia tridentata ssp. wyomingensis* codominant. Semi-arid grasses such as *Achnatherum hymenoides, Aristida purpurea, Bouteloua gracilis, Hesperostipa comata, Pleuraphis jamesii*, or *Poa fendleriana* are often present and may form a graminoid layer with over 25% cover.

CES304.762 CONCEPTUAL MODEL

Environment: This ecological system occurs in the Colorado Plateau, Tavaputs Plateau and Uinta Basin in canyons, gravelly draws, hilltops, mesatops and dry flats at elevations generally below 1800 m. This type extends across northern New Mexico into the southern Great Plains on limestone hills and sandstone breaks. Soils are often rocky, shallow and alkaline. Adjacent upland systems include ~Colorado Plateau Pinyon-Juniper Woodland (CES304.767)$$ and ~Inter-Mountain Basins Montane Sagebrush Steppe (CES304.785)$$ (deeper soils) at higher elevations and ~Inter-Mountain Basins Mixed Salt Desert Scrub (CES304.784)$$ at lower elevations. The environmental description is based on several other references, including Jameson et al. (1962), Brown (1982), West (1983a), Baker and Kennedy (1985), Francis (1986), Dick-Peddie (1993), West and Young (2000), Howard (2003), Fryer (2009), and NatureServe Explorer (2011).

Key Processes and Interactions: The diagnostic species of this system, *Artemisia nova* or *Artemisia bigelovii*, grow in more xeric sites than other *Artemisia* shrublands (Hironaka et al. 1983). This dwarf-shrubland system is associated with shallow, rocky soils which experience extreme drought in summer. The plants are low and widely spaced, which tends to decrease the risk of fire. Fire is uncommon on drier sites because of discontinuous and low fuel buildup on the generally unproductive sites (Fryer 2009). Fire effects on *Artemisia bigelovii* is not known but assumed to be similar to *Artemisia nova* (Howard 2003), with fire-return intervals (FRI) ranging from 35 to over 100 years for xeric, low-productivity sagebrush communities of the Great Basin (Fryer 2009). In general, most sites are thought to have relatively long fire-return intervals (100-200 years) according to LANDFIRE models developed by experts (Fryer 2009). Stands in the western Great Plains typically have higher herbaceous cover (Shaw et al. 1989) which may decrease FRI. These shrubs are fire-sensitive and rarely sprout after burning. They reproduce from light wind-dispersed seeds from adjacent unburned areas to disturbed areas (Howard 1999, 2003, Fryer 2009). It generally takes around 30 years for a burned *Artemisia nova* stand to recover to pre-fire density (Hironaka et al. 1983, Fryer 2009). *Artemisia tridentata ssp. wyomingensis* may be present to codominant and shares similar ecological characteristics on these relatively xeric sites (Howard 1999).

Scattered trees may be present in some stands of this system. Fire reduces sagebrush abundance in both sagebrush and pinyon-juniper systems. Where these systems are adjacent, periodic fire likely prevents establishment of juniper and pinyon trees in sagebrush stands (Wright et al. 1979). In order to maintain dominance of sagebrush, fire-return interval must be long enough to permit sagebrush stands to mature, but short enough to prevent establishment and growth of trees in these sites. Fire-return intervals of 150-250 years for stand-replacing fire will likely maintain these shrublands. Expansion and contraction of trees into sagebrush shrublands are regulated by a combination of climate, fire, and bark beetle infestations with trees seedlings establishing during wetter periods (Wright et al. 1979, Paysen et al. 2000).

Insects are an important component of many shrub-steppe and grassland systems. Mormon crickets and grasshoppers are natural components of many rangeland systems (USDA-APHIS 2003, 2010). There are almost 400 species of grasshoppers that inhabit the western United States with 15-45 species occurring in a given rangeland system (USDA-APHIS 2003). Mormon crickets are also present in many western rangelands and, although flightless, are highly mobile and can migrate large distances consuming much of the forage while travelling in wide bands (USDA-APHIS 2010). Following a high population year for grasshoppers or Mormon crickets and under relatively warm dry spring environmental conditions that favor egg hatching and grasshopper and Mormon cricket survival, there may be large population outbreaks that can utilize 80% or more of the forage in areas as large as 2000 square mile. Conversely, relatively cool and wet spring weather can limit the potential for outbreaks. These outbreaks are naturally occurring cycles and, especially during drought, can denude an area of vegetation leaving it exposed to increased erosion rates from wind and water (USDA-APHIS 2003).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total (LANDFIRE 2007a, BpS 2310640). These are summarized as:

A) Early Development 1 All Structures (shrub-dominated - 10% of type in this stage): Early-seral community dominated by herbaceous vegetation; less than 6% sagebrush canopy cover; up to 24 years post-disturbance. Replacement fire occurs every 250 years on average. Succession to class B after 24 years.

B) Late Development 1 Open (shrub-dominated - 70% of type in this stage): Shrub cover is 0-10%. Mid-seral community with a mixture of herbaceous and shrub vegetation; 6-10% sagebrush canopy cover present; between 20-59 years post-disturbance. Replacement fire (FRI of 240 years) causes a transition to class A, whereas mixed-severity fire (FRI of 100 years) maintains the site in its present condition. In the absence of fire for 120 years, the site will follow an alternative succession path to class C. Otherwise, succession and mixed-severity fire keeps site in class B.

C) Late Development 1 Open (conifer-dominated - 20% of type in this stage): Shrub cover is 10-30%. Late-seral community with a mixture of herbaceous and shrub vegetation; >10% sagebrush canopy cover present; 75+ years post-disturbance. Replacement fire is every 200 years on average (transition to class A), whereas mixed-severity fire happens on average every 140 years due to a diminished herbaceous component compared to class B. Mixed-severity fire causes a transition to class B. Succession will keep the site in class C without fire.

Black sagebrush generally supports more fire than other dwarf sagebrushes. This type generally burns with mixed severity (average FRI of 100-140 years) due to relatively low fuel loads and herbaceous cover. Bare ground acts as a micro-barrier to fire between low-statured shrubs. Oils and resins present in the foliage and stems of sagebrush allow fire to spread. Stand-replacing fires (average FRI of 200-240 years) can occur in this type when successive years of above-average precipitation are followed by an average or dry year. Stand-replacement fires dominate in the late-succession class where the herbaceous component has diminished. Fires may or may not be wind-driven and only cover small areas. This type fits into Fire Regime Groups IV and III LANDFIRE 2007a, BpS 1210310).

Grazing by wild ungulates occurs in this type due to the high palatability of *Artemisia nova* compared to other browse. Native browsing tends to open up the canopy cover of shrubs but does not often change the succession stage (LANDFIRE 2007a, BpS 1210310).

Prolonged drought may reduce the foliar and basal covers of graminoids but not that of shrubs. Reduced foliar cover of graminoids will affect fire behavior. This effect is assumed minor and not included in the model (LANDFIRE 2007a, BpS 1210310).

Threats/Stressors: The primary land uses that alter the natural processes of this system are associated with livestock grazing and introduction of exotic annual grasses. *Artemisia bigelovii* and *Artemisia nova* are utilized by livestock to a much greater degree than other species of *Artemisia*, resulting in low, pruned plants (West 1983a, Howard 2003d, Fryer 2009). Excessive grazing stresses the system through soil disturbance, diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and annual grasses, particularly *Bromus tectorum* and other exotic annuals. The introduction of exotic annual grasses has altered many stands by increasing the amount of fine fuels present that can substantially increase fire frequency and intensity which reduces the cover of fire-sensitive shrubs such as *Artemisia bigelovii* and *Artemisia nova* (Howard 2003d, Fryer 2009).

When grasshopper and Mormon cricket populations reach outbreak levels, they cause significant economic losses for ranchers and livestock producers, especially when accompanied by a drought (USDA-APHIS 2003, 2010). Both rangeland forage and cultivated crops can be consumed by grasshoppers. The U.S. Department of Agriculture's (USDA) Animal and Plant Health Inspection Service (APHIS) is the Federal agency responsible for controlling economic infestations of grasshoppers on western rangelands with a cooperative suppression program. They work with federal land managing agencies to conduct grasshopper suppression. The goal of APHIS's grasshopper program is not to eradicate them but to reduce outbreak populations to less economically damaging levels (USDA-APHIS 2003). This APHIS effort dampens the natural ecological outbreak cycles of grasshoppers and Mormon crickets but does not eradicate the species.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES304.080 Columbia Plateau Low Sagebrush Steppe

CES304.080 CLASSIFICATION

Concept Summary: This ecological system can form the matrix of the landscape and is composed of sagebrush dwarf-shrub-steppe that occurs in a variety of shallow-soil habitats throughout eastern Oregon, northern Nevada and southern Idaho. *Artemisia arbuscula ssp. arbuscula* and close relatives (*Artemisia arbuscula ssp. longiloba* and occasionally *Artemisia nova*) form stands that typically occur on mountain ridges and flanks and broad terraces, ranging from 1000 to 3000 m in elevation. Substrates are shallow, fine-textured soils, poorly drained clays that occur in thin-soil areas and are frequently very stony. Other shrubs and dwarf-shrubs present may include *Purshia tridentata, Eriogonum* spp., and other species of *Artemisia*. Common graminoids include *Festuca idahoensis, Koeleria macrantha, Poa secunda*, and *Pseudoroegneria spicata*. Many forbs also occur and may dominate the herbaceous vegetation, especially at the higher elevations. Isolated individuals of *Juniperus occidentalis* and *Cercocarpus ledifolius* can often be found in this system. This ecological system is closely related to the concept of shallow-dry sagebrush in the resistance-resilience framework.

Related Concepts:

- Antelope Bitterbrush - Idaho Fescue (105) (Shiflet 1994) **><**
- Low Sagebrush (406) (Shiflet 1994) **><**

Distribution: This system is found throughout the basins of eastern Oregon and southern Idaho, south into northern Nevada and northeastern California.

Nations: US

Concept Source: J. Kagan

Description Author: J. Kagan and K.A. Schulz

CES304.080 CONCEPTUAL MODEL

Environment: This system occurs on shallow-soil habitats, ranging from 1000 to 3000 m in elevation.

Climate: Climate is semi-arid with a large proportion of the 20-30 cm of annual precipitation falling as winter snow. The temperature regime is continental, with cold winters, warm summers, a large diurnal temperature range, and a short frost-free season.

Physiography/landform: Stands typically occur on mountain ridges and flanks and broad terraces, but may be associated with flats, depressions, and slopes with soils that are either very shallow or quite poorly drained. In the Columbia River Basin, the vegetation in this system occupies the driest habitats of all the *Artemisia*-dominated stands.

Soil/substrate/hydrology: Substrates are generally fine-textured, usually poorly drained clays that occur in shallow-soiled areas, which are almost always very stony and characterized by recent rhyolite or basalt. Beetle and Johnson (1982) report that *Artemisia arbuscula ssp. arbuscula* grows in soils with a high volume of gravel (even though soil may be in clay textural class or contain a clay-rich layer that impedes drainage), and that *Artemisia arbuscula ssp. longiloba* grows in clay soils, often alkaline, that contain no gravels. Soils dominated by *Artemisia nova* are typically alkaline and calcareous.

Key Processes and Interactions: The diagnostic species of this system, *Artemisia arbuscula ssp. arbuscula, Artemisia arbuscula ssp. longiloba*, or *Artemisia nova*, grow in more xeric sites than other *Artemisia* shrubs (Hironaka et al. 1983), and are highly drought-tolerant. *Artemisia arbuscula* tends to grow where claypan layers exist in the soil profile and soils are often saturated during a portion of the year, while *Artemisia nova* tends to grow where there is a root-limiting layer in the soil profile (LANDFIRE 2007a). This shrubland system is associated with shallow, rocky soils which experience extreme drought in summer. The plants are low and widely spaced, which tends to decrease the risk of fire (Chappell et al. 1997).

Fire influences the density and distribution of shrubs. In general, fire increases the abundance of herbaceous perennials and decreases the abundance of woody plants (WNHP 2011). The fire interval for this system is 110 years (LANDFIRE 2007a). Anecdotal observations indicate that these patches often are not burned during surrounding forest fires. Fire is uncommon because of discontinuous and low fuel buildup on the generally unproductive sites (Young and Palmquist 1992, Fryer 2009, Sawyer et al. 2009). Most sites are thought to have relatively long fire-return intervals (100-200 years) according to LANDFIRE models developed by experts (LANDFIRE 2007a). These shrubs are fire-sensitive and rarely sprout after burning.

The dominant shrub species can easily colonize burns via wind-dispersed seeds from adjacent unburned areas into disturbed areas (Howard 1999, Steinberg 2002a, Fryer 2009). It generally takes around 30 years for a burned stand to recover to pre-fire shrub density (Zamora and Tueller 1973, Hironaka et al. 1983, Howard 1999, Steinberg 2002a, Fryer 2009). However, recovery of this system after fire may take up to 325-450 years (Baker 2006).

Grazing by wild ungulates occurs in this shrubland system. Native browsing tends to open the canopy cover of shrubs but does not often change the successional stage (LANDFIRE 2007a).

Insects are an important component of many shrub-steppe and grassland systems. Mormon crickets and grasshoppers are natural components of many rangeland systems (USDA-APHIS 2003, 2010). There are almost 400 species of grasshoppers that inhabit the western United States with 15-45 species occurring in a given rangeland system (USDA-APHIS 2003). Mormon crickets are also present in many western rangelands and, although flightless, are highly mobile and can migrate large distances consuming much of the forage while travelling in wide bands (USDA-APHIS 2010). Following a high population year for grasshoppers or Mormon crickets and under relatively warm dry spring environmental conditions that favor egg hatching and grasshopper and Mormon cricket survival, there may be large population outbreaks that can utilize 80% or more of the forage in areas as large as 2000 square miles. Conversely, relatively cool and wet spring weather can limit the potential for outbreaks. These outbreaks are naturally occurring cycles and, especially during drought, can denude an area of vegetation leaving it exposed to increased erosion rates from wind and water (USDA-APHIS 2003).

LANDFIRE developed a VDDT model for this system which has three classes (LANDFIRE 2007a, BpS 0811240 and BpS 0911240). Dominant shrub is *Artemisia arbuscula*. Dominant herbaceous species are *Poa secunda* and *Pseudoroegneria spicata*.

A) Early Development 1 All Structures (10% of type in this stage): Zero to 1% low sagebrush cover. Herbaceous cover of bunchgrasses and forbs would fill to about 20-30% cover within a few years.

B) Mid Development 1 Open (40% of type in this stage): Dominant lifeform is herb. Minimum cover = 20%, maximum cover = 40%. Minimum height for herbs is 0.6 m. Scattered and usually small low sagebrush is present, but perennial grasses and forbs continue to dominate. The general formation is that of a shrub savanna. Sagebrush cover is usually 1-5% in this stage.

C) Late Development 1 Open (50% of type in this stage): Sagebrush is codominant with perennial grasses and forbs. Sagebrush and herbaceous cover can be variable depending on site productivity. Bare ground and rock in the interspaces increase on less productive sites. The general formation is that of a shrubland. Expected composition is 50-60% grass; 5-10% forbs; 20-40% shrubs. Windswept ridges with thinner soils may be still more open.

Threats/Stressors: The primary land uses that alter the natural processes of this system are associated with livestock practices, annual exotic species invasion, fire regime alteration, direct soil surface disturbance, and fragmentation. Barbour and Major (1988) report that *Artemisia nova* is utilized by livestock to a much greater degree than other species of *Artemisia*, resulting in low, pruned plants (West 1983a). Both *Artemisia arbuscula* and *Artemisia nova* are considered a valuable browse plant during the spring, fall, and winter months and are often grazed by native ungulates (elk and mule deer) and domestic livestock. Prolonged livestock use can cause a decrease in the abundance of native, perennial bunchgrasses and increase in the cover of shrubs and non-native grass species, such as *Poa bulbosa* and *Poa pratensis*.

Excessive grazing stresses the system through soil disturbance, diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and annual grasses, particularly *Bromus madritensis, Bromus tectorum, Schismus* spp., and other exotic annual grasses. The introduction of exotic annual grasses has altered many stands by increasing the amount of fine fuels present that can substantially increase fire frequency and intensity which reduces the cover of fire-sensitive shrubs such as *Artemisia nova* (Fryer 2009, Sawyer et al. 2009).

Direct and indirect fire suppression are a threat to this system where stands are adjacent to pinyon-juniper woodlands. Over the long term, heavy grazing by livestock removes the fine fuels that carry fire that indirectly leads to a reduction in fire frequencies, which can lead to pinyon-juniper encroachment with subsequent loss of shrub and herbaceous understory (LANDFIRE 2007a).

Human development has impacted many locations throughout the range of this ecological system. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirect through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from stand-replacing fires that occur under extreme fire weather conditions that kill sagebrush and expose bare soil to invasion by exotic herbaceous species or erosion. Invasion by exotic species such as *Bromus tectorum* can alter the fire regime by providing fine fuels that allow for repeated, high-frequency fires that eliminate remaining sagebrush and prevent re-establishment creating extensive annual exotic grasslands. Unchecked erosion can result in topsoil removal.

High-severity environmental degradation appears where occurrences tend to be relatively small (<3 acres) for this matrix type and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion (WNHP 2011). Altered fire regime from too frequent fires can be caused by fine fuel accumulation from invasive annual grasses. This results in loss of shrubs and reduction of all native species, especially dominant native grasses, to <50% total cover. In other instances, ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval to >100 years resulting in regeneration of trees (>10% cover). Bare soil areas are substantial and contribute to long-lasting impacts. Deep ruts from ORVs or machinery may be present, or livestock and/or trails are widespread. Water will be channeled or ponded (WNHP 2011). Connectivity is relictual: embedded in <10% natural habitat; connectivity is essentially absent (WNHP 2011).

Moderate-severity environmental degradation appears where occurrences are moderate (3-10 acres) in size for this matrix type and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion (WNHP 2011). Altered fire regime from too frequent fires caused by fine fuel accumulation from invasive annual grasses results in reduction of shrubs and reduction of all native species, especially dominant native grasses, to 50-79% total cover (WNHP 2011). In other instances, fire suppression and reduction of fine fuels by grazing increased the fire-return interval from 75 to 100 years resulting in regeneration of trees (5-10% cover). Bare soil areas due to human causes are common. There may be disturbance/compaction to several inches. ORVs or other machinery may have left some shallow ruts (WNHP 2011). Connectivity is fragmented: embedded in 10-60% natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape (WNHP 2011).

High-severity disruption of biotic processes occurs where occurrences have low cover of native grassland species (<50% relative cover) (WNHP 2011). Perennial native bunchgrass <30% relative cover and much reduced from site potential (WNHP 2011). Fire-sensitive shrubs absent to rare due to past fires (WNHP 2011). There may be significant cover of trees (>10%) because of fire suppression. Invasive non-native species are abundant (>10% absolute cover to dominant) and relative cover of native Increasers >20% cover (WNHP 2011). Vegetation severely altered from reference standard. Expected strata are absent or dominated by ruderal ("weedy") species, or composed of planted stands of non-characteristic species, or unnaturally dominated by a single species. Most or all indicator/diagnostic species are absent (WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity disruption of biotic processes occurs where occurrences have low cover of native grassland species (50-79% relative cover) (WNHP 2011). Perennial native bunchgrasses 30-50% relative cover or reduced from site potential (WNHP 2011). Fire-sensitive shrubs present recovering from past fires (WNHP 2011). There may be significant cover of trees (5-10%) because of fire suppression (WNHP 2011). Invasive non-native species are abundant (3-10% absolute cover) and relative cover of native increasers is 10-20% cover (WNHP 2011). Species diversity/abundance is different from reference standard condition, but still largely composed of native species characteristic of the type. This may include ruderal ("weedy") species. Many indicator/diagnostic species may be absent (WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.770 Columbia Plateau Scabland Shrubland

CES304.770 CLASSIFICATION

Concept Summary: This ecological system is found in the Columbia Plateau region and consists of extensive low shrublands. These xeric shrublands occur under relatively extreme soil-moisture conditions. Substrates are typically shallow lithic soils with limited water-holding capacity over fractured basalt. Because of poor drainage through basalt, these soils are often saturated from fall to spring by winter precipitation but typically dry out completely to bedrock by midsummer. Vegetation cover is typically low, generally less than 50% and often much less than that. Vegetation is characterized by an open dwarf-shrub canopy dominated by *Artemisia rigida* along with other shrub and dwarf-shrub species, particularly *Eriogonum compositum, Eriogonum douglasii, Eriogonum microthecum, Eriogonum niveum, Eriogonum sphaerocephalum, Eriogonum strictum, Eriogonum thymoides*, and/or *Salvia dorrii*. Other shrubs are uncommon in this system; mixes of *Artemisia rigida* and other *Artemisia* species typically belong to different ecological systems than this. Low cover of perennial bunchgrasses, such as *Danthonia unispicata, Elymus elymoides, Festuca* *idahoensis*, or primarily *Poa secunda*, as well as scattered forbs, including species of *Allium, Antennaria, Balsamorhiza, Lomatium, Phlox*, and *Sedum*, characterize these sites. Individual sites can be dominated by grasses and semi-woody forbs, such as *Nestotus stenophyllus*. Annuals may be seasonally abundant, and cover of moss and lichen is often high in undisturbed areas (1-60% cover).

- Stiff Sagebrush (407) (Shiflet 1994) **<**

Distribution: This system occurs in the Columbia Plateau region of southern Idaho, eastern Oregon and eastern Washington, and extreme northern Nevada.

Nations: US

Concept Source: J. Kagan

Description Author: M.S. Reid and K.A. Schulz

CES304.770 CONCEPTUAL MODEL

Environment: This open, low shrubland ecological system is characteristic of the scablands in the Columbia Basin and portions of the Snake River plain. Elevations range from 190-1830 m.

Climate: Climate is semi-arid and temperate with a winter precipitation peak. Mean annual precipitation ranges from 25-50 cm and occurs primarily in the winter as snow or rain.

Physiography/landform: Stands are found on flat to undulating to rolling plateaus, plains, ridgetops and brows. Sites are nearly level to moderately sloping (to 30%). It occurs on all aspects, but is more common on southern slopes, although given that most sites are flat, aspect is not very significant.

Soil/substrate/hydrology: These xeric shrublands occur under relatively extreme soil-moisture conditions. Substrates are typically shallow lithic soils (7-30 cm) with a high percentage of rock fragments (10-70%), limited water-holding capacity over fractured basalt. This moisture is stored in the soil profile and utilized during the typically dry summers. Because of poor drainage through basalt, these soils are often saturated from fall to spring by winter precipitation but typically dry out completely to bedrock by midsummer. The soils are non-calcareous, sandy to clay loams, with pH of 6.3-6.6. Parent material is restricted to colluvium and residuum derived from basalt and acidic lava. Soil surface is mostly rock, erosion pavement (pebble surface), bare ground, and moss. Litter accumulates under the scattered *Artemisia rigida* plants forming moss-covered mounds up to 20 cm deep. These hummocks persist several years after the death of the dwarf-shrub (Daubenmire 1970, 1992). Moss and lichen cover a significant amount of the ground surface, often with up to 50% cover.

Key Processes and Interactions: This xeric shrubland ecological system is driven by its tolerance of extreme low soil-moisture conditions and very thin soils that can be easily disturbed or eroded. Stands in this system are generally considered to be late-seral with species composition controlled by the harsh edaphic conditions of the site (Daubenmire 1970, Johnson and Simon 1987). While these soils are often saturated from fall to spring by the winter precipitation, they typically dry out completely to bedrock by midsummer (Daubenmire 1970, 1992, Johnson and Simon 1987). *Poa secunda*, a typical dominant graminoid, is well-adapted to these conditions because it starts growing early in the spring and completes its reproductive cycle early while there is still moisture in the soil (Daubenmire 1970, 1992, Johnson and Simon 1987). Also, if there is late summer or early fall precipitation, dormant *Poa secunda* can respond quickly and green up. Daubenmire (1970) and Johnson and Simon (1987) suggest that the basalt bedrock present under these dwarf-shrub/grassland stands is fractured enough to support deeper-rooted dwarf-shrubs. Moss does well in this habitat because of seasonally moist conditions. *Artemisia rigida* is favored winter browse for elk and deer, and moderately palatable to livestock (Johnson and Clausnitzer 1992).

Frost heaving may be severe, causing local soil disturbance in the winter when these thin, saturated soils freeze and push soil and plants up out of the ground. Pedestalled *Artemisia rigida* plants and bunchgrasses are common (Daubenmire 1970, Hironaka et al. 1983).

Fire is thought to be unimportant because it is unlikely that the sparse vegetation in these stands could carry a fire. However, if it does occur the *Artemisia rigida* plants are not tolerant and would be killed (Johnson and Simon 1987, Daubenmire 1992, Johnson and Clausnitzer 1992).

LANDFIRE developed a VDDT model for this system which has three classes (LANDFIRE 2007a, BpS 0810650). This model includes sites where there is potential for pinyon (*Pinus monophylla*) and/or juniper (*Juniperus osteosperma*) establishment in classes C and D.

A) Early Development 1 All Structures (5% of type in this stage): Shrub cover is 0-10%. This class is dominated by sprouting buckwheats and other hemi-shrubs, surviving perennial grasses and forbs and annual forbs. Plant cover is typically extremely low. Sagebrush will be absent and patch size is very small in this class. Rock dominates the visual appearance and may dominate satellite imagery. Succession to class B after 10 years.

B) Mid Development 1 Open (5% of type in this stage): Shrub cover is 0-10%. Young stiff sagebrush appears while the other species reach their more-or-less mature sizes. Plant cover remains low but denser patches are now present, composed mostly of the hemi-shrubs and perennial grasses and forbs. Rock is less dominant visually but may still dominate satellite imagery. Succession to class C after 20 years.

C) Late Development 1 Open (90% of type in this stage): Shrub cover is 0-10%. Stiff sagebrush is fully mature and visually dominates the scene, particularly after spring leaf out and flowering. Total vegetation cover rarely exceeds 25% and is often <15%. Plant height rarely exceeds 0.5 m.

Replacement fire was modeled as mean fire-return interval = 250 years in all three classes, with no other disturbances modeled. Severe droughts can temporarily reduce herbaceous vegetation; however, all the species that occupy this BpS are very drought-tolerant (LANDFIRE 2007a).

Threats/Stressors: The biggest threat is exotic invasive plants (Tisdale 1986, Daubenmire 1992). Common exotics include annual grasses, especially *Bromus tectorum*, and other annual exotic graminoids such as *Bromus arvensis, Bromus briziformis*, and *Taeniatherum caput-medusae*; annual forbs such as *Epilobium brachycarpum, Erodium cicutarium, Holosteum umbellatum, Lactuca serriola*, and *Tragopogon dubius*; and the perennial forb *Hypericum perforatum*. *Bromus tectorum* is moderately dense on some stands and may become abundant during wet years and possibly be dense enough to carry a fire, which would kill fire-sensitive shrubs *Artemisia rigida* (Bunting et al. 1987, Daubenmire 1992, McWilliams 2003b).

Disturbance from heavy use by livestock or vehicles, particularly on dry soils, disrupts the moss/lichen layer and increases exposed rock and bare ground, increasing the threat of invasion by exotic plants (WNHP 2011). The saturated spring soils are vulnerable to trampling, but the rocky soils discourage livestock (Daubenmire 1992). In areas excluded from grazing entirely, *Pseudoroegneria spicata* and *Festuca idahoensis* may dominate with *Artemisia rigida* in some areas, also growing in rock fractures. In addition to drought tolerance, *Poa secunda* is also tolerant of grazing and trampling by livestock (Daubenmire 1970, Ganskopp 1979). With disturbance, such as livestock impacts, comes an increase in erosion pavement and bare ground, and a decrease in moss and lichen cover (Daubenmire 1970, Johnson and Simon 1987).

In addition, large-scale wind and solar power development is becoming more common in the region of the system, potentially increasing fragmentation and facilitating establishment of invasive species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from stand-replacing fires that occur under extreme fire weather conditions that kill sagebrush and expose bare soil to invasion by exotic herbaceous species or erosion. Invasion by exotic species such as *Bromus tectorum* can alter the fire regime by providing fine fuels that allow for repeated, high-frequency fires that eliminate remaining sagebrush and prevent re-establishment, creating extensive annual exotic grasslands (WNHP 2011). Unchecked erosion can results in topsoil removal.

High-severity environmental degradation appears where occurrences tend to be small (<3 acres) for this large- to small-patch type and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion (WNHP 2011). Altered fire regime can be caused by fine fuel accumulation from invasive annual grasses that under extreme fire conditions this system can burn resulting in loss of shrubs and reduction of all native species, especially dominant native grasses. Bare soil areas are substantial and contribute to long-lasting impacts (WNHP 2011). Deep ruts from ORVs or machinery may be present, or livestock and/or trails are widespread. Water will be channeled or ponded (WNHP 2011). Connectivity is relictual: embedded in <10% natural habitat and is essentially absent (WNHP 2011).

Moderate-severity environmental degradation appears where occurrences are moderate (3-25 acres) in size for this large- to small-patch type and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion (WNHP 2011). Altered fire regime can be caused by fine fuel accumulation from invasive annual grasses that under extreme fire conditions can burn resulting in a reduction of cover of shrubs and all native species, especially dominant native grasses. Bare soil areas due to human causes are common with soil disturbance/compaction to several inches deep and shallow ruts from ORVs or other machinery (WNHP 2011). Connectivity is fragmented: embedded in 10-60% natural habitat and is generally low, but varies with mobility of species and arrangement on landscape (WNHP 2011).

High-severity disruption of biotic processes occurs where occurrences have low cover of native grassland species (<50% relative cover) (WNHP 2011). Perennial native bunchgrass <30% relative cover and much reduced from site potential (WNHP 2011). Fire-sensitive shrubs absent to rare due to past fires (WNHP 2011). Vegetation severely altered from reference standard. Expected strata are absent or dominated by ruderal ("weedy") species, or composed of planted stands of non-characteristic species, or unnaturally dominated by a single species. Most or all indicator/diagnostic species are absent (WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes from occurring, and create barriers to natural movement of animal and plant populations. Biological soil crust, if present, is found only in protected areas (WNHP 2011). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity disruption of biotic processes occurs where occurrences have low cover of native grassland species (50-85% relative cover) (WNHP 2011). Invasive non-native species are abundant (3-10% absolute cover) and relative cover of native increasers is 10-20% cover (WNHP 2011). Species diversity/abundance is different from reference standard condition, but still largely composed of native species characteristic of the type; this may include ruderal ("weedy") species. Many indicator/diagnostic species may be absent (WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Biological soil crust is present in protected areas and with a minor component elsewhere (WNHP 2011). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.794 Wyoming Basins Dwarf Sagebrush Shrubland and Steppe

CES304.794 CLASSIFICATION

Concept Summary: This windswept ecological system is composed of dwarf sagebrush shrubland and shrub-steppe that forms matrix vegetation and large patches on the margins of high-elevation basins in central and southern Wyoming. Typical sites are gently rolling hills and long, gently sloping pediments and fans. These sites are very windy and have shallow, often rocky soils (*Artemisia nova* and *Artemisia tripartita ssp. rupicola*) or have shallow, poorly drained, fine-textured soils (*Artemisia arbuscula*). The distinguishing feature of this system is a short-shrub stratum in which dwarf-shrubs (<30 cm tall) contribute at least two-thirds of the woody canopy. Four sagebrush taxa may dominate the shrub stratum: *Artemisia tripartita ssp. rupicola, Artemisia nova, Artemisia arbuscula ssp. longiloba*, and wind-dwarfed *Artemisia tridentata ssp. wyomingensis*. Two or more of these sagebrushes often codominate, but any of them may occur alone. Where graminoids are common and tall, the vegetation often has the appearance of grassland without shrubs; the presence of shrubs is obvious only when the vegetation is viewed up close. Where graminoids contribute less cover, the vegetation is a compact shrubland. The herbaceous component of the vegetation includes both rhizomatous and bunch-form graminoids, cushion plants, and other low-growing forbs. *Bouteloua gracilis*, a common species of ~Inter-Mountain Basins Big Sagebrush Steppe (CES304.778)$$ in Wyoming, is absent.

Distribution: This system occurs throughout the basins of central and southern Wyoming, extending south into adjacent portions of Colorado. It also occurs on the eastern side of the Continental Divide in Montana, where *Artemisia nova* shrublands are found on calcareous substrates.

Nations: US

Concept Source: K.A. Schulz

Description Author: M.S. Reid, G.P. Jones and K.A. Schulz

CES304.794 CONCEPTUAL MODEL

Environment: *Climate:* Climate is semi-arid with 20-30 (45) cm of annual precipitation. The temperature regime is continental, with cold winters, warm summers, large diurnal ranges, and a short frost-free season.

Physiography/landform: This windswept ecological system of dwarf sagebrush shrubland and shrub-steppe occurs from 1500 to 3200 m elevation. These sites are very windy, gently rolling hills and long, gently sloping pediments and fans, broad ridgetops, the ridges of low mountains and the margins of high-elevation basins.

Soil/substrate/hydrology: Soils are variable but are often shallow and rocky. *Artemisia nova* generally occupies medium- to coarse-textured soils, often with a large volume of rock fragments and frequently calcareous. *Artemisia arbuscula*-dominated stands have poorly drained, very heavy, montmorillonite (smectite) clay soils with some coarse fragments, usually effectively very shallow to a hard clay pan, not deep enough to support either big sagebrush or deep-rooted grasses. Those two sagebrushes do grow together sometimes. *Artemisia tripartita ssp. rupicola*-dominated stands have coarse-textured (gravelly), well-drained shallow soils.

Key Processes and Interactions: The key ecological factors for this system are the harsh, windswept, semi-arid climate with a short growing season and shallow soils. *Artemisia nova* and *Artemisia tripartita ssp. rupicola* dwarf-shrublands are associated with shallow, rocky soils which experience extreme drought in summer, whereas *Artemisia arbuscula*-dominated stands occur on shallow, poorly drained, fine-textured soils.

Fire is not important in this ecosystem, because it occurs very infrequently. Plants are low and widely spaced so there is little fuel to carry a fire. Replacement fire is predicted to occur every 300 years (LANDFIRE 2007a). Fire effects are variable depending on dominant species. *Artemisia arbuscula ssp. longiloba, Artemisia nova*, and *Artemisia tridentata ssp. wyomingensis* are generally killed by burning and do not resprout, so fire impacts can be severe (Young 1983, Howard 1999, Steinberg 2002a, Fryer 2009). However, *Artemisia tripartita ssp. rupicola* shrubs can sprout from the stump after being top-killed by fire and will reproduce both by seed and by layering (Tirmenstein 1999k). Hironaka et al. (1983) notes that some populations may have variation in this ability.

LANDFIRE developed a VDDT model for this system which has two classes (LANDFIRE 2007a, BpS 2210720):

A) Early Development 1 All Structures (herbaceous-dominated-30% of type in this stage): Grass-and-forb-dominated site for approximately 125 years. Black/low sagebrush seedlings are young and begin to establish towards the end of this seral period. Replacement fire occurs every 300 years

B) Late Development 1 Open (shrub-dominated-70% of type in this stage): Black/low sagebrush with mid-height late-seral grasses (150 or more years).

Soil erosion caused by native ungulates sometimes can occur in these stands when they trail across them, especially in spring and fall when the sites are wet. The sites are resilient and resistant to trampling in summer and winter, when they are dry or frozen (LANDFIRE 2007a).

Threats/Stressors: The primary threats that alter the natural processes of this system are poor livestock practices, annual exotic species invasion, fire regime alteration, direct soil surface disturbance, and fragmentation. Barbour and Major (1988) report that *Artemisia nova* is utilized by livestock to a much greater degree than other species of *Artemisia*, resulting in low, pruned plants (West 1983a). Both *Artemisia arbuscula* and *Artemisia nova* are considered a valuable browse plant during the spring, fall, and winter months and are often grazed by native ungulates (elk and mule deer) and domestic livestock. While grazing appears to have little effect on shrub densities, it does tend to decrease the abundance of tall bunchgrasses and increase the cover of forbs such as *Arenaria congesta* (Johnston 2001). Shrubs are favored in overgrazed ranges because heavy grazing may deplete the perennial graminoid layer leaving only a shrub layer that may increase at the expense of grass cover (Hironaka et al. 1983). Grazing also favors non-native, grazing-tolerant grass species such as *Poa bulbosa* and *Poa pratensis*.

Excessive grazing also stresses the system through soil disturbance, diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and annual grasses, particularly *Bromus tectorum*, and other exotic annual grasses. The introduction of exotic annual grasses has altered many stands by increasing the amount of fine fuels present that can substantially increase fire frequency and intensity which reduces the cover of fire-sensitive shrubs such as *Artemisia nova* (Fryer 2009).

Direct and indirect fire suppression are a threat to this system where stands are adjacent to pinyon-juniper woodlands. Over the long term, heavy grazing by livestock removes the fine fuels that carry fire that indirectly leads to a reduction in fire frequencies, which can lead to pinyon-juniper encroachment with subsequent loss of shrub and herbaceous understory (LANDFIRE 2007a).

Human development has impacted many locations throughout Wyoming. High- and low-density urban and industrial developments have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining or oil and gas operations can drastically impact natural vegetation. Large-scale wind power development is expanding in this system, fragmenting the habitat and facilitating establishment of invasive species. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from stand-replacing fires that occur under extreme fire weather conditions that kills sagebrush and expose bare soil to invasion by exotic herbaceous species or erosion. Invasion by exotic species such as *Bromus tectorum* can alter the fire regime by providing fine fuels that allow for repeated, high-frequency fires eliminate remaining sagebrush and preventing re-establishment creating extensive annual exotic grasslands. Unchecked erosion can result in topsoil removal.

High-severity environmental degradation appears where occurrences tend to be relatively small (<30 acres) for this large-patch type and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from too frequent fires can be caused by fine fuel accumulation from invasive annual grasses that results in loss of shrubs and reduction of all native species, especially dominant native grasses, to <50% total cover. In other instances, ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval to >100 years resulting in regeneration of trees (>10% cover).

Moderate-severity environmental degradation appears where occurrences are moderate (30-50 acres) in size for this large-patch type and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion. Altered fire regime from too frequent fires caused by fine fuel accumulation from invasive annual grasses results in reduction of shrubs and reduction of all native species, especially dominant native grasses, to 50-79% total cover. In other instances, ongoing fire suppression and reduction of fine fuels by grazing increased the fire-return interval from 75 to 100 years resulting in regeneration of trees (5-10% cover).

High-severity disruption of biotic processes appears where occurrences have low cover of native grassland species (<50% relative cover). There may be significant cover of trees (>10%) because of fire suppression. Invasive non-native species are abundant (>10% absolute cover to dominant). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity disruption of biotic processes appears where occurrences have low cover of native grassland species (50-85% relative cover). There may be significant cover of trees (5-10%) because of fire suppression. Invasive non-native species are abundant (3-10% absolute cover). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

M169. Great Basin-Intermountain Tall Sagebrush Steppe & Shrubland

CES304.083 Columbia Plateau Steppe and Grassland

CES304.083 CLASSIFICATION

Concept Summary: This system occurs throughout much of the Columbia Plateau. It is a bunchgrass-dominated grassland or steppe that is similar floristically to big sagebrush-dominated steppe, but is defined by a more frequent fire regime and the absence or low cover of shrubs over large areas. These are large, extensive grasslands, not grass-dominated patches within the sagebrush shrub-steppe ecological system. Soils are variable, ranging from relatively deep, fine-textured often with coarse fragments, and non-saline often with a microphytic crust, to stony volcanic-derived clays to alluvial sands. This grassland is dominated by perennial bunchgrasses and forbs (>25% cover), sometimes with a sparse (<10% cover) shrub layer. Associated graminoids include *Achnatherum hymenoides, Elymus elymoides, Elymus lanceolatus ssp. lanceolatus, Hesperostipa comata, Festuca idahoensis,* *Koeleria macrantha, Poa secunda*, and *Pseudoroegneria spicata*. Common forbs are *Phlox hoodii, Arenaria* spp., and *Astragalus* spp. Shrubs such as *Chrysothamnus viscidiflorus, Ericameria nauseosa, Tetradymia* spp., or *Artemisia* spp. are often present in disturbed stands. Areas with deeper soils are rare because of conversion to other land uses. The rapid fire-return regime of this ecological system maintains a grassland structure by retarding shrub invasion, and landscape isolation and fragmentation limit seed dispersal of native shrub species. Fire frequency is presumed to be less than 20 years. Through isolation from a seed source, combined with repeated burning, these are "permanently" (more than 50 years) converted to grassland.

Related Concepts:

CES304.083 CONCEPTUAL MODEL

Environment: These are large extensive grassland ecosystems, not grass-dominated patches within sagebrush shrub-steppe ecological system. This system occurs throughout much of the Columbia Plateau and is found at slightly higher elevations farther south. Soil depth and soil texture within precipitation zones largely drive the distribution of shrub-steppe and grassland (WNHP 2011). Geographically (climatically), this steppe system is associated with ~Inter-Mountain Basins Big Sagebrush Steppe (CES304.778)$$, rings the driest portion of the basin that supports the big sagebrush shrubland and the semi-desert shrub-steppe systems, and is bounded by montane woodlands and the Palouse prairie. It is found in landscapes that favor frequent ignition sources and fuels that spread fire, and few natural firebreaks. Biological soil crust is very important in this ecological system (WNHP 2011).

Climate: Climate is semi-arid, cool temperate with annual precipitation ranging from 18-40 cm and high inter-annual variation. Much of the precipitation falls as snow or spring rain; however, growing-season drought is characteristic. Temperatures are continental with large annual and diurnal variation. Winter precipitation dominates and promotes cool-season grasses.

Physiography/landform: Stands occur on valley floors, alluvial fans, floodplains, stabilized dunes, mesic uplands, swales, and rocky slopes. Slopes are variable from gentle to very steep.

Soil/substrate/hydrology: Soils are variable, ranging from relatively deep, fine-textured often with coarse fragments, and non-saline often with a biological soil crust, to stony volcanic-derived clays to alluvial sands. Burrowing animals and their predators likely played important roles in creating small-scale patch patterns (WNHP 2011).

Key Processes and Interactions: In the Columbia Plateau this grassland ecosystem occurs in a mosaic with sagebrush steppe vegetation and includes sagebrush steppe habitats where fire has removed the sagebrush; thus, due to change in fire regime, this type has expanded at the expense of sagebrush steppe (LANDFIRE 2007a).

Columbia Plateau ecosystems are more sensitive to grazing than grasslands in the Great Plains as they did not evolve with the same duration, seasonality, and severity of large native ungulate grazing (Mack and Thompson 1982, Burkhart 1996). In general, native ungulate grazing was dispersed and occurred during the winter and spring when forage was available.

These grasslands are defined by a more frequent fire regime and the absence or low cover of shrubs over large areas, occasionally entire landforms. The historic frequency was 30-100 years (LANDFIRE 2007a). The natural fire regime of this ecological system likely maintains a patchy distribution of shrubs so the general aspect of the vegetation is a grassland. Post-fire shrub recruitment is limited and rate is estimated to be 25 acres in 50 years under ideal conditions for *Artemisia tridentata* (WNHP 2011). These shrubs produce large quantities of small seeds beginning at age 3-4 years of which 90% of the seed is dispersed within 9 m (30 feet) of the parent and few seeds are carried more than 30 m (100 feet) (Tirmenstein 1999c). Biological soil crust is very important in this ecological system (LANDFIRE 2007a).

LANDFIRE developed a somewhat different VDDT model for this system which has three classes (LANDFIRE 2007a, BpS 0911230):

A) Early Development 1 All Structures (herbaceous-dominated - 5% of type in this stage): Herbaceous cover is variable (10-50%). Grassland having just burned. Young, green vegetation. Lasts one year before natural succession to class B.

B) Mid Development 1 Open (herbaceous-dominated - 80% of type in this stage): Herbaceous cover 51-90%. Perennial bunchgrass with solid cryptogam cover, large bluebunch wheatgrasses, lower *Poa secunda* and forb cover, greater forb diversity. Patches are anywhere from 2-50 years old. Replacement fire is the primary disturbance (MFR=50 years).

C) Late Development 1 Closed (herbaceous-dominated - 15% of type in this stage): Herbaceous cover 51-90%. Shrub cover is 0-30%. Native grassland with shrubs beginning to get a foothold, or small pockets of remnants from the original fire expanding into the grassland. It equals the early-seral states in Wyoming big sagebrush steppe ecological system. Patches within this matrix die back due to competition/maintenance, but this does not have a profound effect on class condition. Replacement fire occurs every 16-17 years on average.

Shrubs may increase following heavy grazing and/or with fire suppression, particularly in moist portions in the northern Columbia Plateau where it forms a landscape mosaic pattern with shallow-soil scabland shrublands.

Threats/Stressors: Conversion of this type has commonly come from conversion to invasive non-native species such as *Bromus tectorum, Centaurea solstitialis, Hypericum perforatum*, and *Poa pratensis*. These invasive species increase post disturbance including long-term excessive grazing by livestock, or direct soil disturbance from severe trampling by livestock and roads. Altered fire regimes such as repeated, high-frequency fire has eliminated shrubs and created extensive grasslands dominated by non-native invasive annual grass *Bromus tectorum* and other non-native annual species (Pellant 1990, 1996). Additionally, in some places fire suppression has allowed succession and conversion to shrublands (LANDFIRE 2007a, WNHP 2011). The primary land uses that alter the natural processes of this system are associated with livestock practices, annual exotic species, fire regime alteration, direct soil surface disturbance, and fragmentation from roads and agriculture (WNHP 2011).

Ecosystems in the Columbia Basin are more sensitive to livestock grazing than grasslands in the Great Plains as they did not evolve with the same duration, seasonality, and severity of large native ungulate grazing (Mack and Thompson 1982, Burkhart 1996). In the early 1900s, heavy sheep and cattle grazing led to an increase of shrubs into much of the area. Excessive grazing stresses the system through soil disturbance, trampling and displacing the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and exotic annual grasses, particularly *Bromus tectorum* (Pellant 1990, 1996). Persistent grazing will further diminish perennial cover, expose bare ground, and increase exotic annuals. Currently, fire further stresses livestock-altered vegetation by increasing exposure of bare ground and consequent increases in exotic annuals and decrease in perennial bunchgrass. In more mesic steppe, fire is not as important in maintenance of perennial grasses and forbs. Fescue dominates more heavily on north aspects and moist sites, which have a lower fire frequency (LANDFIRE 2007a). Shrubs may increase with fire suppression, particularly in moist portions in the northern Columbia Plateau where it forms a landscape mosaic pattern with shallow-soil scabland shrublands.

Any disturbances to soil and bunchgrass layers, such as vehicle tracks and chaining shrubs, will increase the probability of alteration of vegetation structure and composition and response to fire as discussed above. Johnson and Swanson (2005) note that *Festuca idahoensis* decreases following fire, but following a flush of annuals, these sites regain pre-fire cover after a few years. Repeated, high-frequency fire has eliminated the sagebrush and the seed sources of sagebrush, creating extensive grasslands (LANDFIRE 2007a). Currently, cheatgrass and other introduced grasses often invade these habitats after fire. Too much fire has turned steppe into annual grasslands in many areas and has turned large areas of shrubland into grasslands (LANDFIRE 2007a).

Fragmentation of shrub-steppe by agriculture increases cover of annual grass, total annual/biennial forbs, bare ground, decreases cover of perennial forbs and biological soil crusts, and reduces obligate insects (Quinn 2004), obligate birds and small mammals (Vander Haegen et al. 2000, 2001). These fragmentation responses are similarly expected in steppe vegetation (WNHP 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing or too frequent fire where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<25 acres) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion (WNHP 2011). Altered fire regime from historic range of variability (FRI = 30-100 years) such as frequent fire that removes shrubs and native perennial grasses from system and allows invasion of annual, non-native grasses the increase fire frequency (WNHP 2011), or fire suppression and reduction of fine fuels by grazing has extended the fire-return interval to >100 years (Landfire 2007a) resulting in regeneration of shrubs and/or trees (>10 % cover). Biological soil crust, if present, is found only in protected areas (WNHP 2011).

Moderate-severity environmental degradation appears where occurrences are moderate (25-125 acres) in size and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion (WNHP 2011). Altered fire regime from fire suppression and reduction of fine fuels by grazing increased the fire-return interval to >100 years (Landfire 2007a) resulting in regeneration of shrubs and/or trees (5-10% cover). Biological soil crust is present in protected areas and with a minor component elsewhere (WNHP 2011).

High-severity disruption of biological processes appears where occurrences have low cover of native grassland species (<50% relative cover) (WNHP 2011). There may be significant cover of shrubs and/or trees (>10%) because of fire suppression. Invasive non-native species such as *Bromus tectorum* are abundant (>10% absolute cover) (Pellant 1996, WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity disruption of biological processes appears where occurrences have low cover of native grassland species (50-85% relative cover) (WNHP 2011). There may be significant cover of shrubs and/or trees (5-10%) because of fire suppression. Invasive non-native species such as *Bromus tectorum* are abundant (3-10% absolute cover) (Pellant 1996, WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.774 Great Basin Xeric Mixed Sagebrush Shrubland

CES304.774 CLASSIFICATION

Concept Summary: This ecological system occurs in the Great Basin on dry flats and plains, alluvial fans, rolling hills, rocky hillslopes, saddles and ridges at elevations between 1000 and 2600 m. Sites are dry, often exposed to desiccating winds, with typically shallow, rocky, non-saline soils. Shrublands are dominated by *Artemisia nova* (mid and low elevations), *Artemisia arbuscula ssp. longicaulis*, or *Artemisia arbuscula ssp. longiloba* (higher elevation) and may be codominated by *Artemisia tridentata ssp. wyomingensis* or *Chrysothamnus viscidiflorus*. Other shrubs that may be present include *Atriplex confertifolia, Ephedra* spp., *Ericameria* spp., *Grayia spinosa, Lycium shockleyi, Picrothamnus desertorum*, and *Tetradymia* spp. The herbaceous layer is likely sparse and composed of perennial bunchgrasses, such as *Achnatherum hymenoides, Achnatherum speciosum, Achnatherum thurberianum, Elymus elymoides*, or *Poa secunda*.

CES304.774 CONCEPTUAL MODEL

Environment: *Climate:* Climate is semi-arid with 20 to 30 cm of annual precipitation and warm summers and cold winters.

Physiography/landform: This ecological system is widely distributed in the interior Great Basin of the western United States on dry flats and plains, alluvial fans, rolling hills and foothills, saddles and ridges at elevations between 1000 and 2600 m. Sites are xeric, flat to steep, and often exposed to desiccating winds or with typically shallow, rocky, non-saline soils. It occupies flat to steeply sloping upland sites, on a wide variety of topographic positions. Sloping sites tend to have southerly aspects.

Soil/substrate/hydrology: Sites with low slope tend to have deeper soils, while those with steeper slopes have shallow to moderately deep soils that are well-drained. Soil texture is loam, sandy loam, or clay loam (Hansen and Hoffman 1988), and there is often a significant amount of coarse fragments in the soil profile. Hironaka et al. (1983) reported that most of the habitat occurred on calcareous soils, often with a cemented duripan. Low sagebrush tends to grow where claypan layers exist in the soil profile and soils are often saturated during a portion of the year; black sagebrush tends to grow where there is a root-limiting layer in the soil profile, whereas Wyoming sagebrush and basin big sagebrush generally occur on moderately deep to deep soils that are well-drained (LANDFIRE 2007a). The environmental description is based on several other references, including Blackburn and Tueller (1970), Zamora and Tueller (1973), Hironaka et al. (1983), West (1983a), Barbour and Major (1988), Chappell et al. (1997), Howard (1999), Steinberg (2002a), Barbour et al. (2007a), Fryer (2009), and Sawyer et al. (2009).

Key Processes and Interactions: The diagnostic species of this system, *Artemisia nova, Artemisia arbuscula ssp. longicaulis*, or *Artemisia arbuscula ssp. longiloba*, grow in more xeric sites than other *Artemisia* shrublands (Hironaka et al. 1983). This shrubland system is associated with shallow, rocky soils which experience extreme drought in summer. The plants are low and widely spaced, which tends to decrease the risk of fire (Chappell et al. 1997). Fire is uncommon because of discontinuous and low fuel buildup on the generally unproductive sites (Young and Palmquist 1992, Fryer 2009, Sawyer et al. 2009). Most sites are thought to have relatively long fire-return intervals (100-200 years) according to LANDFIRE models developed by experts (LANDFIRE 2007a). These shrubs are fire-sensitive and rarely sprout after burning. They reproduce from light wind-dispersed seeds from adjacent unburned areas into disturbed areas (Howard 1999, Steinberg 2002a, Fryer 2009). It generally takes around 30 years for a burned stand to recover to pre-fire density (Zamora and Tueller 1973, Hironaka et al. 1983, Howard 1999, Steinberg 2002a, Fryer 2009). *Artemisia tridentata ssp. wyomingensis* may be present to codominant and shares similar ecological characteristics on these relatively xeric sites (Howard 1999).

Scattered trees may be present in some stands of this system. Fire reduces sagebrush abundance in both sagebrush and pinyon-juniper systems. Where these systems are adjacent, periodic fire likely prevents establishment of juniper and pinyon trees in sagebrush stands (Wright et al. 1979). Blackburn and Tueller (1970) noted rapid invasion of these communities by *Juniperus osteosperma* and *Pinus monophylla* at some sites in Nevada. In order to maintain dominance of sagebrush, fire-return interval must be long enough to permit sagebrush stands to mature, but short enough to prevent establishment and growth of trees in these sites.

Fire-return intervals of 150-250 years for stand-replacing fire will likely maintain these shrublands. Expansion and contraction of trees into sagebrush shrublands are regulated by a combination of climate, fire, and bark beetle infestations with trees seedlings establishing during wetter periods (Wright et al. 1979, Clifford et al. 2008).

The black and low sagebrush type tends to occur adjacent to ~Inter-Mountain Basins Big Sagebrush Shrubland (CES304.777)$$. The Wyoming big sagebrush and basin big sagebrush types create a mosaic within the black and low sagebrush types. These big sagebrush types have a different fire regime that acts to carry the fire, with black and low sagebrush serving as firebreaks most of the time (LANDFIRE 2007a).

Black sagebrush (*Artemisia nova*) generally supports more fire than other dwarf sagebrushes (LANDFIRE 2007a). This type generally burns with mixed severity (average FRI of 100-140 years) due to relatively low fuel loads and herbaceous cover (LANDFIRE 2007a). Bare ground acts as a micro-barrier to fire between low-statured shrubs. Stand-replacing fires (average FRI of 200-240 years) can occur in this type when successive years of above-average precipitation are followed by an average or dry year (LANDFIRE 2007a). Stand-replacement fires dominate in the late-successional class where the herbaceous component has been diminished or where trees dominate (LANDFIRE 2007a). This type fits best into Fire Regime Group IV (LANDFIRE 2007a).

Grazing by wild ungulates occurs in this shrubland system. Native browsing tends to open up the canopy cover of shrubs but does not often change the successional stage (LANDFIRE 2007a).

Insects are an important component of many shrub-steppe and grassland systems. Mormon crickets and grasshoppers are natural components of many rangeland systems (USDA-APHIS 2003, 2010). There are almost 400 species of grasshoppers that inhabit the western United States with 15-45 species occurring in a given rangeland system (USDA-APHIS 2003). Mormon crickets are also present in many western rangelands and, although flightless, are highly mobile and can migrate large distances consuming much of the forage while travelling in wide bands (USDA-APHIS 2010). Following a high population year for grasshoppers or Mormon crickets and under relatively warm dry spring environmental conditions that favor egg hatching and grasshopper and Mormon cricket survival, there may be large population outbreaks that can utilize 80% or more of the forage in areas as large as 2000 square mile. Conversely, relatively cool and wet spring weather can limit the potential for outbreaks. These outbreaks are naturally occurring cycles and, especially during drought, can denude an area of vegetation leaving it exposed to increased erosion rates from wind and water (USDA-APHIS 2003).

LANDFIRE developed a VDDT model for this system which has three classes (LANDFIRE 2007a, BpS 1210790). This model includes sites where there is potential for pinyon (*Pinus monophylla*) and/or juniper (*Juniperus osteosperma*) establishment in classes C and D.

A) Early Development 1 All Structures (15% of type in this stage): Shrub cover is 0-5%. Early-seral community dominated by herbaceous vegetation; less than 6% sagebrush canopy cover; up to 24 years post-disturbance. Fire-tolerant shrubs (green/low rabbitbrush) are first sprouters after stand-replacing, high-severity fire. Replacement fire (mean FRI of 250 years) maintains vegetation in class A. Prolonged drought every 200 years on average maintains vegetation in class A. Succession to class B after 25 years.

B) Mid Development 1 Open (60% of type in this stage): Mid-seral community with a mixture of herbaceous and shrub vegetation; 6-25% sagebrush (sagebrush/brush) canopy cover present; between 20-59 years post-disturbance. Drought every 200 years causes two transitions: 50% of times drought thins shrubs while maintaining vegetation in class B, whereas 50% of times drought causes a stand-replacing event. Replacement fire (FRI of 250 years) causes a transition to class A, whereas mixed-severity fire (FRI of 100 years) maintains the site in its present condition. In the absence of fire for at least 120 years, the site will follow an alternative successional path to class C. Otherwise, succession and mixed-severity fire keeps site in class B.

C) Late Development 1 Open (15% of type in this stage): Late-seral community with a mixture of herbaceous and shrub vegetation; 10-25% sagebrush canopy cover present; and dispersed conifer seedlings and saplings established at less than 6% cover (*Juniperus osteosperma* and/or *Pinus monophylla*). Insects attack the vegetation in this state every 60 years on average but does not cause a transition to another state. Severe droughts (return interval of 200 years) cause two thinning disturbances: to class B (50% of times) and within class C. Replacement fire is every 200 years on average, whereas mixed-severity fire is less frequent than in class B (FRI of 130 years). Succession is to class D after 75 years.

D) Late Development 1 Closed (10% of type in this stage): Late-seral community with a closed canopy of conifer trees (6-40% cover). The degree of tree canopy closure differs depending on whether it is a low sagebrush (maximum 15%) or black sagebrush (maximum 40%) community. In low sagebrush communities a mixture of herbaceous and shrub vegetation with >10% sagebrush canopy cover would still be present. In black sagebrush communities the herbaceous and shrub component would be greatly reduced (<1%). When Ips beetle outbreaks occur the pinyon pine component is reduced (return interval of 60 years): 75% of times thinning is not intense enough to cause a transition whereas in 25% of cases a transition to class C will occur. The only fire is replacement (FRI of 150 years) and driven by a greater amount of woody fuel than in previous states. Prolonged droughts have the same effect as before.

Threats/Stressors: The primary land uses that alter the natural processes of this system are associated with livestock grazing and introduction of exotic annual grasses. Barbour and Major (1988) report that *Artemisia nova* is utilized by livestock to a much greater degree than other species of *Artemisia*, resulting in low, pruned plants (West 1983a). Excessive grazing stresses the system through soil disturbance, diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and annual grasses, particularly *Bromus madritensis, Bromus tectorum, Schismus* spp., and other exotic annual grasses. The introduction of exotic annual grasses has altered many stands by increasing the amount of fine fuels present that can substantially increase fire frequency and intensity which reduces the cover of fire-sensitive shrubs such as *Artemisia nova* (Fryer 2009, Sawyer et al. 2009).

Direct and indirect fire suppression are a threat to this system where stands are adjacent to pinyon-juniper woodlands. Over the long term, heavy grazing by livestock removes the fine fuels that carry fire that indirectly leads to a reduction in fire frequencies, which can lead to pinyon-juniper encroachment with subsequent loss of shrub and herbaceous understory (LANDFIRE 2007a).

When grasshopper and Mormon cricket populations reach outbreak levels, they cause significant economic losses for ranchers and livestock producers, especially when accompanied by a drought (USDA-APHIS 2003, 2010). Both rangeland forage and cultivated crops can be consumed by grasshoppers. The U.S. Department of Agriculture's (USDA) Animal and Plant Health Inspection Service (APHIS) is the Federal agency responsible for controlling economic infestations of grasshoppers on western rangelands with a cooperative suppression program. They work with federal land managing agencies to conduct grasshopper suppression. The goal of APHIS's grasshopper program is not to eradicate them but to reduce outbreak populations to less economically damaging levels (USDA-APHIS 2003). This APHIS effort dampens the natural ecological outbreak cycles of grasshoppers and Mormon crickets but does not eradicate the species.

Human development has impacted many locations throughout the range of this system. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.
Ecosystem Collapse Thresholds: Ecological collapse tends to result from stand-replacing fires that occur under extreme fire weather conditions that kill sagebrush and expose bare soil to invasion by exotic herbaceous species or erosion. Invasion by exotic species such as *Bromus tectorum* can alter the fire regime by providing fine fuels that allow for repeated, high-frequency fires that eliminate remaining sagebrush and prevent re-establishment creating extensive annual exotic grasslands. Unchecked erosion can result in topsoil removal.

High-severity environmental degradation appears where occurrences tend to be relatively small (<30 acres) for this large-patch type and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from too frequent fires can be caused by fine fuel accumulation from invasive annual grasses that results in loss of shrubs and reduction of all native species, especially dominant native grasses, to <50% total cover; or in other instances, ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval to >100 years resulting in regeneration of trees (>10% cover).

Moderate-severity environmental degradation appears where occurrences are moderate (30-50 acres) in size for this large patch type and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion. Altered fire regime from too frequent fires caused by fine fuel accumulation from invasive annual grasses results in reduction of shrubs and reduction of all native species, especially dominant native grasses, to 50-79% total cover; or in other instances fire suppression and reduction of fine fuels by grazing increase the fire-return interval from 75 to 100 years resulting in regeneration of trees (5-10% cover).

High-severity disruption of biotic processes appears where occurrences have low cover of native grassland species (<50% relative cover. There may be significant cover of trees (>10%) because of fire suppression. Invasive non-native species are abundant (>10% absolute cover to dominant). connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity disruption of biotic processes appears where occurrences have low cover of native grassland species (50-85% relative cover). There may be significant cover of trees (5-10%) because of fire suppression. Invasive non-native species are abundant (3-10% absolute cover). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations.; Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.777 Inter-Mountain Basins Big Sagebrush Shrubland

CES304.777 CLASSIFICATION

Concept Summary: This ecological system occurs throughout much of the interior western U.S., typically in broad basins between mountain ranges, plains and foothills between 800 and 2500 m elevation. Soils are typically deep, well-drained and non-saline. These shrublands are dominated by *Artemisia tridentata ssp. tridentata* (not as common in Wyoming or Montana but possibly on stabilized part of Killpecker Dunes in Wyoming) and/or *Artemisia tridentata ssp. wyomingensis* (predominant in Wyoming and Montana). Scattered *Juniperus* spp., *Sarcobatus vermiculatus*, and *Atriplex* spp. may be present in some stands. *Ericameria nauseosa, Chrysothamnus viscidiflorus, Purshia tridentata* (not commonly in Montana or Wyoming), or *Symphoricarpos oreophilus* may codominate disturbed stands (e.g., in burned stands, these may become more predominant). Perennial herbaceous components typically contribute less than 25% vegetative cover. Common graminoid species can include *Achnatherum hymenoides, Bouteloua gracilis, Elymus lanceolatus, Festuca idahoensis* (not in Montana or Wyoming), *Hesperostipa comata, Leymus cinereus, Pleuraphis jamesii* (not present in northeastern portions of the range), *Pascopyrum smithii, Poa secunda*, or *Pseudoroegneria spicata* (not in Wyoming). Dunes in the Red Desert have areas of large basin big sage with very dense canopies. In Wyoming, this system is likely to only contain *Artemisia tridentata ssp. tridentata*.

Distribution: This system occurs throughout much of the interior western U.S., typically in broad basins between mountain ranges, plains and foothills. Its core distribution is in the Great Basin, but it extends north into the Columbia Basin and west into the foothills of the Sierra Nevada and Cascades, and east into the Colorado Plateau, Wyoming Basins and central and eastern Montana, although much of the sagebrush in this region is more steppe in physiognomy.

CES304.777 CONCEPTUAL MODEL

Environment: This ecological system occurs throughout much of the interior western U.S., typically in broad basins between mountain ranges, plains and foothills between 1500 and 2500 m elevation.

Climate: The climate where this system occurs is semi-arid with annual precipitation ranging from 18-40 cm and high inter-annual variation. Much of the precipitation falls as snow, and growing-season drought is characteristic. Temperatures are continental with large annual and diurnal variation. In drier regions, these shrublands are usually associated with perennial or ephemeral stream drainages with water tables less than 3 m from the soil surface.

Physiography/landform: Sites supporting this system include flat to steeply sloping uplands on alluvial fans and terraces, toeslopes, lower and middle slopes, draws, badlands, and deep, well-drained alluvial bottomlands foothills and basins and plains (Barker and McKell 1983).

Soil/substrates/hydrology: In drier regions, these shrublands are usually associated with perennial or ephemeral stream drainages with water tables less than 3 m from the soil surface. Substrates are typically deep, well-drained and non-saline, fine- to medium-textured alluvial soils with some source of subirrigation during the summer season, but moderately deep upland soils with ample moisture storage also support these shrublands. Some stands occur on deep, sandy soils, or soils that are highly calcareous (Hironaka et al. 1983). Although this system may grade into sites with alkaline soils at the edge of internally drained basins, *Artemisia tridentata* is a non-halophyte and requires low salinity for optimum growth. The importance of perennial bunch grasses, the most typical herbaceous associates, is favored with greater spring and summer rain, which increases northward and eastward.

The environmental description is based on several references, including Brown (1982a), Hironaka et al. (1983), West (1983a), Barbour and Billings (1988), Knight (1994), Shiflet (1994), Holland and Keil (1995), Reid et al. (1999), West and Young (2000), Barbour et al. (2007a), and Sawyer et al. (2009).

Key Processes and Interactions: Complex ecological interactions of fire regimes and climate patterns result in equally complex patterns of species structure and composition in *Artemisia tridentata* stands. Prolonged drought on the more xeric sites may result in lower shrub cover. Flooding may also cause plant mortality if the soil remains saturated for an extended period of time. The Aroga moth is capable of defoliating large acreages (i.e., >1000 acres, but usually 10-100 acres). Heavy grazing by wildlife can remove the fine fuels that support mixed-severity fires and result in woody fuel buildup that leads to severe, stand-replacement fires (LANDFIRE 2007a, BpS 1210800).

Big sagebrush reproduces from seed only, so stands are inhibited by fire as *Artemisia tridentata* does not sprout after burning (Howard 1999, Tirmenstein 1999c). Increasing fire frequency can eliminate the shrubs from the stands (Daubenmire 1970, Tirmenstein 1999c). With a change in fire frequency, species composition will be altered as well (West 1983a). With a high fire frequency (every 2-5 years), perennial grasses and shrubs are eliminated and non-native annual grasses dominate (Whisenant 1990, D'Antonio and Vitousek 1992). At fire-return intervals of 10-30 years, short-lived resprouting shrubs such as *Chrysothamnus* or *Tetradymia* spp. dominate. At fire-return intervals of 30-70 years, a mixture of perennial bunch grasses and non-sprouting shrubs is maintained (Johnson 2000b). Finally, in the complete absence of fire, deep-rooted shrubs such as *Artemisia tridentata* become dominant. At higher-elevation sites with absence of fire (>100 years), *Pinus monophylla* and *Juniperus osteosperma* trees may invade and eventually dominate sites (Tirmenstein 1999c).

Insects are an important component of many shrub-steppe and grassland systems. Mormon crickets and grasshoppers are natural components of many rangeland systems (USDA-APHIS 2003, 2010). There are almost 400 species of grasshoppers that inhabit the western United States with 15-45 species occurring in a given rangeland system (USDA-APHIS 2003). Mormon crickets are also present in many western rangelands and, although flightless, are highly mobile and can migrate large distances consuming much of the forage while travelling in wide bands (USDA-APHIS 2010). Following a high population year for grasshoppers or Mormon crickets and under relatively warm dry spring environmental conditions that favor egg hatching and grasshopper and Mormon cricket survival, there may be large population outbreaks that can utilize 80% or more of the forage in areas as large as 2000 square mile. Conversely, relatively cool and wet spring weather can limit the potential for outbreaks. These outbreaks are naturally occurring cycles and, especially during drought, can denude an area of vegetation leaving it exposed to increased erosion rates from wind and water (USDA-APHIS 2003).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total and two classes (classes D & E) that model conversion to forest systems (LANDFIRE 2007a, BpS 1210800). These are summarized as:

A) Early Development 1 - All Structures (15% of type in this stage): Early development is dominated by grasses and forbs with scattered shrubs representing <10% upper canopy cover. Post-replacement disturbance; grass-dominated with scattered shrubs. Fuel loading discontinuous. Surface fire occurs every 200 years on average but has no effect on succession. Succession to class B after 20 years.

B) Mid Development 1 Open (shrub-dominated - 50% of type in this stage): Shrub cover 11-50%. Shrubs and herbaceous vegetation can be codominant, fine fuels bridge the woody fuels, but fuel discontinuities are possible. Replacement fire accounts for 80% of fire activity (mean FRI of 125 years), whereas mixed-severity fire occurs every 500 years on average (20% of fire activity) and maintains vegetation in class B. Succession to class C after 40 years.

C) Mid Development 1 Closed (shrub-dominated - 25% of type in this stage): Shrubs dominate the landscape; fuel loading is primarily woody vegetation. Shrub density sufficient in old stands to carry the fire without fine fuels. Establishment of pinyon and juniper seedlings and saplings widely scattered. Replacement fire (mean FRI of 100 years) and rare flood events (return interval of 333 years) cause a transition to class A. Prolonged drought (mean return interval of 100 years) and insect/disease (every 75 years on average) cause a transition to class B. Succession to class D after 40 years.

D) Late Development 1 Open (5% of type in this stage): Shrubs may still represent the dominant lifeform with pinyon and juniper saplings common (1-15% upper canopy cover). Pinyon-juniper encroachment where disturbance has not occurred for at least 100 years (tree species cover <15%). Saplings and young trees are the dominant lifeform. Sagebrush cover (<25%) and herbaceous cover decreasing compared to class C. Replacement fire occurs every 125 years on average. Insect/disease (every 75 years) and prolonged drought (every 100 years) thin both trees and shrubs, causing a transition to class C. Succession to class E after 50 years.

E) Late Development 1 Closed (5% of type in this stage): Shrubland encroached with mature pinyon and/or juniper (cover 16-90%) where disturbance does not occur for at least 50 years in class D. Shrub cover <10% and graminoids scattered. Replacement fire occurs every 125 years on average. Prolonged drought thins trees, causing a transition to class B.

Threats/Stressors: Conversion of this type has come from agriculture (wheat farming and non-native hay production) where soils are deeper and water sources are available. Rangeland management such as sagebrush reduction treatments (frequent burning, herbicide spraying, and mechanical techniques such as plowing or mowing, and planting *Agropyron cristatum*) also convert large areas (Wambolt and Payne 1986, Beck et al. 2012). Substantial area has been lost due to invasive non-native species such as *Bromus tectorum, Centaurea solstitialis, Hypericum perforatum, Poa pratensis, Taeniatherum caput-medusae*, and *Ventenata dubia* (Young and Evans 1971, 1973, Mack 1981b, D'Antonio and Vitousek 1992, Chambers et al. 2007a, D'Antonio et al. 2009, Chambers et al.

2013, Miller et al. 2014). These invasive species increase post-disturbance, including long-term excessive grazing by livestock, or direct soil disturbance from severe trampling by livestock, ORVs and roads. Altered fire regimes such as repeated, high-frequency fires have eliminated shrubs and created extensive grasslands dominated by non-native invasive annual grass *Bromus tectorum* and other non-native annual species (Pellant 1990, 1996). Additionally, in some places fire suppression has allowed succession and conversion to woodlands (Tirmenstein 1999c, LANDFIRE 2007a, WNHP 2011).

The primary land uses that alter the natural processes of this system are associated with livestock management practices, annual exotic plant species, fire regime alteration, direct soil surface disturbance, and landscape fragmentation (WNHP 2011). Excessive grazing stresses the system through soil disturbance, diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and annual grasses, particularly *Bromus tectorum* and other exotic annual bromes. If soil moisture is sufficient and sagebrush seeds are available, grazing can result in increased shrub density depending on the amount of cheatgrass in the understory. There are strong links between foliose lichens and ecosystem health. Severe trampling breaks lichens into fragments too small to re-establish and eventually leads to foliose lichen elimination (Rosentreter and Eldridge 2002).

Fire further stresses livestock-altered vegetation by increasing exposure of bare ground and consequently increases exotic annuals and decreases perennial bunchgrass and sagebrush abundance. Presettlement stand-replacing fire frequency was 40-60 years, with smaller fires every 20-25 years (Wright et al. 1979). Repeated burning every few years or burning in summer will reduce the cover of perennial grasses and allow invasive forbs and cheatgrass to increase. Following a fire, sagebrush must re-establish itself from seed, and recovery is slow (Bunting et al. 1987). Fire favors shrubs such as *Ericameria nauseosa* that can resprout after fire (Tirmenstein 1999b). Fine fuel adjacency from exotic annual grasses, such as *Bromus tectorum, Taeniatherum caput-medusae, Bromus madritensis*, and *Schismus* spp., currently represents the most important fuelbed component in the system and can substantially increase the fire frequency. Locally in areas with a high fire frequency (every 2-5 years) or high-severity fire, perennial grasses and shrubs may be eliminated and non-native annual grasses will dominate (Pellant 1990, 1996).

Fire suppression, even in the absence of livestock grazing impacts, can increase shrub density that in turn reduces bunchgrass cover or results in increased grass litter and fire fuel. Both conditions increase the probability of fire and vegetation responses that increase annual grass abundance following fire (Davies et al. 2009). Fire suppression can lead to pinyon-juniper encroachment with subsequent loss of shrub and herbaceous understory where adjacent to pinyon-juniper woodlands (LANDFIRE 2007a).

Any soil and bunchgrass layer disturbances, such as vehicle tracks or chaining shrubs, will increase the probability of alteration of vegetation structure and composition, and response to fire as discussed above. Loss of shrub density and degradation of the bunchgrass layer's native diversity has been found to decrease the presence of obligate shrub-steppe birds (Vander Haegen et al. 2000). Fragmentation of shrub-steppe by agriculture increases cover of annual grasses, total annual/biennial forbs, and bare ground, and decreases cover of perennial forbs and biological soil crusts, and reduces populations of obligate insects (Quinn 2004), obligate birds and small mammals (Vander Haegen et al. 2000, 2001).

Human development has impacted many locations throughout the type distribution. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations and energy development facilities can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances allow invasive non-native species to become established and outcompete and replace the dominant native perennial species.

High-severity environmental degradation appears where occurrences tend to be relatively small (<30,000 acres) for this matrix type (CNHP 2010) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from too frequent fires can be caused by fine fuel accumulation from invasive annual grasses. This results in loss of shrubs and reduction of all native species especially dominant native grasses to <50% total cover (WNHP 2011). In other instances, ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval >100 years (Tirmenstein 1999c) resulting in regeneration of trees (>10% cover).

Moderate-severity environmental degradation appears where occurrences are moderate (30,000-50,000 acres) in size for this matrix type (CNHP 2010) and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion. Altered fire regime from too frequent fires caused by fine fuel accumulation from invasive annual grasses results in reduction of shrubs and reduction of all native species especially dominant native grasses to 50-79% total cover (WNHP 2011). Fire suppression and reduction of fine fuels by grazing increased the fire-return interval from 70-100 years (Tirmenstein 1999c) resulting in regeneration of trees (5-10% cover).

High-severity disruption appears where occurrences have low cover of native grassland species (<50% relative cover) (WNHP 2011). There may be significant cover of trees (>10%) because of fire suppression. Invasive non-native species are abundant (>10% absolute cover to dominant) (CNHP 2010, WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity disruption appears where occurrences have low cover of native grassland species (50-85% relative cover) (WNHP 2011). There may be significant cover of trees (5-10%) because of fire suppression. Invasive non-native species are abundant (3-10% absolute cover) (CNHP 2010, WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.778 Inter-Mountain Basins Big Sagebrush Steppe

CES304.778 CLASSIFICATION

Concept Summary: This widespread matrix-forming ecological system occurs throughout much of the Columbia Plateau and northern Great Basin, east into the Wyoming Basins, central Montana, and north and east onto the western fringe of the Great Plains in South Dakota. It is found at slightly higher elevations farther south. Relative to other portions of the distribution, in central Montana this system occurs in areas with more summer rain than winter snow precipitation, more overall annual precipitation, and it occurs on glaciated landscapes. Across the entire distribution of this type, soils are typically deep and non-saline, often with a microphytic crust. This shrub-steppe is dominated by perennial grasses and forbs (>25% cover) with *Artemisia tridentata ssp. tridentata* (this is not at all important in Wyoming occurrences), *Artemisia tridentata ssp. xericensis, Artemisia tridentata ssp. wyomingensis, Artemisia tripartita ssp. tripartita* (Snake River valley in Wyoming), *Artemisia cana ssp. cana*, and/or *Purshia tridentata* dominating or codominating the open to moderately dense (10-40% cover) shrub layer. *Atriplex confertifolia, Chrysothamnus viscidiflorus, Ericameria nauseosa, Sarcobatus vermiculatus, Tetradymia* spp., or *Artemisia frigida* may be common especially in disturbed stands. In Montana and Wyoming, stands are more mesic, with more biomass contributed by grasses, have less shrub diversity than stands farther west, and 50 to 90% of the occurrences are dominated by *Artemisia tridentata ssp. wyomingensis* with *Pascopyrum smithii*. Associated graminoids can include *Achnatherum hymenoides, Calamagrostis montanensis, Elymus lanceolatus ssp. lanceolatus, Koeleria macrantha, Poa secunda, Pascopyrum smithii, Hesperostipa comata, Nassella viridula, Bouteloua gracilis*, and *Pseudoroegneria spicata*. Important rhizomatous species include *Carex filifolia* and *Carex duriuscula*, which are very common and important in the eastern distribution of this system in both Wyoming and Montana. *Festuca idahoensis* is uncommon in this system, although it does occur in areas of higher elevations/precipitation; *Festuca campestris* is also uncommon. In Wyoming, both *Nassella viridula* and *Pseudoroegneria spicata* rarely occur, with the latter typically found in eastern Wyoming on ridgetops and rocky slopes outside of this system. In Montana, there is an absence of *Festuca* spp., except *Vulpia octoflora*. Common forbs are *Phlox hoodii, Arenaria* spp., *Opuntia* spp., *Sphaeralcea coccinea, Dalea purpurea, Liatris punctata*, and *Astragalus* spp. Areas with deeper soils more commonly support *Artemisia tridentata ssp. tridentata* but have largely been converted for other land uses. The natural fire regime of this ecological system likely maintains a patchy distribution of shrubs, so the general aspect of the vegetation is a grassland. Shrubs may increase following heavy grazing and/or with fire suppression, particularly in moist portions of the northern Columbia Plateau where it forms a landscape mosaic pattern with shallow-soil scabland shrublands. Where fire frequency has allowed for shifts to a native grassland condition, maintained without significant shrub invasion over a 50- to 70-year interval, the area would be considered ~Columbia Basin Foothill and Canyon Dry Grassland (CES304.993)$$. This ecological system is closely related to the warm-dry sagebrush in the resistance-resilience framework.

Distribution: This system occurs throughout much of the Columbia Plateau, the northern Great Basin, central and southeastern Montana, and Wyoming, and is found at slightly higher elevations farther south.

Nations: CA, US

Concept Source: K.A. Schulz

Description Author: G. Kittel, M.S. Reid, K.A. Schulz

CES304.778 CONCEPTUAL MODEL

Environment: This widespread matrix-forming ecological system occurs throughout much of the Columbia Plateau and northern Great Basin, east into the Wyoming Basins, central Montana, and north and east onto the western fringe of the Great Plains in Montana and South Dakota. It is found at slightly higher elevations farther south.

Climate: Climate is semi-arid and continental with annual precipitation ranging from 18-40 cm and with high inter-annual variation. Precipitation amount and time vary depending on location, with stands in the western portion of its range receiving winter/spring precipitation and very little summer precipitation, whereas stands in the eastern portion of its range receive both winter and summer precipitation. Much of the precipitation falls as snow, and growing-season drought is characteristic. Temperatures are continental with large annual and diurnal variation. In central Montana, this system differs slightly, with more summer rain than winter precipitation, more precipitation annually, and it occurs on glaciated landscapes.

Physiography/landform: Stands occur on stream terraces, point bars, valley floors, alluvial fans, floodplains, washes, gullies, stabilized dunes, mesic uplands, swales, and rocky slopes. Slopes are variable from gentle to very steep.

Soil/substrates/hydrology: Soils are typically deep and non-saline, often with a microphytic crust.

The environmental description is based on several references, including Daubenmire (1970), Mueggler and Stewart (1980), Brown (1982a), Hironaka et al. (1983), West (1983c), Barbour and Billings (1988), Knight (1994), Holland and Keil (1995), Howard (1999), Tirmenstein (1999c), West and Young (2000), Barbour et al. (2007a), and Sawyer et al. (2009).

Key Processes and Interactions: The natural fire regime of this ecological system likely maintains a patchy distribution of shrubs, so the general aspect of the vegetation is a grassland. Shrubs may increase following heavy grazing and/or with fire suppression, particularly in moist portions of the northern Columbia Plateau where it forms a landscape mosaic pattern with shallow-soil scabland shrublands. Response to grazing can be variable depending on the type of grazer and the season in which grazing occurs. *Hesperostipa comata* can increase in abundance in response to either grazing or fire. In central and eastern Montana (and possibly elsewhere), complexes of prairie dog towns are common in this ecological system. Microphytic crust is very important in this ecological system.

Complex ecological interactions of fire regimes and climate patterns result in equally complex patterns of species structure and composition in *Artemisia tridentata* stands. Prolonged drought on the more xeric sites may reduce shrub cover. Flooding may also cause mortality if the soil remains saturated for an extended period of time. The Aroga moth is capable of defoliating large acreages (i.e., >1000 acres, but usually 10-100 acres). Heavy grazing by wildlife can remove the fine fuels that support mixed-severity fires and result in woody fuel buildup that leads to severe, stand-replacement fires (LANDFIRE 2007a, BpS 1210800).

Big sagebrush stands are inhibited by fire as *Artemisia tridentata* does not sprout after burning (Tirmenstein 1999c). Conversely, increasing fire frequency significantly will eliminate the shrubs from the stands (Daubenmire 1970, Tirmenstein 1999c). With a change in fire frequency, species composition will be altered as well (West 1983c). With a high fire frequency (every 2-5 years), perennial grasses and shrubs are eliminated and non-native annual grasses dominate. At fire-return intervals of 10-30 years, short-lived resprouting shrubs such as *Chrysothamnus* or *Tetradymia* spp. dominate. At fire-return intervals of 30-70 years, a mixture of perennial bunchgrasses and non-sprouting shrubs is maintained (Johnson 2000b). Finally, in the complete absence of fire, deep-rooted shrubs such as *Artemisia tridentata* become dominant. At higher-elevation sites with absence of fire (>100 years), *Pinus monophylla* and *Juniperus osteosperma* trees may invade and eventually dominate sites (Tirmenstein 1999c).

Insects are an important component of many shrub-steppe and grassland systems. Mormon crickets and grasshoppers are natural components of many rangeland systems (USDA-APHIS 2003, 2010). There are almost 400 species of grasshoppers that inhabit the western United States with 15-45 species occurring in a given rangeland system (USDA-APHIS 2003). Mormon crickets are also present in many western rangelands and, although flightless, are highly mobile and can migrate large distances consuming much of the forage while travelling in wide bands (USDA-APHIS 2010). Following a high population year for grasshoppers or Mormon crickets and under relatively warm dry spring environmental conditions that favor egg hatching and grasshopper and Mormon cricket survival, there may be large population outbreaks that can utilize 80% or more of the forage in areas as large as 2000 square miles. Conversely, relatively cool and wet spring weather can limit the potential for outbreaks. These outbreaks are naturally occurring cycles and, especially during drought, can denude an area of vegetation leaving it exposed to increased erosion rates from wind and water (USDA-APHIS 2003).

Climatic variability may have been as important a disturbance agent as fire in these areas. Prolonged drought may have helped to reduce the density and cover of sagebrush. The size of the area affected by the drought would vary from 100s-1000s of acres and may be related to soil type (LANDFIRE 2007a).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has four classes in total (LANDFIRE 2007a, BpS 0911250). These are summarized as:

A) Early Development 1 All Structures (15% of type in this stage): Herbaceous canopy cover is variable (0-50%). This class is dominated by forbs with varying presence of grasses. Post-fire cover and recovery rates vary greatly depending on fire severity and post-fire precipitation amounts and timing as well as pre-fire species composition. This stage lasts 9-15 years, depending on how quickly sagebrush is able to begin reoccupying the area. Replacement fire (MFRI= 100 years) resets.

B) Mid Development 1 Open (30% of type in this stage): Dominant lifeform is herbaceous (20-40% cover), shrub cover 0-10%. Scattered and usually small sagebrush are present, but perennial grasses and forbs continue to dominate. The general formation is that of a shrub savanna. Sagebrush cover is usually 1-5% in this stage. Stands are 15-35 years old. Succession to class C. Replacement fire (MFRI= 100 years) reset to class A. Surface fires (MFRI=1000 years) maintain in class B.

C) Late Development 1 Open (35% of type in this stage): Shrubs have canopy cover of 11-20%. Sagebrush is codominant with the perennial grasses and forbs. The general formation is that of a shrub-steppe. Stands are 35-70 years old; succession to class D. Replacement fire (MFRI=100 years) reset to class A. Mixed fire (MFRI= 50 years) opens the stand to class B. Surface fire (MFRI=1000 years) keeps in class C.

D) Late Development 1 Closed (20% of type in this stage): Shrubs have canopy cover of 21-30%. Sagebrush is dominant with relatively low cover of perennial grasses and forbs. Sagebrush cover can be variable, with the lowest productivity sites reaching only about 15% canopy cover with large areas of bare ground and rock in the interspaces. The general formation is that of a shrubland. Stands are greater than about 70 years old. Replacement fire (MFRI=85 years) reset to class A. Mixed fire (MFRI=85 years) opens the stand to class B.

Threats/Stressors: Conversion of this type has commonly come from agriculture (wheat farming and non-native hay production) where soils are deeper. Rangeland management such as sagebrush reduction treatments (frequent burning, herbicide spraying, and mechanical techniques such as plowing or mowing, and planting *Agropyron cristatum*) also convert large areas (Wambolt and Payne 1986, Beck et al. 2012). Another major conversion type is due to invasive non-native species such as *Bromus tectorum, Centaurea solstitialis, Hypericum perforatum, Poa pratensis, Taeniatherum caput-medusae* and *Ventenata dubia* (Young and Evans 1971, 1973, Mack 1981b, Pellant 1990, 1996, D'Antonio and Vitousek 1992, Chambers et al. 2007a, 2013, D'Antonio et al. 2009). These invasive species increase post-disturbance, including long-term excessive grazing by livestock, or direct soil disturbance from severe trampling by livestock, ORVs and roads. Altered fire regimes, such as repeated, high-frequency fires have eliminated shrubs and created extensive grasslands dominated by non-native invasive annual grass *Bromus tectorum* and other non-native annual species. Additionally, in some places fire suppression has allowed succession and conversion to woodlands (Tirmenstein 1999c, LANDFIRE 2007a, WNHP 2011).

The primary land uses that alter the natural processes of this system are associated with livestock management practices, invasive annual plant species, fire regime alteration, direct soil surface disturbance, and fragmentation. Excessive grazing stresses the system through soil disturbance, diminishing or eliminating the biological soil crust, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and annual grasses, particularly *Bromus tectorum* and other exotic annual bromes. If soil moisture is sufficient and sagebrush seeds are available, grazing can result in increased shrub density. There are strong links between foliose lichens and ecosystem health. Severe trampling breaks lichens into fragments too small to re-establish and eventually leads to foliose lichen elimination (Rosentreter and Eldridge 2002). Domestic livestock grazing is a widespread disturbance factor in sagebrush systems and can affect ecosystem condition. Inappropriate livestock grazing, in terms of stocking rate or season of use, can alter species composition, ecosystem function and structure (Dyksterhuis 1949, as cited by Veblen et al. 2011).

Fire further stresses livestock-altered vegetation by increasing exposure of bare ground and consequently increases exotic annuals and decreases perennial bunchgrass and sagebrush abundance. Fire suppression, even in the absence of livestock grazing impacts, can increase shrub density that in turn reduces bunchgrass cover or results in increased grass litter and fire fuel. Both conditions increase the probability of fire and vegetation responses that increase annual grass abundance following fire (Davies et al.

2009). Any soil and bunchgrass layer disturbances, such as vehicle tracks or chaining shrubs, will increase the probability of alteration of vegetation structure and composition, and response to fire as discussed above. Loss of shrub density and degradation of the bunchgrass layer's native diversity decreases obligate shrub-steppe birds (Vander Haegen et al. 2000).

Fragmentation of shrub-steppe by agriculture increases cover of annual grasses, total annual/biennial forbs, and bare ground, and decreases cover of perennial forbs and biological soil crusts and reduces obligate insects (Quinn 2004) and obligate birds and small mammals (Vander Haegen et al. 2001). Fine fuel adjacency from alien annual grasses, such as *Bromus tectorum*, currently represents the most important fuelbed component in the system and can substantially increase the fire frequency. With a high fire frequency (every 2-5 years), perennial grasses and shrubs are eliminated and non-native annual grasses dominate. At fire-return intervals of 10-30 years, short-lived resprouting shrubs such as *Chrysothamnus* or *Tetradymia* spp. dominate. This expansion of juniper trees into *Artemisia tridentata*-dominated ecosystems has many effects on the ecology of the site, including reduction of understory cover and species, increased fuel load as trees grow and expand, resulting eventually in large, high-severity fires with high tree and shrub mortality (Miller et al. 2011, 2014). These severely burned areas are highly susceptible to invasion by annual grasses, often resulting in conversion to *Bromus tectorum*-dominated stands (Chambers et al. 2007a, Condon et al. 2011). Conversion of *Artemisia tridentata* ecosystems to invasive non-native annual grasses causes habitat degradation, fragmentation and loss for several species, including sage-grouse (*Centrocercus* spp.) which is now at risk for federal listing (Knick et al. 2003).

An assessment was conducted by Veblen et al. (2011) to evaluate rangewide impacts of livestock grazing across the sagebrush distribution. Most information on range condition is at the local scale and not consistently collected for regional or rangewide assessment; however, the study was able to compile and utilize available data. Using Land Health Standards (LHS) data and sagebrush vegetation characteristics, the study compared LHS across a subset of allotments within the sagebrush biome. Results showed 798 allotments (70%) that met and 333 allotments that did not meet LHS. Livestock grazing was identified as the reason for unmet standards for 132 (approximately 15%) of the 333 allotments that did not meet standards. Therefore, across the sagebrush distribution, a relatively small percentage of allotments are being significantly impacted by livestock grazing.

When grasshopper and Mormon cricket populations reach outbreak levels, they cause significant economic losses for ranchers and livestock producers, especially when accompanied by a drought (USDA-APHIS 2003, 2010). Both rangeland forage and cultivated crops can be consumed by grasshoppers. The U.S. Department of Agriculture's (USDA) Animal and Plant Health Inspection Service (APHIS) is the Federal agency responsible for controlling economic infestations of grasshoppers on western rangelands with a cooperative suppression program. They work with federal land managing agencies to conduct grasshopper suppression. The goal of APHIS's grasshopper program is not to eradicate them but to reduce outbreak populations to less economically damaging levels (USDA-APHIS 2003). This APHIS effort dampens the natural ecological outbreak cycles of grasshoppers and Mormon crickets but does not eradicate the species.

Human development has impacted many locations throughout the type distribution. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances allow invasive non-native species to become established and outcompete and replace the dominant native perennial species. Fire further stresses livestock-altered vegetation by increasing exposure of bare ground and consequently increases exotic annuals and decreases perennial bunchgrass and sagebrush abundance.

High-severity environmental degradation appears where occurrences tend to be relatively small (<30,000 acres) for this matrix type (CNHP 2010) and have evidence of excessive livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and sheet and rill erosion. Altered fire regime from too frequent fires caused by build ups of fine fuels from invasion of non-native annual grasses resulting in loss of shrubs and reduction of all native species especially dominant native grasses to <50% total cover (WNHP 2011). Altered fire regime from historic and ongoing fire suppression and reduction of fine fuels by grazing has extended the fire-return interval >100 years (Tirmenstein 1999c) resulting in regeneration of trees (>10% cover).

Moderate-severity environmental degradation appears where occurrences are moderate (30,000-50,000 acres) in size for this matrix type (CNHP 2010) and have evidence of heavy livestock grazing (low perennial grass cover) and/or mechanical disturbance from vehicles resulting in soil compaction and erosion. Altered fire regime from too frequent fires caused by build ups of fine fuels from invasion of non-native annual grasses resulting in reduction of shrubs and reduction of all native species especially dominant native grasses to 50-79% total cover (WNHP 2011). Altered fire regime from fire suppression and reduction of fine fuels by grazing increased the fire-return interval from 70-100 years (Tirmenstein 1999c) resulting in regeneration of trees (5-10% cover).

High-severity biotic disruption appears where occurrences have low cover of native grassland species (<50% relative cover) (WNHP 2011). Increased fire frequency with annual grass is the biggest disruption. There may be significant cover of trees (>10%) because of fire suppression. Invasive non-native species are abundant (>10% absolute cover to dominant) (CNHP 2010, WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

Moderate-severity biotic disruption appears where occurrences have low cover of native grassland species (50-79% relative cover) (WNHP 2011). There may be significant cover of trees (5-10%) because of fire suppression. Invasive non-native species are abundant (3-10% absolute cover) (CNHP 2010, WNHP 2011). Connectivity is severely hampered by fragmentation from roads and/or agriculture that restrict or prevent natural ecological processes such as fire from occurring, and create barriers to natural movement of animal and plant populations. Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem.

CES304.785 Inter-Mountain Basins Montane Sagebrush Steppe

CES304.785 CLASSIFICATION

Concept Summary: This ecological system includes sagebrush communities occurring at foothills (in Wyoming) to montane and subalpine elevations across the western U.S. from 1000 m in eastern Oregon and Washington to over 3000 m in the Southern Rockies. In Montana, it occurs on isolated mountains in the north-central portion of the state and possibly along the Boulder River south of Absarokee and at higher elevations. In British Columbia, it occurs between 450 and 1650 m in the southern Fraser Plateau and the Thompson and Okanagan basins. Climate is cool, semi-arid to subhumid. This system primarily occurs on deep-soiled to stony flats, ridges, nearly flat ridgetops, and mountain slopes. In general, this system is found on fine-textured soils, some source of subsurface moisture or more mesic sites, zones of higher precipitation, and areas of snow accumulation. Across its range, this is a compositionally diverse system. It is composed primarily of *Artemisia tridentata ssp. vaseyana, Artemisia cana ssp. viscidula*, and related taxa such as *Artemisia tridentata ssp. spiciformis*. *Purshia tridentata* may codominate or even dominate some stands. *Artemisia arbuscula ssp. arbuscula*-dominated shrublands commonly occur within this system on rocky or windblown sites. Other common shrubs include *Symphoricarpos* spp., *Amelanchier* spp., *Ericameria nauseosa, Peraphyllum ramosissimum, Ribes cereum*, and *Chrysothamnus viscidiflorus*. *Artemisia tridentata ssp. wyomingensis* may be present to codominant if the stand is clearly montane as indicated by montane indicator species such as *Festuca idahoensis, Leucopoa kingii*, or *Danthonia intermedia*. Most stands have an abundant perennial herbaceous layer (over 25% cover, in many cases over 50% cover), but this system also includes *Artemisia tridentata ssp. vaseyana* shrublands. Common graminoids include *Danthonia intermedia, Festuca arizonica, Festuca idahoensis, Hesperostipa comata, Poa fendleriana, Elymus trachycaulus, Bromus carinatus, Poa secunda, Deschampsia cespitosa, Calamagrostis rubescens*, and *Pseudoroegneria spicata*. Species of *Achnatherum* are common, including *Achnatherum nelsonii ssp. dorei, Achnatherum nelsonii ssp. nelsonii, Achnatherum hymenoides*, and others. In many areas, wildfires can maintain an open herbaceous-rich steppe condition, although at most sites, shrub cover can be unusually high for a steppe system (>40%), with the moisture providing equally high grass and forb cover. This ecological system is closely related to the cool-moist sagebrush in the resistance-resilience framework.

Distribution: This system is found at montane and subalpine elevations across the western U.S. from 1000 m in eastern Oregon and Washington to over 3000 m in the Southern Rockies. In British Columbia, it occurs in the southern Fraser Plateau and the Thompson and Okanagan basins. This system occurs in mapzone 20 on the Rocky Mountain island ranges and on the western edge with mapzone 19.

Description Author: R. Crawford, M.S. Reid and K.A. Schulz

CES304.785 CONCEPTUAL MODEL

Environment: This ecological system includes sagebrush communities occurring at foothills (in Wyoming) to montane and subalpine elevations across the western U.S. from 1000 m elevation in eastern Oregon and Washington to over 3000 m in the Southern Rockies. In Montana, it occurs in isolated mountains in the north-central portion of the state and possibly along the Boulder River south of Absarokee and at higher elevations. In British Columbia, it occurs between 450 and 1650 m in the southern Fraser Plateau and the Thompson and Okanagan basins.

Climate: Climate is cool, semi-arid to subhumid with yearly precipitation ranging from 25 to 90 cm/year. Much of this precipitation falls as snow. In general, this system occurs on fine-textured soils, some source of subsurface moisture or more mesic sites, zones of higher precipitation, and areas of snow accumulation.

Physiography/landform: This system primarily occurs on deep-soiled to stony flats, ridges, nearly flat ridgetops, and mountain slopes. Stands occur on all aspects, but the higher-elevation occurrences may be restricted to south- or west-facing slopes.

Soil/substrates/hydrology: Soils generally are moderately deep to deep, well-drained, and of loam, sandy loam, clay loam, or gravelly loam textural classes; soils often have a substantial volume of coarse fragments and are derived from a variety of parent materials.

The environmental description is based on several other references, including Daubenmire (1970), Young et al. (1977), Mueggler and Stewart (1980), Brown (1982a), Hironaka et al. (1983), West (1983c), Barbour and Billings (1988), Padgett et al. (1989), Knight (1994), Hansen et al. (1995), Holland and Keil (1995), Howard (1999), Johnson (2000b), West and Young (2000), Barbour et al. (2007a), and Sawyer et al. (2009).

Key Processes and Interactions: Complex ecological interactions of fire regimes and climate patterns result in equally complex patterns of species structure and composition in *Artemisia tridentata* stands (Johnson 2000b). Healthy stands often have a very productive herbaceous understory that is high quality forage for livestock.

Like other big sagebrush subspecies, *Artemisia tridentata ssp. vaseyana* stands are inhibited by fire as *Artemisia tridentata* does not sprout after being top-killed by fire and may take over 10 years to form stands with 20% or more cover (Johnson 2000b, Sawyer et al. 2009). Winward (1991) suggests *Artemisia tridentata ssp. vaseyana* shrublands have a natural fire regime of 10-30 years. Presettlement fires tended to be patchy, forming a mosaic of different age and density of shrubs because of different fire intensity across the landscape (Winward 1991, Tart 1996). Regeneration of mountain big sagebrush is from on-site or off-site seed and, depending on circumstances of the environment and seed source, *Artemisia tridentata ssp. vaseyana* seeds may sprout abundantly or very sparsely the following spring after burning (Johnson 2000b). Establishment after severe fires may proceed more slowly (Bunting et al. 1987, Johnson 2000b). Increasing fire frequency significantly will eliminate the shrubs from the stands (Daubenmire 1970, Johnson 2000b). Stand species composition will be altered with changes in fire frequency (West 1983c). With a high fire frequency (every 2-5 years), perennial grasses and shrubs are eliminated and non-native annual grasses dominate. At fire-return intervals of 10-30 years, short-lived resprouting shrubs such as *Chrysothamnus* or *Tetradymia* spp. dominate. At fire-return intervals of 30-70 years, a mixture of perennial bunch grasses and non-sprouting shrubs is maintained (Johnson 2000b). Finally, in the complete absence of fire, deep-rooted shrubs such as *Artemisia tridentata* become dominant. At higher-elevation sites with absence of fire (>100 years), trees such as *Pinus monophylla, Juniperus occidentalis*, and *Juniperus osteosperma* may invade and eventually dominant sites (Young et al. 1977, Bunting 1990, Johnson 2000b).

In addition, prolonged drought on the more xeric sites may reduce shrub cover. Flooding may also cause mortality if the soil remains saturated for an extended period of time. The Aroga moth is capable of defoliating large acreages (i.e., >1000 acres), but usually affected areas are relatively small (10-100 acres). Of the three big sagebrush subspecies and black sagebrush, *Artemisia tridentata ssp. vaseyana* was found to be the most palatable browse for elk (Wambolt 1995, 1996). These big game preference differences may make it more sensitive to effects of browsing. Heavy grazing in these mountain shrub-steppes may decrease fire frequency due to consumption of herbaceous forage (fine fuels), resulting in increased shrub density (woody fuel buildup) that leads to severe, stand-replacement fires (LANDFIRE 2007a, BpS 1211260).

LANDFIRE developed a state-and-transition vegetation dynamics VDDT model for this system which has five classes in total and two classes (classes D & E) that model conversion to forest systems (LANDFIRE 2007a, BpS 1211260). These are summarized as:

A) Early Development 1 Open (herbaceous-dominated - 20% of type in this stage): Herbaceous cover is variable but typically >50% (50-80%). Shrub cover is 0-5%. Replacement fire (mean fire return interval (FRI) of 80 years) setbacks succession by 12 years. Succession to class B after 12 years.

B) Mid Development 1 Open (shrub-dominated - 50% of type in this stage): Shrub cover 6-25%. Mountain big sagebrush cover up to 20%. Herbaceous cover is typically >50%. Initiation of conifer seedling establishment. Replacement fire mean FRI is 40 years. Succession to class C after 38 years.

C) Late Development 1 Closed (shrub-dominated - 15% of type in this stage): Shrubs are the dominant lifeform with canopy cover of 26-45+%. Herbaceous cover is typically <50%. Conifer (juniper, pinyon-juniper, ponderosa pine or white fir) cover <10%. Insects and disease every 75 years on average will thin the stand and cause a transition to class B. Replacement fire occurs every 50 years on average. In the absence of fire for 80 years, vegetation will transition to class D. Otherwise, succession keeps vegetation in class C.

D) Late Development 1 Open (conifer-dominated - 10% of type in this stage): Conifers are the upper lifeform (juniper, pinyon-juniper, ponderosa pine, limber pine or white fir). Conifer cover is 11-25%. Shrub cover generally less than mid-development classes but remains between 26-40%. Herbaceous cover <30%. The mean FRI of replacement fire is 50 years. Insects/diseases thin the sagebrush, but not the conifers, every 75 years on average, without causing a transition to other classes. Succession is from class C to class D after 50 years.

E) Late Development 2 Closed (conifer-dominated - 5% of type in this stage): Conifers are the dominant lifeform (juniper, pinyon-juniper, ponderosa pine, limber pine or white fir). Conifer cover ranges from 26-80% (pinyon-juniper 36-80% (Miller and Tausch 2001), juniper 26-40% (Miller and Rose 1999) and white fir 26-80%). Shrub cover 0-20%. Herbaceous cover <20%. The mean FRI for replacement fire is longer than in previous states (75 years). Conifers are susceptible to insects/diseases that cause diebacks (transition to class D) every 75 years on average (LANDFIRE 2007a). The woodland systems that this montane sagebrush system would succeed into vary by location.

Threats/Stressors: Conversion of *Artemisia tridentata* ecosystems to invasive, non-native grasses and forbs causes habitat degradation, fragmentation and loss for several species, including sage-grouse (*Centrocercus* spp.) which is now being considered for federal listing (Knick et al. 2003). Another potential means to ecological conversion of mountain sagebrush shrubland system is succession to conifer woodlands. With severe fire regime alteration and extended fire suppression, trees, especially junipers and pinyons, colonized these shrublands and grow to the eventual exclusion of the shade-intolerant sagebrush (LANDFIRE 2007a).

The primary land uses that alter the natural processes of this system are associated with domestic livestock grazing and introduction of exotic grasses. Excessive grazing stresses the system through soil disturbance, altering the composition of perennial species, and increasing the establishment of native disturbance-increasers and grasses, particularly *Poa pratensis*, a grazing-tolerant, exotic perennial grass. Excessive cattle grazing will decrease the abundance of native bunch grasses such as *Festuca idahoensis, Koeleria macrantha*, and *Pseudoroegneria spicata*, and increase the cover of grazing-tolerant grass species and forbs (Tart 1996). Overgrazing by sheep will also decrease some forbs, such as species of *Geranium, Ligusticum, Packera*, and *Potentilla*, and increase others, such as species of *Achillea, Antennaria, Arenaria*, and *Lupinus* (Tart 1996). In general, heavy grazing also favors shrubs that increase in density and cover and reduces the herbaceous layer (fine fuels) that allows fire to spread, which reduces fire frequency (Tart 1996).

Domestic livestock grazing is a widespread disturbance factor in sagebrush systems and can affect ecosystem condition (Veblen et al. 2011). Inappropriate livestock grazing, in terms of stocking rate or season of use, can alter species composition, ecosystem function and structure (Dyksterhuis 1949, as cited by Veblen et al. 2011). An assessment was conducted by Veblen et al. (2011) to evaluate rangewide impacts of livestock grazing across the sagebrush biome. Most information on range condition is at the local scale and not consistently collected for regional or rangewide assessment; however, the study was able to compile and utilize available data. Using LHS data and sagebrush vegetation characteristics, the study compared LHS across a subset of allotments within the sagebrush biome. Results showed 798 allotments (70%) that met and 333 allotments that did not meet LHS. Livestock grazing was identified as the reason for unmet standards for 132 (approximately 15%) of the 333 allotments that did not meet standards. Therefore, across the sagebrush biome, a relatively small percentage of allotments are being significantly impacted by livestock grazing.

Human development has impacted many locations throughout the type's distribution. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

Ecosystem Collapse Thresholds: Ecological collapse tends to result from severe overgrazing where perennial plant cover is reduced enough to allow removal of topsoil by sheet and rill erosion or surface disturbances allow invasive non-native species to become established and outcompete and replace the dominant native perennial species. Altered fire regime further stresses livestock-altered vegetation by increasing exposure of bare ground and consequently dominance of exotic species and loss of perennial bunchgrass and sagebrush. Alteration of vegetation is extensive and no restoration potential. System remains fundamentally compromised despite restoration of some processes (CNHP 2010).

Another means to ecological collapse is conversion of mountain sagebrush shrublands to conifer woodlands. With extended fire suppression, trees, especially junipers and pinyons, colonized these shrublands and grow to the eventual exclusion of the shade-intolerant sagebrush.

High-severity environmental degradation appears where occurrences tend to be relatively small (<30,000 acres) in size and have evidence of excessive livestock grazing (low native perennial grass cover) and/or mechanical disturbance from vehicles, resulting in soil compaction and continued disturbance throughout stand. Microbiotic crusts are >75% removed, occurring only in small pockets naturally protected from livestock and off-road vehicle use (CNHP 2010). Soil erosion may be severe in places (CNHP 2010). Connectivity is severely hampered by fragmentation from anthropogenic alterations such as a high density of roads (e.g., oil and gas exploration and development or exurban development) that has heavily impacted sites creating barriers to fire and as a source of invasive non-native species (CNHP 2010). Major human-caused alteration of surrounding landscape. Adjacent surrounding systems are mostly converted to agricultural or urban uses (CNHP 2010).

Moderate-severity environmental degradation appears where occurrences tend to be relatively small (30,000 -50,000 acres) in size and have evidence of heavy livestock grazing (low native perennial grass cover) and/or mechanical disturbance from vehicles, resulting in soil compaction and continued disturbance throughout stand. Microbiotic crusts are removed from more than 25% of the area, or are in various stages of degradation throughout the occurrence (CNHP 2010). Soil erosion and gullying may be observed in patches (up to 30%) within the stand (CNHP 2010). Connectivity of adjacent systems surrounding occurrence is fragmented by alteration with limited connectivity (CNHP 2010). Surrounding landscape is a mosaic of agricultural or semi-developed areas with >50% natural or semi-natural vegetation. Some non-natural barriers are present. Significant disturbance, but easily restorable (CNHP 2010).

Disruption of Biotic Processes

High-severity disruption appears where alteration of vegetation is extensive and restoration potential is low and system remains fundamentally compromised despite restoration of some processes (CNHP 2010). Invasive exotics with major potential to alter structure and composition, such as *Bromus inermis, Poa pratensis, Bromus tectorum*, are present and non-native species dominate with native increasers such as *Aristida* spp., *Balsamorhiza* sp., *Elymus elymoides, Gutierrezia sarothrae*, and *Wyethia* sp. (CNHP 2010). Reproductive capability of native perennial plants severely reduced (CNHP 2010). There is significant cover of trees (>10%) because of fire suppression and invasion from adjacent woodlands (LANDFIRE 2007a). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Shrubland bird populations in sharp decline.

Moderate-severity disruption appears where alteration of vegetation is extensive but potentially restorable over several decades (CNHP 2010). Invasive exotics with major potential to alter structure and composition, such as *Bromus inermis, Poa pratensis*, and *Bromus tectorum*, are likely present and non-native species codominate with native increasers such as *Aristida* spp., *Balsamorhiza* sp., *Elymus elymoides, Gutierrezia sarothrae*, and *Wyethia* sp. (CNHP 2010).

Reproductive capability of native perennial plants severely reduced (CNHP 2010). There may be trees present because of fire suppression and invasion from adjacent woodlands (LANDFIRE 2007a). Native plant species diversity and the diversity and abundance of animal populations are low when compared to an intact ecosystem. Shrubland bird populations in sharp decline.

M095. Great Basin-Intermountain Xeric-Riparian Scrub

CES304.781 Inter-Mountain Basins Wash

CES304.781 CLASSIFICATION

Concept Summary: This barren and sparsely vegetated (generally <10% plant cover) ecological system is restricted to intermittently flooded streambeds and banks that are often lined with shrubs such as *Sarcobatus vermiculatus, Ericameria nauseosa, Fallugia paradoxa, Artemisia tridentata ssp. tridentata*, and/or *Artemisia cana ssp. cana* (in more northern and mesic stands) that form relatively dense stringers in open dry uplands. *Grayia spinosa* may dominate in the Great Basin. Shrubs form a continuous or intermittent linear canopy in and along drainages but do not extend out into flats. Typically it includes patches of saltgrass meadow where water remains for the longest periods. In parts of Wyoming, stringers or patches of *Artemisia tridentata ssp. tridentata* are large and distinct enough from surrounding upland vegetation due to the influence of the wash that they can be classified separately. However, small intermittent washes may also be included with adjacent uplands if vegetation is not different enough floristically or structurally from uplands (e.g., just a little denser canopy). Soils are variable but are generally less alkaline than those found in the playa system. Desert scrub species (e.g., *Acacia greggii, Prosopis* spp.) that are common in the Mojave, Sonoran and Chihuahuan desert washes are not present. This type can occur in limited portions of the southwestern Great Plains.

M118. Intermountain Basins Cliff, Scree & Badland Sparse Vegetation

CES304.765 Colorado Plateau Mixed Bedrock Canyon and Tableland

CES304.765 CLASSIFICATION

Concept Summary: The distribution of this ecological system is centered on the Colorado Plateau where it is composed of barren and sparsely vegetated landscapes (generally <10% plant cover) of steep cliff faces, narrow canyons, and open tablelands of predominantly sedimentary rocks, such as sandstone, shale, and limestone. Some eroding shale layers similar to ~Inter-Mountain Basins Shale Badland (CES304.789)$$ may be interbedded between the harder rocks. The vegetation is characterized by very open tree canopy or scattered trees and shrubs with a sparse herbaceous layer. Common species includes *Pinus edulis, Pinus ponderosa, Juniperus* spp., *Cercocarpus intricatus*, and other short-shrub and herbaceous species, utilizing moisture from cracks and pockets where soil accumulates.

- Pinyon - Juniper: 239 (Eyre 1980) **><**

Distribution: Colorado Plateau.

Nations: US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES304.765 CONCEPTUAL MODEL

Environment: This system includes limestone escarpments and plateaus occurring in a relatively narrow band of unvegetated or sparsely vegetated badlands formed by the red beds of the Claron (Wasatch) Formation along the eastern edge of the Pausaugunt Plateau (Bryce Canyon) and the western edge of the Markagunt Plateau (Cedar Breaks National Monument) (Graybosch and Buchanan 1983). It includes areas of which often 90% of the exposed surface consists of barren rock. It forms, or includes, areas of fixed bedrock forming the vertical or near-vertical parts on the plateau faces. The rocks forming such areas are predominantly limestone-capped plateaus. These areas are highly erodible and form the basic scenic structure of Bryce Canyon and Cedar Breaks national parks. The area is generally too steep to allow any significant soil development. Scattered plants obtain a precarious foothold in the crevices of the rocks. Knolls may form at the base of the cliffs.

This ecological system also includes sandstone and shale escarpments, which form, or include, areas of fixed bedrock forming the vertical or near-vertical parts of canyon walls and plateau faces. The scenic cliffs of the East Tavaputs area, e.g., the Book Cliffs, are excellent examples of this. The rocks forming such areas are predominantly sandstone and shale with some limestone and marlstone. These areas are unstable and rocks are frequently rolling down onto the talus slopes below (often forming ~Inter-Mountain Basins Shale Badland (CES304.789)$$). The area is generally too steep to allow any significant soil development. Scattered plants obtain a precarious foothold in the crevices of the rocks. Knolls may form at the base of the cliffs. The larger drainages (e.g., East Fork Parachute Creek) plunge several hundred feet at this escarpment, which creates scenic and lush hanging gardens. Many of these escarpments are over 305 m (1000 feet) in height and provide excellent habitat for cliff-nesting birds such as peregrine falcons and golden eagles.

The Claron limestone, a Tertiary deposit, is divisible into Red Eocene beds and White Oligocene beds, which differ somewhat in presence or absence of pigmentation in the form of iron and manganese oxides, and in amounts of sand and conglomerates in the limestone (Graybosch and Buchanan 1983). The Claron Formation is characterized by a rapid rate of erosion, largely a function of creep resulting from winter freeze-thaw activity and wash away by summer thunderstorm runoff (Graybosch and Buchanan 1983). Freeze-thaw cycles are most pronounced on south-facing slopes. Soil development is limited. Infiltration rates are low and runoff high.

Key Processes and Interactions: This ecological system has a naturally high rate of erosion. Fires are infrequent and not an important ecological process.

CES304.081 Columbia Plateau Ash and Tuff Badland

CES304.081 CLASSIFICATION

Concept Summary: This ecological system of the Columbia Plateau region is composed of barren and sparsely vegetated substrates (<10% plant cover) typically derived from highly eroded volcanic ash and tuff. Landforms are typically rounded hills and plains that form a rolling topography. The harsh soil properties and high rate of erosion and deposition are driving environmental variables supporting sparse dwarf-shrubs and forbs. Characteristic species include *Grayia spinosa, Artemisia tridentata, Salvia dorrii, Achnatherum* sp., *Eriogonum* sp., *Sarcobatus vermiculatus, Purshia tridentata*, and *Atriplex confertifolia*. Characteristic forbs are short-lived annuals, including *Cleome, Mentzelia, Camissonia*, and *Mimulus* species, although these habitats often support endemic perennial forbs.

Related Concepts:

Distribution: This system is found on the Columbia Plateau of southern Idaho west into southern Oregon, northern Nevada, and extreme northeastern California.

Nations: US

Concept Source: J. Kagan

Description Author: J. Kagan

CES304.779 Inter-Mountain Basins Cliff and Canyon

CES304.779 CLASSIFICATION

Concept Summary: This ecological system ranges from Wyoming and Utah west to the Pacific states. It is found from foothill to subalpine elevations and includes barren and sparsely vegetated landscapes (generally <10% plant cover) of steep cliff faces, narrow canyons, and smaller rock outcrops of various igneous, sedimentary, and metamorphic bedrock types. Also included is vegetation of unstable scree and talus slopes that typically occurs below cliff faces. Widely scattered trees and shrubs may include *Abies concolor, Pinus edulis, Pinus flexilis, Pinus monophylla, Juniperus* spp., *Artemisia tridentata, Purshia tridentata, Cercocarpus ledifolius, Ephedra* spp., *Holodiscus discolor*, and other species often common in adjacent plant communities.

Related Concepts:

Distribution: This system ranges from Wyoming and Utah west to the Pacific states.

Nations: US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES304.779 CONCEPTUAL MODEL

Environment: This sparsely vegetated ecological system occurs in the interior western U.S. and ranges up to subalpine elevations. It includes barren and sparsely vegetated sites (generally < 10% plant cover) of steep cliff faces, canyons, and smaller rock outcrops of various igneous, sedimentary, and metamorphic bedrock types. Also included is vegetation of unstable scree and talus slopes that typically occur below cliff faces. Establishment and growth of sparse vegetation occur on these sites because of limited soil moisture in extremely well-drained sites, lack of suitable sites, or relatively high soil moisture in the case of escarpment woodlands growing on outcrops on lower-elevation, semi-arid sites (Knight 1999). Other low-moisture soils include those with heavy clay and clay loam textures that limit water infiltration. Environmental information is compiled from Hess and Wasser (1982), Holland and Keil (1995), Knight (1999), Reid et al. (1999), Barbour et al. (2007), and Sawyer et al. (2009).

Key Processes and Interactions: Plant species are variable with various life history traits, although most can colonize harsh sites and many are fairly long-lived. Vegetation establishment and growth are limited on these sparsely vegetated sites for different ecological reasons. In relatively mesic climates in the montane zone, there may be a lack of suitable sites for establishment or frequent disturbance may limit plant growth on unstable substrates such as talus and repeatedly disturbed sites such as avalanche chutes. Soil moisture may limit plant growth on sites with excessively well-drained, shallow soils. On lower-elevation, semi-arid sites, deeper-rooted trees and shrubs may establish in rock cracks and well-drained coarse-textured soils because these sites are relatively mesic when compared to surrounding sites. When it rains, runoff collects in superficial cracks in rocky escarpments and infiltrates deeply in coarse-textured soils where deep-rooted woody plants can access soil moisture (Knight 1999). This soil moisture/texture relationship is termed "inverse texture effect" (Noy-Meir 1973, Sala et al. 1988).

Burning is generally not a significant factor on the vegetated sites because fuel amounts are too low and discontinuous to carry fire (Knight 1999). Fire-return intervals would be very long.

Threats/Stressors: Introduced annuals may invade the limited growing sites and deplete soil moisture from native species.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

CES304.789 Inter-Mountain Basins Shale Badland

CES304.789 CLASSIFICATION

Concept Summary: This widespread ecological system of the Intermountain western U.S. is composed of barren and sparsely vegetated substrates (<10% plant cover) typically derived from marine shales but also includes substrates derived from siltstones and mudstones (clay). In southern Wyoming , the shales are not marine in origin, but often have bentonite, derived from volcanic ash deposition that occurred during several eruptions of the Yellowstone volcanic fields. Landforms are typically rounded hills and plains that form a rolling topography. The harsh soil properties and high rate of erosion and deposition are driving environmental variables supporting sparse dwarf-shrubs, e.g., *Atriplex corrugata, Atriplex gardneri, Artemisia pedatifida*, and herbaceous vegetation.

Related Concepts:

Distribution: This system is found in the intermountain western U.S., from Arizona and New Mexico north to Idaho and Montana. It is confirmed by Oregon and Washington reviewers to not occur in either of those states.

Nations: US

CES304.791 Inter-Mountain Basins Volcanic Rock and Cinder Land

CES304.791 CLASSIFICATION

Concept Summary: This ecological system occurs in the intermountain western U.S. and is limited to barren and sparsely vegetated volcanic substrates (generally <10% plant cover) such as basalt lava (malpais), basalt dikes with associated colluvium, basalt cliff faces and uplifted "backbones," tuff, cinder cones or cinder fields. It may occur as large-patch, small-patch and linear (dikes) spatial patterns. Vegetation is variable and includes a variety of species depending on local environmental conditions, e.g., elevation, age and type of substrate. At montane and foothill elevations scattered *Pinus ponderosa, Pinus flexilis*, or *Juniperus* spp. trees may be present. Shrubs such as *Ephedra* spp., *Atriplex canescens, Eriogonum corymbosum, Eriogonum ovalifolium*, and *Fallugia paradoxa* are often present on some lava flows and cinder fields. Species typical of sand dunes such as *Andropogon hallii* and *Artemisia filifolia* may be present on cinder substrates.

Related Concepts:

Distribution: This system occurs in the Intermountain western U.S. and is limited to barren and sparsely vegetated volcanic substrates. It occurs in Montana along the Rocky Mountain Front (east of the Continental Divide).

Nations: US

Concept Source: K.A. Schulz

Description Author: NatureServe Western Ecology Team

CES304.791 CONCEPTUAL MODEL

Environment:

Key Processes and Interactions: This ecological system is relatively young (geologically speaking). Lichens are the primary erosion process in this system, and therefore, soil buildup is a slow process. Lichens are susceptible to changes in air quality (Brodo et. al. 2001) and are considered a good indicator of air quality.

Threats/Stressors:

Ecosystem Collapse Thresholds:

4.B.1.Na. Eastern North American Alpine Tundra

M131. Eastern North American Alpine Tundra

CES201.567 Acadian-Appalachian Alpine Tundra

CES201.567 CLASSIFICATION

Concept Summary: Restricted to the Northern Appalachians and the Gaspe Peninsula, this system encompasses vegetation above treeline on northeastern mountains. In New Hampshire, climatic treeline occurs at 1495 m (4900 feet) or greater in elevation, following the 10-12°C July isotherm, but can also occur at lower elevations with high wind exposure, fire history, or shallow soils. Wind, snow, and cloud-cover fog are prominent environmental factors. Most of the cover is dwarf-shrubland, lichen, or sparse vegetation; islands of taller shrubs may occur in protected spots. The dominant plants are ericads (*Vaccinium uliginosum* is diagnostic and often dominant, with several other alpine-restricted ericads such as *Phyllodoce caerulea* and *Loiseleuria procumbens*) and cushion-plants such as *Diapensia lapponica*. *Carex bigelowii* is a characteristic and, in some places, locally dominant sedge. This system includes wetland depressions, small alpine bogs, within the surrounding upland matrix.

Related Concepts:

Distribution: This system is found at higher summits of the northern Appalachian Mountains, from northern New England and the Adirondacks into the Canadian maritimes, including Labrador, Nova Scotia and the Gaspé Peninsula.

Nations: CA, US

Concept Source: S.C. Gawler

Description Author: S.C. Gawler and L.A. Sneddon

CES201.567 CONCEPTUAL MODEL

Environment: This system is restricted to high elevations above climatic treeline, ranging from 1460 m (4900 feet) in New Hampshire to 730 m (2400 feet) at Gros Morne National Park in Labrador.

Key Processes and Interactions: Low temperature, snow accumulation, atmospheric moisture, topography, aspect, and degree of exposure to wind are the primary agents of disturbance to these systems. The degree of wind exposure and snow accumulation is directly related to topographic position. Summits and steep slopes are exposed to high winds, and receive less snow accumulation than more gentle slopes. Ravines collect abundant snowpack, which serves to protect the underlying plants from extreme weather conditions well into the spring (Sperduto and Kimball 2011). The alpine - treeline ecotone is controlled by a variety of climate variables; exposure as a result of topography and mechanical damage caused by ice and wind appear to be largely responsible for the ecotone (Kimball and Weihrauch 2000).

Threats/Stressors: Some subalpine summits were originally denuded by fire of either natural or human origin, resulting in the ecosystem's exceeding the "resiliency threshold." Succession to the forested state would have been greatly impeded by soil loss and exposure. Once devoid of tree cover, however, these systems typically do not contain enough fuel to sustain fire. Other subalpine sites are influenced by extreme exposure, which arrests succession regardless of the origin of the treeless state. Because of the high scenic value of these systems, human activities (i.e., hiking trails) are a localized source of persistent stress and disturbance. Most systems retain significant areas of natural vegetation with localized trampling of vegetation, soil erosion, and unofficial trail development. Some areas have been heavily trampled or reduced to gravel or bedrock with little hope of recovery at current recreational levels (Sperduto and Cogbill 1999). Potential climate change effects may include decreased snowpack and earlier snowmelt and resulting earlier loss of frost hardiness and greater exposure to low-temperature events when frost-sensitive (Wipf et al. 2009). Other threats include construction of communication towers and acid rain deposition (NYNHP 2013i).

Ecosystem Collapse Thresholds: Current environmental degradation results primarily from hiker traffic. Future degradation is likely to occur as a result of climate change. Climatic events that alter cloud frequency, wind, precipitation and ice-loading could influence the shifts in the treeline - alpine ecotone (Kimball and Weihrauch 2000). Shifts that favor expansion of krummholz and forest at the expanse of alpine tundra would dramatically decrease the already limited areas occupied by this vegetation. Patch size is too small to sustain full diversity and full function of the type. (e.g., smallest 30% of known or historic occurrences, or both; indicator species and characteristic species are sparse to absent) (Faber-Langendoen et al. 2011).

4.B.1.Nb. Western North American Alpine Tundra

M099. Rocky Mountain-Sierran Alpine Tundra

CES206.899 Mediterranean California Alpine Bedrock and Scree

CES206.899 CLASSIFICATION

Concept Summary: This system occurs in limited alpine environments mostly concentrated in the Sierra Nevada, but also on Mount Shasta and as far south as the Peninsular Ranges and White Mountains. Alpine elevations begin around 3500 m (10,600 feet) in the southern mountain ranges and 2700 m (8200 feet) in the southern Cascades. These are barren and sparsely vegetated alpine substrates, typically including both bedrock outcrops and scree slopes, with nonvascular (lichen)-dominated communities. This also encompasses a limited area of "alpine desert" with unstable sandy substrates and scattered individuals of *Astragalus* spp., *Arabis* spp., *Draba* spp., and *Oxytropis* spp., which mostly fall to the east of the Sierra Nevada crest. Exposure to desiccating winds, rocky and sometimes unstable substrates, and a short growing season limit plant growth.

Related Concepts:

CES206.939 Mediterranean California Alpine Dry Tundra

CES206.939 CLASSIFICATION

Concept Summary: These dry meadows typically occur between 3200 and 4500 m (9700-13,600 feet) elevation in the northern Sierra Nevada, Klamath Mountains and Cascade Range. They are typically found on gentle to steep slopes, flat ridges and upper basins where the soil is thin and the water supply is constant and strongly regulated by snowpatch patterns. These sites are generally very well-drained and xeric once the snow melts. The system is commonly composed of a mosaic of small-patch plant communities that are dominated by sedges, grasses and forbs. Characteristic species include *Phlox diffusa, Phlox covillei, Erigeron pygmaeus, Podistera nevadensis, Carex congdonii, Calamagrostis purpurascens, Eriogonum incanum, Carlquistia muirii (= Raillardella muirii), Castilleja nana, Erigeron compositus, Eriogonum ovalifolium, Eriogonum gracilipes*, etc. There is a rocky mesic version of this system with *Hulsea algida, Saxifraga tolmiei, Carex helleri, Ranunculus eschscholtzii, Polemonium eximium, Salix reticulata* (rarely), *Oxyria digyna, Sibbaldia procumbens*, etc. that could be found near snowmelt patches generally on sheltered, steep, rocky slopes. Alpine dry tundra typically intermingles with alpine bedrock and scree, ice field, fell-field, alpine dwarf-shrubland, and alpine/subalpine wet meadows.

CES206.900 Mediterranean California Alpine Fell-Field

CES206.900 CLASSIFICATION

Concept Summary: This ecological system occurs in limited alpine environments mostly concentrated in the Sierra Nevada but also on Mount Shasta and as far south as the Peninsular Ranges and White Mountains. Alpine elevations begin around 3500 m (10,600 feet) in the southern mountain ranges and 2700 m (8200 feet) in the southern Cascades. Wind scours fell-fields free of snow in the winter, exposing the plants to severe environmental stress. These systems typically have immature soils. Most fell-field plants are cushioned or matted, frequently succulent, flat to the ground in rosettes, and often densely hairy and thickly cutinized. Common species include *Ribes cereum, Linanthus pungens (= Leptodactylon pungens), Ericameria discoidea, Castilleja nana, Minuartia nuttallii (= Arenaria nuttallii), Phlox condensata, Draba densifolia, Oxyria digyna*, and *Aquilegia pubescens*. Plants cover 15-50%, while exposed rock makes up the rest. Fell-fields are usually nested within or adjacent to alpine tundra dry meadows.

Related Concepts:
- Alpine Grassland (213) (Shiflet 1994) **>**

Distribution: This system occurs in limited alpine environments mostly concentrated in the Sierra Nevada but also on Mount Shasta and as far south as the Peninsular Ranges and White Mountains.

Nations: MX, US

Concept Source: P. Comer and T. Keeler-Wolf

Description Author: P. Comer, T. Keeler-Wolf, G. Kittel

CES206.900 CONCEPTUAL MODEL

Environment: These are wind-scoured fell-fields that are free of snow in the winter, such as ridgetops and exposed saddles, exposing the plants to severe environmental stress. Soils on these windy unproductive sites are shallow, stony, low in organic matter, and poorly developed; wind deflation often results in a gravelly pavement. Fell is Gaelic for stone, and these are stone fields. Sites are stable for 100s to 1000s of years as soils develop. Alpine elevations begin around 3500 m (10,600 feet) in the southern Sierra Nevada and 2700 m (8200 feet) in the southern Cascades.

Key Processes and Interactions: TNC model information: Avalanches on steeper slopes where soil accumulates can cause infrequent soil-slips, which expose bare ground.

Very small burns of a few square meters (replacement fire) caused by lightning strikes are a rare disturbance, although lighting storms are frequent in those elevations. The calculation of lightning strike frequency was not based on fire-return intervals but on the number of strikes (in this case, five) per 1000 possible locations per year, thus 0.005.

Alpine rodents (pikas, marmots, etc.) cause common but generally small-scale disturbances in this system. Native herbivores (Rocky Mountain bighorn sheep, mule deer, and elk) were common in the alpine but probably did not greatly affect vegetation cover because animals move frequently as they reduce vegetation cover.

Threats/Stressors:

Ecosystem Collapse Thresholds:

CES306.810 Rocky Mountain Alpine Dwarf-Shrubland

CES306.810 CLASSIFICATION

Concept Summary: This widespread ecological system occurs above upper timberline throughout the Rocky Mountain cordillera, including alpine areas of ranges in Utah and Nevada, and north into Canada. Elevations are above 3360 m in the Colorado Rockies but drop to less than 2100 m in northwestern Montana and in the mountains of Alberta. This system occurs in areas of level or concave glacial topography, with late-lying snow and subirrigation from surrounding slopes. Soils have become relatively stabilized in these sites, are moist but well-drained, strongly acidic, and often with substantial peat layers. Vegetation in these areas is controlled by snow retention, wind desiccation, permafrost, and a short growing season. This ecological system is characterized by a semi-continuous layer of ericaceous dwarf-shrubs or dwarf willows which form a heath type ground cover less than 0.5 m in height. Dense tuffs of graminoids and scattered forbs occur. *Dryas octopetala* or *Dryas integrifolia* communities are not included here, except for one very moist association, because they occur on more windswept and drier sites than the heath communities. Within these communities, *Cassiope mertensiana, Salix arctica, Salix reticulata, Salix vestita*, or *Phyllodoce empetriformis* can be dominant shrubs. *Vaccinium* spp., *Ledum glandulosum, Phyllodoce glanduliflora*, and *Kalmia microphylla* may also be shrub associates. The herbaceous layer is a mixture of forbs and graminoids, especially sedges, including, *Erigeron* spp., *Luetkea pectinata, Antennaria lanata, Oreostemma alpigenum, Pedicularis* spp., *Castilleja* spp., *Deschampsia cespitosa, Caltha leptosepala, Erythronium* spp., *Juncus parryi, Luzula piperi, Carex spectabilis, Carex nigricans*, and *Polygonum bistortoides*. Fell-fields often intermingle with the alpine dwarf-shrubland.

CES306.810 CONCEPTUAL MODEL

Environment: This widespread ecological system occurs above upper timberline throughout the Rocky Mountain cordillera, including alpine areas of ranges in Utah and Nevada, and north into Canada. Elevations are above 3360 m in the Colorado Rockies but drop to less than 2100 m in northwestern Montana and in the mountains of Alberta. This system occurs in areas of level or concave glacial topography, with late-lying snow and subirrigation from surrounding slopes. Soils have become relatively stabilized in these sites, are moist but well-drained, strongly acidic, and often with substantial peat layers. Vegetation in these areas is controlled by snow retention, wind desiccation, permafrost, and a short growing season.

CES306.811 Rocky Mountain Alpine Fell-Field

CES306.811 CLASSIFICATION

Concept Summary: This ecological system is found discontinuously at alpine elevations throughout the Rocky Mountains, west into the mountainous areas of the Great Basin, and north into the Canadian Rockies. Small areas are represented in the west side of the Okanagan Ecoregion in the eastern Cascades. These are wind-scoured fell-fields that are free of snow in the winter, such as ridgetops and exposed saddles, exposing the plants to severe environmental stress. Soils on these windy unproductive sites are shallow, stony, low in organic matter, and poorly developed; wind deflation often results in a gravelly pavement. Most fell-field plants are cushioned or matted, frequently succulent, flat to the ground in rosettes and often densely haired and thickly cutinized. Plant cover is 15-50%, while exposed rocks make up the rest. Fell-fields are usually within or adjacent to alpine tundra dry meadows. Common species include *Arenaria capillaris, Geum rossii, Kobresia myosuroides, Minuartia obtusiloba, Myosotis asiatica, Paronychia pulvinata, Phlox pulvinata, Sibbaldia procumbens, Silene acaulis, Trifolium dasyphyllum*, and *Trifolium parryi*.

CES306.816 Rocky Mountain Alpine Turf

CES306.816 CLASSIFICATION

Concept Summary: This widespread ecological system occurs above upper treeline throughout the Rocky Mountain cordillera, including alpine areas of ranges in Utah and Nevada, and isolated alpine sites in the northeastern Cascades. It is found on gentle to moderate slopes, flat ridges, valleys, and basins, where the soil has become relatively stabilized and the water supply is more or less constant. Vegetation in these areas is controlled by snow retention, wind desiccation, permafrost, and a short growing season. This system is characterized by a dense cover of low-growing, perennial graminoids and forbs. Rhizomatous, sod-forming sedges are the dominant graminoids, and prostrate and mat-forming plants with thick rootstocks or taproots characterize the forbs. Dominant species include *Artemisia arctica, Carex elynoides, Carex siccata, Carex scirpoidea, Carex nardina, Carex rupestris, Festuca brachyphylla, Festuca idahoensis, Geum rossii, Kobresia myosuroides, Phlox pulvinata*, and *Trifolium dasyphyllum*. Many other graminoids, forbs, and prostrate shrubs can also be found, including *Calamagrostis purpurascens, Deschampsia cespitosa, Dryas octopetala, Leucopoa kingii, Poa arctica, Saxifraga* spp., *Selaginella densa, Sibbaldia procumbens, Silene acaulis, Solidago* spp., and *Trifolium parryi*. Although alpine dry tundra is the matrix of the alpine zone, it typically intermingles with alpine bedrock and scree, ice field, fell-field, alpine dwarf-shrubland, and alpine/subalpine wet meadow systems.

Description Author: R. Crawford and M.S. Reid

CES306.816 CONCEPTUAL MODEL

Environment: This widespread ecological system occurs above upper treeline throughout the Rocky Mountain cordillera, including alpine areas of ranges in Utah and Nevada, and isolated alpine sites in the northeastern Cascades. It is found on gentle to moderate slopes, flat ridges, valleys, and basins, where the soil has become relatively stabilized and the water supply is more-or-less constant. Vegetation in these areas is controlled by snow retention, wind desiccation, permafrost, and a short growing season. Stands in Great Basin ranges are often less extensive and sometimes patchy because of more xeric conditions. Adjacent systems include ~Rocky Mountain Alpine Bedrock and Scree (CES306.809)$$ and ~Rocky Mountain Alpine Fell-Field (CES306.811)$$ with ~Rocky Mountain Subalpine Dry-Mesic Spruce-Fir Forest and Woodland (CES306.828)$$ or ~Rocky Mountain Subalpine-Montane Limber-Bristlecone Pine Woodland (CES306.819)$$ near treeline. Inclusions of the small-patch ~Rocky Mountain Alpine-Montane Wet Meadow (CES306.812)$$ occur in wet areas below snow deposition areas and alpine basins. The environmental description is based on several references, including Cox (1933), Schwan and Costello (1951), Bamberg (1961), Willard (1963), Bamberg and Major (1968), Lewis (1970), Thilenius (1975), Komarkova (1976, 1980), Douglas and Bliss (1977), Baker (1980a), Hess (1981), Meidinger and Pojar (1991), Zwinger and Willard (1996), Cooper et al. (1997), Ecosystems Working Group (1998), Reid et al. (1999), Neely et al. (2001), NCC (2002), and NatureServe (2011).

Key Processes and Interactions: Vegetation in these areas is controlled by snow retention, wind desiccation, permafrost and a short growing season. Dry summers associated with major drought years (mean return interval of 100 years) would favor grasses over forbs, whereas wet summers result in a more diverse mixture of forbs and graminoids. Dry turf dominated by graminoids such as *Carex elynoides, Carex rupestris*, or *Kobresia myosuroides* is intolerant of deep snow cover and occurs on wind-scoured slopes and ridges (Willard 1963). These species are efficient in obtaining water due to the turf-forming root system. Much of the soil moisture in dry turf is from summer precipitation, whereas mesic alpine slopes and meadows occur on sites with moderate snow accumulation or receive additional moisture from melting snowbeds. Lewis (1970) reports that *Carex rupestris* can send its roots under the edge of boulderfields and rock channels to obtain additional moisture.

Kobresia myosuroides is a major late-seral community in the alpine (Cox 1933, Willard 1963, Hess 1981, Komarkova 1986). Willard (1963) states that the *Kobresia myosuroides* stands on Trail Ridge, Colorado, are very old. Osburn (1958b) estimates that a minimum of 100 years are necessary for the formation of 1 inch of humus soil under present alpine conditions in the Front Range of Colorado. This estimate would suggest that some stands on Trail Ridge are 800 to 1300 years old.

Native large herbivores (Rocky Mountain bighorn sheep, mule deer and elk) are common in the alpine but probably do not greatly affect vegetation cover because animals move frequently as they reduce vegetation cover. Willard (1963) and Komarkova (1976) both remark on the abundance of pocket gopher (*Thomomys talpoides fossor*) activity within stands dominated by *Carex elynoides*. They state that due to the gophers' grazing, small patches of the plant communities are left isolated. Pocket gophers also dig tunnels beneath the soil surface of *Trifolium dasyphyllum* and *Silene acaulis* stands, eating the roots and bulbs of the plants. Pocket gophers kill individual plants in the stands by clipping the roots of the vegetation or smothering the aboveground portion of the plants with soil. The freshly aerated, bare soil is invaded by species from ~*Carex elynoides - Carex rupestris - Kobresia myosuroides* Rocky Mountain Alpine Turf Alliance (A3155)$$. *Polemonium viscosum* stands are short-lived, however, possibly due to the loose soil substrate that is subject to erosion by wind and water (Willard 1963, Marr and Willard 1970, Zwinger and Willard 1996). Meadow voles (*Microtus* sp.) live in alpine meadows, feeding on the stems and blades of graminoids. When vole populations are high, however, the small mammals also feed on cushion plants, shredding the centers of *Silene acaulis* and *Trifolium nanum*. Seedlings from erect-form species, such as *Geum rossii*, become established in the dead parts of the cushion plants. Once established, the erect-form species shade and outcompete the remaining cushion plants. Willard (1963) suggests that *Geum rossii* stands may be expanding into adjacent cushion plant communities.

Very small burns of a few square meters (replacement fire) caused by frequent lightning strikes may occur as a rare disturbance where there is enough fuel buildup. Lewis (1970) reports that *Carex rupestris* can send its roots under the edge of boulderfields and rock channels to obtain additional moisture.

Threats/Stressors: Grazing by domestic sheep used to be more widespread in this high-elevation system, and can still impact some stands where there are sheep ranching operations. Effects of sheep grazing depend on vegetation and vary with stocking rates and management with heavy grazing usually resulting in depletion and increased erosion rates.

Human development has impacted many locations throughout the ecoregion. High- and low-density urban and industrial developments also have large impacts. For example, residential development has significantly impacted locations within commuting distance to urban areas. Impacts may be direct as vegetation is removed for building sites or more indirectly through natural fire regime alteration, and/or the introduction of invasive species. Mining operations can drastically impact natural vegetation. Road building and power transmission lines continue to fragment vegetation and provide vectors for invasive species.

M101. Vancouverian Alpine Tundra

CES204.853 North Pacific Alpine and Subalpine Bedrock and Scree

CES204.853 CLASSIFICATION

Concept Summary: This ecological system includes all the exposed rock and rubble above the forest line (subalpine parkland and above) in the North Pacific mountain ranges and is restricted to the highest elevations in the Cascade Range, from southwestern British Columbia south into northern California, and also north into southeastern Alaska. It is composed of barren and sparsely vegetated alpine substrates, typically including both bedrock outcrops and scree slopes, upper mountain slopes, summits and nunataks. Nonvascular- (lichen-) dominated communities are common. Exposure to desiccating winds, rocky and sometimes unstable substrates, and a short growing season limit plant growth. In Alaska, this system usually occurs above alpine dwarf-shrub, herbaceous meadow, and dwarf-shrub-herbaceous systems typically at elevations higher than 915 m (3000 feet) (possibly higher in southeastern Alaska). There can be sparse cover of forbs, grasses, lichens, shrubs and small trees, but the total vascular plant cover is typically less than 25% due to the high cover of exposed rock. Species composition is variable and may include *Artemisia arctica, Astragalus alpinus, Carex microchaeta, Minuartia arctica, Salix rotundifolia, Saxifraga sibirica (= Saxifraga bracteata), Saxifraga bronchialis, Sibbaldia procumbens*, and *Silene acaulis*. Common nonvascular genera include *Racomitrium* and *Stereocaulon*.

CES204.862 North Pacific Dry and Mesic Alpine Dwarf-Shrubland, Fell-Field and Meadow

CES204.862 CLASSIFICATION

Concept Summary: This ecological system occurs above the environmental limit of trees, at the highest elevations of the mountain regions of the Pacific Northwest coast. It is confined to the coldest, wind-blown areas above treeline and above the subalpine parkland. This system is found at elevations above 2350 m (7200 feet) in the Klamath Mountains and Cascades north into the Cascade Range and Coast Mountains of British Columbia. It is commonly composed of a mosaic of plant communities with characteristic species including *Cassiope mertensiana, Phyllodoce empetriformis, Phyllodoce glanduliflora, Luetkea pectinata, Saxifraga tolmiei*, and *Carex* spp. It occurs on slopes and in depressions where snow lingers, the soil has become relatively stabilized, and the water supply is more or less constant. Vegetation in these areas is controlled by snow retention, wind desiccation, permafrost, and a short growing season. This system includes all vegetated areas in the alpine zone of the North Pacific. Typically it is a mosaic of dwarf-shrublands, fell-fields, tundra (sedge turfs), and sparsely vegetated snowbed communities. Small patches of krummholz (shrub-form trees) are also part of this system and occur at the lower elevations. Communities are dominated by graminoids, foliose lichens, dwarf-shrubs, and/or forbs. Vegetation cover ranges from about 5 or 10% (snowbeds) to nearly 100%. The alpine tundra of the northern Cascades has floristic affinities with many mountain regions in western North America. The strongest relationships are with the Arctic and Cordilleran regions to the north and east.

5.A.2.Wb. Temperate Intertidal Shore

M106. Temperate Pacific Seaweed Intertidal Vegetation

CES204.879 Temperate Pacific Intertidal Flat

CES204.879 CLASSIFICATION

Concept Summary: Coastal flats are found along the north Pacific Coast from Kodiak Island and Cook Inlet, Alaska, south to central California. Tidal flats form a narrow band along oceanic inlets and are more extensive at the mouths of larger rivers. Algae are the dominant vegetation on mud or gravel flats where little vascular vegetation is present due to the daily (in some cases twice daily) tidal flooding of salt or brackish water. Characteristic species include *Vaucheria longicaulis* and *Enteromorpha* spp. Vascular species are sparse, if present, and may include salt-tolerant species such as *Eleocharis palustris, Salicornia* spp., *Plantago maritima, Glaux maritima*, and other plants common to lower salt marshes; cover is less than 10%. The dominant processes are tectonic uplift or subsidence, isostatic rebound, and sediment deposition.

5.A.3.We. Temperate Seagrass Aquatic Vegetation

M184. Temperate Pacific Seagrass Intertidal Vegetation

CES200.882 North Pacific Maritime Eelgrass Bed

CES200.882 CLASSIFICATION

Concept Summary: Eelgrass beds are found throughout the coastal areas of the North Pacific Coast, from southern Oregon (Coos Bay) north into the Gulf of Alaska, Cook Inlet, and Bristol Bay coasts. Intertidal zones are found with clear water in bays, inlets and lagoons, typically dominated by macrophytic algae and marine aquatic angiosperms along the temperate Pacific Coast. Subtidal portions are never exposed while intertidal areas support species that can tolerate exposure to the air. Common substrates include marine silts, but may also include exposed bedrock and cobble, where many algal species become attached with holdfasts. Subtidal/lower intertidal in clear water. Substrate is usually marine silts, but may be cobble. Beds are dominated by *Zostera marina*.

5.B.2.Na. North American Freshwater Aquatic Vegetation

M109. Western North American Freshwater Aquatic Vegetation

CES200.876 Temperate Pacific Freshwater Aquatic Bed

CES200.876 CLASSIFICATION

Concept Summary: Freshwater aquatic beds are found throughout the humid temperate regions of the Pacific Coast of North America. They are small patch in size, confined to lakes, ponds, oxbows, and slow-moving portions of rivers and streams. In large bodies of water, they are usually restricted to the littoral region where penetration of light is the limiting factor for growth. A variety of rooted or floating aquatic herbaceous species may dominate, including *Azolla* spp., *Nuphar polysepala, Polygonum* spp., *Potamogeton* spp., *Ranunculus* spp., and *Wolffia* spp. Submerged vegetation, such as *Myriophyllum* spp., *Ceratophyllum* spp., and *Elodea* spp., is often present. These communities occur in water too deep for emergent vegetation.

6.B.1.Na. Eastern North American Temperate Cliff, Scree & Rock Vegetation

M111. Eastern North American Cliff & Rock Vegetation

CES202.689 Central Interior Acidic Cliff and Talus

CES202.689 CLASSIFICATION

Concept Summary: This system is found primarily in the Interior Highlands, including the Ozarks, Ouachita, and Interior Low Plateau ecoregions, extending marginally north and west along the Missouri and Mississippi rivers. Sandstone outcrops and talus ranging from moist to dry typify this system. It is typically sparsely vegetated; however, on moister sites with more soil development, several fern species and sedges (*Carex* spp.) can establish. Wind and water erosion are the major dynamic processes influencing this system.
Related Concepts:

Distribution: This system is found primarily in the Interior Highlands, including the Ozark, Ouachita, and Interior Low Plateau ecoregions. It extends marginally into the Central Tallgrass Prairie Ecoregion along the Missouri and Mississippi rivers.
Nations: US
Concept Source: S. Menard, T. Foti, R. Evans
Description Author: S. Menard, T. Foti, R. Evans, M. Pyne and J. Drake

CES202.689 CONCEPTUAL MODEL

Environment: Sandstone outcrops and talus ranging from moist to dry typify this system. Examples range from sparsely to moderately well-vegetated. Soil development is limited to cracks and ledges. Slope aspect and angle are strongly related to the amount of available moisture on a site. Steep, south- or west-facing slopes are drier than less steep east- or north-facing slopes. Some sites have seepage along the cliff face. Shading by adjacent forests can impact cliffs below the height of nearby trees.
Key Processes and Interactions: Wind and water erosion are the major dynamic processes influencing this system.
Threats/Stressors: The difficulty in accessing examples of this system has prevented extensive use by humans. Some sites have been partially or completely destroyed by quarrying. Reduction in fire frequency in nearby vegetation could allow expansion of woody species where they are able to grow. Rock climbing can have local effects on vegetation and erosion but is unlikely to have widespread impacts. Logging, heavy grazing, or residential development above cliff faces can cause increased water runoff over the cliff and increased sediment transport from upslope (Kost et al. 2007, WNHI 2012). Due to the typically infertile conditions in this system, the vegetative component is slow to recover from disturbance.
Ecosystem Collapse Thresholds: Ecological collapse tends to occur when sites are destroyed by quarrying or when vegetation is removed by erosion.

CES202.690 Central Interior Calcareous Cliff and Talus

CES202.690 CLASSIFICATION

Concept Summary: This system is found primarily in non-Appalachian portions of the "central interior division" of the United States. It ranges from the Ouachitas east to the Cumberlands and north into the Western Allegheny Plateau and Lake states. Limestone and dolomite outcrops and talus distinguish this system. Examples range from moist to dry and from sparsely to moderately well-vegetated. Woodland species such as *Thuja occidentalis* can establish along the ridgetops, on ledges, and talus. Understory species can range from grassland species, such as *Andropogon gerardii* on drier slopes, to more mesic species in areas with higher moisture and more soil development. Wind and water erosion along with fire are the primary natural dynamics influencing this system. Some associations included here are rocky openings in forest stands, sometimes with moisture present from groundwater seepage. Also included are wet and dry cliffs. The flora of these wetter examples may include (across the broad range of the system) *Aconitum noveboracense, Adiantum capillus-veneris, Adoxa moschatellina, Aquilegia canadensis, Asplenium rhizophyllum, Boehmeria cylindrica, Chrysosplenium alternifolium var. sibiricum, Cystopteris bulbifera, Cystopteris bulbifera, Dichanthelium depauperatum, Heuchera americana, Heuchera americana var. hirsuticaulis, Heuchera villosa var. arkansana, Hydrangea arborescens, Impatiens pallida, Lobelia siphilitica, Toxicodendron radicans*, and *Woodsia obtusa*.

Distribution: This system is found primarily in non-Appalachian portions of the "central interior division" of the United States, from the Ouachitas east to the Cumberlands and north into the Western Allegheny Plateau and Great Lake states.
Nations: US
Concept Source: S. Menard
Description Author: S. Menard, J. Drake and M. Pyne

CES202.690 CONCEPTUAL MODEL

Environment: Limestone and dolomite outcrops and talus distinguish this system. Examples range from moist to dry and from sparsely to moderately well-vegetated. Soil development is limited to cracks and ledges. Slope aspect and angle are strongly related to the amount of available moisture on a site. Steep, south- or west-facing slopes are drier than less steep east- or north-facing slopes. Some sites have seepage along the cliff face. Shading by adjacent forests can impact cliffs below the height of nearby trees.
Key Processes and Interactions: Wind and water erosion along with fire are the primary natural dynamics influencing this system. Fires could spread from more vegetated communities adjacent to calcareous cliffs and could burn vegetation on the edges of this community. A study in a similar cliff system in southern Ontario found no relationship between cliff patch size and diversity or richness (Haig et al. 2000).
Threats/Stressors: The difficulty in accessing examples of this system has prevented extensive use by humans. Some sites have been partially or completely destroyed by quarrying. Reduction in fire frequency in nearby vegetation could allow expansion of woody species where they are able to grow. Rock climbing can have local effects on vegetation and erosion but is unlikely to have widespread impacts. Logging, heavy grazing, or residential development above cliff faces can cause increased water runoff over the cliff and increased sediment transport from upslope (Kost et al. 2007, WNHI 2012). Due to the typically infertile conditions in this system, the vegetative component is slow to recover from disturbance.
Ecosystem Collapse Thresholds: Ecological collapse tends to occur when sites are destroyed by quarrying or when vegetation is removed by erosion or increased fire frequency.

CES202.309 Cumberland Acidic Cliff and Rockhouse

CES202.309 CLASSIFICATION

Concept Summary: This sandstone cliff ecological system is found in the Cumberland Plateau and Mountain regions of the southeastern United States. Examples are extremely steep or vertical rock faces exposed along bluffs often associated with rivers. The aspect is variable but best developed on south- and west-facing sites. Plants are infrequent due to the lack of crevices capable of accumulating soil, the highly acidic nature of the bedrock, and the frequent weathering and erosion of the substrate. Lichen cover may be extensive in places, especially on the more exposed portions. These cliffs are also prone to harsh climatic conditions; frequent disturbances include drought stress and wind and storm damage. As a result, examples are characterized by sparse herbaceous cover and few, if any, trees. Vegetation consists of scattered individuals of *Asplenium montanum, Silene rotundifolia*, and other species rooted in crevices and erosion pockets. In some parts of its range, this system is the primary or sole habitat for rare endemic species, such as *Minuartia cumberlandensis* and *Ageratina luciae-brauniae*. This system includes a mosaic of cavelike features (often called "rockhouses") and associated sandstone box canyons in the western Appalachian foothills regions of Kentucky, Alabama, West Virginia, and possibly southeastern Ohio. Where present, the rockhouses are a prominent and diagnostic feature of the system.
Related Concepts:

- Virginia Pine: 79 (Eyre 1980) **<**

Distribution: This ecological system occurs in a limited area of the Cumberland Plateau of northern Alabama, northwestern Georgia, eastern Kentucky, eastern Tennessee, West Virginia, and possibly southwestern Virginia. Rockhouses also occur in southeastern

Ohio (Rockhouse 349) and in western Pennsylvania (Walck et al. 1996) along Laurel and Chestnut Ridges of the Laurel Highlands in the Central Appalachian Plateau ecoregion (E. Zimmerman pers. comm. 2013).
Nations: US
Concept Source: R. Evans
Description Author: R. Evans, M. Pyne, S.C. Gawler and C. Nordman

CES202.309 CONCEPTUAL MODEL

Environment: The rockhouses are the most unique and diagnostic feature of the system. These unusual geologic features are created by spray and rock-cracking from seasonal flowing waterfalls at the heads of canyons amidst thick layers of sandstone from the Mississippian and Pennsylvanian geologic periods. The ceiling of the rockhouse may be 50 m tall, and they can be as much as 50 m deep (Walck et al. 1996, A. Weakley pers. comm. 2006). They require sufficient flowing water and freezing and thawing to weather the thick beds of sandstone. These conditions seem to be restricted to the western margin of the Appalachian Plateau.
Key Processes and Interactions: Within rockhouses, there are three distinct habitats: ceiling, backwall, and floor. The dripline defines the outer edge of the ceiling and floor. The ceiling generally slopes back from the dripline to the backwall, which is deeply shaded and generally stays moist. Shading in the rockhouse is greater in the summer when deciduous trees in front of the rockhouse are leafed out. Light levels vary from very low at the backwall (Farrar 1998) to relatively high, especially in winter, when leaves are down (Walck et al. 1996). The combination of shade and the stable and moderate microclimate of rockhouses has maintained a habitat suitable for unusual, disjunct and endemic plants (Walck et al. 1996), including tropical ferns and bryophytes (Farrar 1998) which may have persisted in these habitats since pre-Pleistocene times when there was a tropical or subtropical climate (Farrar 1998). Temperatures inside rockhouses are higher in the winter and lower in the summer than outside the rockhouses, and while rockhouse habitats are protected from rain, they tend to have higher humidities than the surrounding areas (Walck et al. 1996).
Threats/Stressors: Threats to the special flora of rockhouses include damage from hiking, camping, rockclimbing, rappelling, trampling, smoke and heat from campfires, digging for artifacts, and collection of rare plants (Walck et al. 1996). Flooding of rockhouses is a threat, from dam construction and impoundment (Farrar 1998, Walck et al. 1996). The invasive exotic plant *Microstegium vimineum* may also be a threat (Walck et al. 1996); it occurs very close to some rockhouses. Logging around rockhouses is a threat, especially on private lands (Walck et al. 1996, Farrar 1998). Fragmentation of the surrounding forests by roads, pipelines, powerline rights-of-way, and conversion of forests to other uses is a threat.
Ecosystem Collapse Thresholds: Ecosystem collapse tends to result from human impacts, including trampling of the rockhouse floor area, campfires in the rockhouse, and to a lesser extent logging the surrounding forest. Due to the ease of access to rockhouses on popular public recreation lands, in about 30% of rockhouses, the floor areas have become >70% disturbed by trampling (Ferguson and Gardner 1986, cited in Walck et al. 1996). Logging around rockhouses can change the humid and moderate microclimate of rockhouses, and is a threat, especially on private lands (Walck et al. 1996, Farrar 1998). Campfires in the rockhouse can destroy plants by burning, too much heat, and smoke. Ecosystem collapse is characterized by trampled rockhouse floor areas, and lacking unusual, disjunct or endemic plants (Walck et al. 1996), flooding as a result of damming of creeks or rivers, and a change of the stable and humid microclimate due to habitat conversion, logging, or fragmentation of the surrounding forest (Farrar 1998).

CES201.025 Great Lakes Acidic Rocky Shore and Cliff

CES201.025 CLASSIFICATION

Concept Summary: This system is found in the Great Lakes region of the U.S. and Canada where exposed bedrock dominates the shoreline. The bedrock may consist of acidic igneous, metamorphic, or sedimentary rock. Some bedrock shorelines are solid rock, others more cobbly or fragmented. The bedrock may be relatively horizontal or tilted, rounded or blocky, and sometimes cliff-like. The leading edge of the shoreline may be heavily impacted by wave action and winter ice movement, decreasing in effect with distance inland. Vegetation varies from sparse nonvascular vegetation to open-treed or shrubby communities along the same transect.
Related Concepts:
Distribution: Found in the Great Lakes region of the U.S. and Canada, where exposed bedrock dominates the shoreline.

CES201.569 Laurentian-Acadian Acidic Cliff and Talus

CES201.569 CLASSIFICATION

Concept Summary: This cliff system occurs at low to mid elevations, well below treeline, from New England west to the Great Lakes. It consists of vertical or near-vertical cliffs and the talus slopes below, formed on hills of granitic or otherwise acidic bedrock. Most of the substrate is dry and exposed, but small (occasionally large) areas of seepage are often present. Vegetation in seepage areas tends to be more well-developed and floristically different from the surrounding dry cliffs. The vegetation is patchy and often sparse, punctuated with patches of small trees (e.g., *Betula* and *Picea* spp.). Calciphilic species are absent. In north-facing or other sheltered settings where cold air accumulates at the bottom of slopes, a shrubland of heaths and reindeer lichens can develop. This system differs from the more southerly ~North-Central Appalachian Acidic Cliff and Talus (CES202.601)$$ in the more boreal affinities of its flora, for example *Picea* spp. rather than *Juniperus virginiana*.

CES201.570 Laurentian-Acadian Calcareous Cliff and Talus

CES201.570 CLASSIFICATION

Concept Summary: This cliff system occurs at low to mid elevations, well below treeline, from New England west to the Great Lakes. It consists of vertical or near-vertical cliffs and the talus slopes below, where weathering and/or bedrock chemistry produce circumneutral to calcareous pH and enriched nutrient availability. The vegetation is often sparse but may include patches of small trees. *Thuja occidentalis* may dominate on some cliffs (and reach very old ages, upwards of 1000 years). *Fraxinus* spp. and *Tilia americana* are woody indicators of the enriched setting.

CES202.601 North-Central Appalachian Acidic Cliff and Talus

CES202.601 CLASSIFICATION

Concept Summary: This system comprises sparsely vegetated to partially wooded cliffs and talus slopes in the Central Appalachians and adjacent ecoregions, occurring on rocks of acidic lithology and lacking any indicators of enriched conditions. This cliff system occurs at low to mid elevations from central New England south to Virginia, and up to 1500 m in West Virginia. It consists of vertical or near-vertical cliffs and the talus slopes below, formed on hills of granitic, sandstone, or otherwise acidic bedrock. In some cases, especially in periglacial areas, this system may take the form of upper-slope boulderfields without adjacent cliffs, where talus forms from freeze/thaw action cracking the bedrock. Most of the substrate is dry and exposed, but small (occasionally large) areas of seepage are often present. Vegetation in seepage areas tends to be more well-developed and floristically different from the surrounding dry cliffs. The vegetation is patchy and often sparse, punctuated with patches of small trees that may form woodlands in places. *Juniperus virginiana* is a characteristic tree species, *Toxicodendron radicans* a characteristic woody vine, and *Polypodium virginianum* a characteristic fern. Within its range, *Pinus virginiana* is often present.

Distribution: This system is found from central New England and New York south to Virginia.
Nations: US
Concept Source: S.C. Gawler
Description Author: S.C. Gawler, L.A. Sneddon and M. Pyne

CES202.601 CONCEPTUAL MODEL

Environment: This cliff system consists of vertical or near-vertical cliffs at low to mid elevations and the talus slopes below, formed on hills of granitic, sandstone, or otherwise acidic bedrock. Most of the substrate is dry and exposed, but small (occasionally large) areas of seepage are often present.

Key Processes and Interactions: Periodic rockslides maintain the open character of this system. Fire is generally not an important factor, since steep slopes and rockslides prevent extensive vegetation development, limiting litter accumulation.

Threats/Stressors:

Ecosystem Collapse Thresholds:

CES202.603 North-Central Appalachian Circumneutral Cliff and Talus

CES202.603 CLASSIFICATION

Concept Summary: This cliff system occurs at low to mid elevations from central New England south to Virginia and West Virginia. It consists of vertical or near-vertical cliffs and steep talus slopes where weathering and/or bedrock lithology produce circumneutral to calcareous pH and enriched nutrient availability. Substrates include limestone, dolomite and other rocks. The vegetation varies from sparse to patches of small trees, in places forming woodland or even forest vegetation. *Fraxinus americana, Tilia americana*, and *Staphylea trifolia* are woody indicators of the enriched setting. *Thuja occidentalis* may occasionally be present but is more characteristic of the related Laurentian-Acadian system to the north. The herb layer is typically not extensive but includes at least some species that are indicators of enriched conditions, e.g., *Impatiens pallida, Pellaea atropurpurea, Asplenium platyneuron*, or *Woodsia obtusa*.

CES202.330 Southern Appalachian Montane Cliff and Talus

CES202.330 CLASSIFICATION

Concept Summary: This system consists of steep to vertical or overhanging rock outcrops (and related steep talus slopes) of the Southern Blue Ridge and adjacent parts of other ecoregions. It occurs on lower slopes, usually in river gorges or bluffs. The sparse vegetation is limited to plants growing on bare rock, small ledges, and crevices. Vegetation is primarily bryophytes, lichens, and herbs, with sparse trees and shrubs rooted in deeper soil pockets and crevices.

Related Concepts:

- Montane Acidic Cliff (Schafale and Weakley 1990) **<**
- Montane Calcareous Cliff (Schafale and Weakley 1990) **<**
- Montane Mafic Cliff (Schafale and Weakley 1990) **<**

Distribution: Scattered throughout the Southern Appalachians and incidentally into adjacent ecoregions, from northern Alabama and Georgia through Virginia.

Nations: US

Concept Source: M. Schafale and R. Evans

Description Author: M. Schafale, R. Evans, M. Pyne

CES202.330 CONCEPTUAL MODEL

Environment: This system occurs on steep rock outcrops on lower slopes and occasionally higher in topographically sheltered sites. River gorges are probably the most common landforms, with bluffs of more open river valleys or meandering rivers also common. The substrate is mostly bare bedrock, which is steep to vertical or overhanging. Most examples are on felsic metamorphic rock such as gneiss or schist, a smaller number on mafic metamorphic rock or felsic or mafic igneous rock. [Examples may occur on any kind of rock except limestone and dolomite, with felsic metamorphic rock the most common in the Southern Blue Ridge and sandstone the most common in the Cumberland Mountains. Mafic metamorphic rocks form a less common but important fraction of examples, along with some more extreme rocks such as quartzite.] The physical structure of cliffs of metamorphic rock is usually irregular, with some ledges and crevices. [Sedimentary rocks often form more vertical cliffs, but with bedding planes and joints forming deep crevices that provide rooting sites.] Moisture levels vary drastically over short distances. Seepage of groundwater from adjacent soils or through rock fractures often creates permanently or seasonally flooded microsites, while lack of soil makes other portions extremely dry. In less sheltered topography, slope aspect affects overall moisture levels to some degree. Rock or soil chemistry appears to be the most important factor affecting different associations on sites that have the physical structure to belong to this system. Elevation may also be an important factor causing variation, though few examples are known at high elevation.

Key Processes and Interactions: The dynamics of this system have received little study. Most cliff communities are probably stable over long periods of time, with fine-scale disturbances affecting microsites. Rock falls, slides, and other mass movement are rare, but represent catastrophic disturbance to part or all of a cliff, and may be important in the long term for keeping cliffs open. Animal movements may be locally important. Fire probably has little effect on cliffs, which have too little vegetation to carry fire and which tend to occur in topography that is not conducive to fire spread. Because of the limited natural disturbance and the fragility of soil and vegetation, human disturbance by trampling edges and by climbing may be particularly destructive.

CES202.356 Southern Interior Calcareous Cliff

CES202.356 CLASSIFICATION

Concept Summary: This ecological system encompasses calcareous cliffs of the Southern Ridge and Valley and adjacent areas of the Cumberland Plateau with a few disjunct localities in the Southern Appalachians. This system includes vertical to near-vertical rock faces of limestone and dolomite. These cliffs are typically dry but may contain relatively small embedded seepage patches. Both wet and, more commonly, dry expressions are included. Due to harsh edaphic conditions, including verticality, these cliffs are nearly unvegetated, however, *Asplenium ruta-muraria* and *Pellaea atropurpurea* may be characteristic plants. Some cliffs have scattered *Thuja occidentalis* trees which may be very old (>800 years) and more genetically diverse than northern populations. This system also covers a narrow zone of vegetation, often herbaceous, at the horizontal clifftop where growing conditions are harsh and often gladelike.

Related Concepts:

- Eastern Redcedar: 46 (Eyre 1980) **<**
- Northern White-Cedar: 37 (Eyre 1980) **<**

Distribution: This system is found in the Southern Ridge and Valley and adjacent areas of the Cumberland Plateau with a few disjunct localities in the Southern Appalachians.

Nations: US

Concept Source: R. Evans, C. Nordman, M. Pyne

Description Author: R. Evans, C. Nordman, M. Pyne

CES202.356 CONCEPTUAL MODEL

Environment: This system includes vertical to near-vertical rock faces of limestone and dolomite. These cliffs are typically dry but may contain relatively small embedded seepage patches. Both wet and, more commonly, dry expressions are included. Disjunct examples in the southern Appalachians attributed to this system include Hot Springs and Linville Caverns area. It presumably includes both the Bull Cave and Calf Cave area in the Smokies.

CES202.386 Southern Piedmont Cliff

CES202.386 CLASSIFICATION

Concept Summary: This ecological system consists of steep to vertical or overhanging rock outcrops in the Piedmont. They occur on lower to midslopes, usually in river gorges or bluffs. The sparse vegetation is limited to plants growing on bare rock, small ledges, and crevices. Vegetation is primarily bryophytes, lichens, and herbs, with sparse trees and shrubs rooted in deeper soil pockets and crevices. The types of plants that may grow on cliffs are limited by the harsh conditions to those with adaptations to drought and limited nutrients. Examples of this system occur on steep rock outcrops on lower slopes, occasionally higher in topographically sheltered sites. River bluffs are the primary setting. Cliffs may have any aspect, but north-facing cliffs seem to be more common. The substrate is mostly bare bedrock, which is steep to vertical or overhanging. Most examples are on felsic metamorphic rock such as gneiss or schist, but a smaller number occur on mafic metamorphic rock, felsic or mafic igneous rock, or sedimentary rock. Vascular plants are limited to sparse rooting sites in soil pockets, ledges, and crevices.

Related Concepts:

- Piedmont Calcareous Cliff (Schafale and Weakley 1990) **<**
- Piedmont Mafic Cliff (Schafale and Weakley 1990) **<**
- Piedmont/Coastal Plain Acidic Cliff (Schafale and Weakley 1990) **<**

Distribution: Scattered throughout the Piedmont and incidentally into the Coastal Plain, from northern Alabama and Georgia north into Virginia.

Nations: US

Concept Source: M. Schafale

Description Author: M. Schafale and M. Pyne

CES202.386 CONCEPTUAL MODEL

Environment: Examples of this system occur on steep rock outcrops on lower slopes, occasionally higher in topographically sheltered sites. River bluffs are the primary setting. Cliffs may have any aspect, but north-facing cliffs seem to be more common. The substrate is mostly bare bedrock, which is steep to vertical or overhanging. Most examples are on felsic metamorphic rock such as gneiss or schist, a smaller number on mafic metamorphic rock, felsic or mafic igneous rock, or sedimentary rock. The physical structure of most cliffs in the Piedmont is irregular, with some ledges and crevices, and with steep, vertical, and even overhanging portions intermixed. Moisture levels vary drastically over short distances. Seepage of ground water from adjacent soils or through rock fractures often creates permanently or seasonally flooded microsites, while lack of soil makes other portions extremely dry. In less sheltered topography, slope aspect affects overall moisture levels to some degree. Rock or soil chemistry appears to be the most important factor affecting different associations on sites that have the physical structure to belong to this system.

Key Processes and Interactions: The dynamics of this system have received little study. Most cliff communities are probably stable over long periods of time, with fine-scale disturbances affecting microsites. Rock falls, slides, and other mass movement are rare, but represent catastrophic disturbance to part or all of a cliff, and may be important in the long term for keeping cliffs open. The types of plants that may grow on cliffs are limited by the harsh conditions to those with adaptations to drought and limited nutrients (Edwards et al. 2013). Animal movements may be locally important. Fire probably has little effect on cliffs, which have too little vegetation to carry fire and which tend to occur in topography that is not conducive to fire spread. Because of the limited natural disturbance and the fragility of soil and vegetation, human disturbance by trampling of edges and by climbing may be particularly destructive.

Threats/Stressors: Some sites are vulnerable to development near cliff edges, which can degrade the habitats as well as the aesthetics. Cliff edges are vulnerable to erosion and compaction from traffic by hikers, horses, all-terrain vehicles, and bicycles (McLean 1989). Some sites are well-protected against destruction, but at others human climbing, scrambling, and exploration can cause damage to biological resources and accelerate erosion of the substrate (Schafale and Weakley 1990). Lower cliffs associated with river bluff sites could become permanently flooded if rivers are impounded. Some invasive exotic plants exploit open cliff habitats, including *Paulownia tomentosa*. Other invasive exotic plants that could be problematic are *Centaurea biebersteinii (= Centaurea stoebe ssp. micranthos, = Centaurea maculosa), Elaeagnus umbellata*, and *Lespedeza cuneata*.

Ecosystem Collapse Thresholds: Ecosystem collapse would result from changes to the substrate, such as from clearing of the surrounding forest, mining of the rock which composes the cliffs, residential or commercial development on the cliff edges, invasive exotic plants, and disturbance from recreational use. Damming and impoundment of rivers could permanently flood lower portions of cliffs associated with river bluff sites. Ecosystem collapse is characterized by dominance of the cliff area by invasive exotic plants, removal of rock from the cliff, and loss of the characteristic vegetation. The possible effects of climate change to this very dry habitat are probably limited. A wetter climate could accelerate the pace of woody plant succession, but probably not to a degree that would fundamentally change it.

M115. Great Plains Badlands Vegetation

CES303.663 Western Great Plains Badlands

CES303.663 CLASSIFICATION

Concept Summary: This ecological system is found within the northern Great Plains region of the United States and Canada with some of the better known and extensive examples in North and South Dakota. In contrast to ~Western Great Plains Cliff and Outcrop (CES303.665)$$, this system is typified by extremely dry and easily eroded, consolidated clay soils with bands of sandstone or isolated consolidates and little to no cover of vegetation (usually less than 10% but can be as high as 20%). Vegetated patches within the badlands system may have cover higher than 20%. In north-central Montana, badlands often are a mosaic of bare substrate with small patches of grasses and/or shrubs that may exceed 10% cover. In those areas with vegetation, species can include scattered individuals of many dryland shrubs or herbaceous taxa, including *Grindelia squarrosa, Gutierrezia sarothrae* (especially with overuse and grazing), *Sarcobatus vermiculatus, Atriplex gardneri, Artemisia pedatifida, Eriogonum* spp., *Muhlenbergia cuspidata, Pseudoroegneria spicata*, and *Arenaria hookeri*. Patches of *Artemisia* spp. can also occur. This system can occur where the land lies well above its local base level or below and is created by several factors, including elevation, rainfall, carving action of streams, and parent material.

Related Concepts:
- Western Great Plains Badlands (Rolfsmeier and Steinauer 2010) =

Distribution: This system ranges throughout the northern Great Plains region of the United States and Canada. Some of the best and well-known examples occur in North and South Dakota. Its western-most occurrence in Wyoming needs to be clarified, but it does occur in the eastern portion of that state.

Nations: CA?, US

Concept Source: S. Menard and K. Kindscher

Description Author: S. Menard, K. Kindscher, G. Kittel and M.S. Reid

CES303.663 CONCEPTUAL MODEL

Environment: A combination of factors such as elevation, rainfall, carving action of streams and parent material can contribute to the development of this system. This system is primarily a type of mature dissection with finely textured drainage pattern and steep slopes. This system contains extremely dry and easily erodible, consolidated clayey soils with bands of sandstone or isolated consolidates. This system is found within an arid to semi-arid climate with infrequent, but torrential, rains that cause erosion.

Key Processes and Interactions: This system contains highly erodible soils that can be strongly influenced by infrequent, but often torrential, rains.

M116. Great Plains Cliff, Scree & Rock Vegetation

CES303.664 Southwestern Great Plains Canyon

CES303.664 CLASSIFICATION

Concept Summary: This ecological system occurs in both perennial and intermittent stream canyons of the southwestern Great Plains. Soils can range from deep loams to alluvial to sandy. The mosaic of soil types which have developed from sandstone, limestone, basalt, and shale parent materials creates a complex mosaic of grasslands, shrublands and woodlands within the canyon system (Shaw et al. 1989). Although the system combines many elements from ~Southern Rocky Mountain Juniper Woodland and Savanna (CES306.834)$$, ~Rocky Mountain Lower Montane-Foothill Shrubland (CES306.822)$$, ~Western Great Plains Shortgrass Prairie (CES303.672)$$, and other shrublands, the varied geology, diverse soil types, and topographic dynamics together form a distinct ecological system characteristic of the canyons and dissected mesas of the southwestern Great Plains.

Vegetation varies both regionally and locally depending on latitude, aspect, slope position and substrate and can range from riparian vegetation to xeric or mesic woodlands and shrublands. Rock outcrops with sparse vegetation are also common. Open to moderately dense pinyon-juniper woodlands occupy most of the canyonland slopes. Scattered *Pinus edulis* may occur within these community types but are never dominant. Woodlands may be floristically similar to and intergrade with ~Southern Rocky Mountain Juniper Woodland and Savanna (CES306.834)$$ but are distributed along rocky outcrops, canyon slopes and mesas. *Juniperus monosperma* is the most common tree species and forms extensive woodlands with a grassy understory of *Bouteloua eriopoda, Bouteloua gracilis, Bouteloua hirsuta, Bouteloua curtipendula*, and *Pleuraphis jamesii*, or sometimes with an open shrub layer dominated by *Cercocarpus montanus*. In Kansas, *Juniperus virginiana* can become more dominant and replace *Juniperus monosperma*. Isolated patches of *Pinus ponderosa* or *Populus tremuloides* are found in some locations. Shrublands occur on canyon bottoms, in narrow side canyons, and integrate with woodlands on upper slopes. A mosaic of shrub species is characteristic of canyon walls and slopes and varies with substrate and moisture availability. Common species include *Artemisia bigelovii, Cercocarpus montanus, Rhus trilobata, Ribes* spp., *Ptelea trifoliata, Philadelphus microphyllus*, and *Yucca glauca*. *Frankenia jamesii* and *Glossopetalon spinescens var. meionandrum* form a community restricted to gypsiferous and calciferous soils. Canyon floors often support a degraded shrubby grassland of *Ericameria nauseosa* and *Cylindropuntia imbricata* with a grassy understory.

Because of the varied topography, relatively permanent water along streambeds and southern location, these canyonlands have a rich herpetofauna (Mackessy 1998). This system provides good habitat for a number of snake species that are otherwise uncommon in the Central Shortgrass Prairie ecoregion. Occasional seeps and springs of the canyon walls provide habitat for rare ferns.

Related Concepts:
- Pinyon - Juniper: 239 (Eyre 1980) **<**

Distribution: This system occurs in dry canyons and mesas in the southwestern portion of the Western Great Plains, ranging from Purgatoire and Apishipa canyons, tributaries of the Arkansas River in Colorado, and east into Kansas, Oklahoma and possibly north Texas.

Nations: US

Concept Source: K. Decker, K. Schulz, S. Menard and K. Kindscher

Description Author: S. Menard and K. Kindscher

CES303.664 CONCEPTUAL MODEL

Environment: This ecological system occurs in both perennial and intermittent stream canyons of the southwestern Great Plains. Soils can range from deep loams to alluvial to sandy. The mosaic of soil types which have developed from sandstone, limestone, basalt, and shale parent materials creates a complex mosaic of grasslands, shrublands and woodlands within the canyon system (Shaw et al. 1989).

CES303.665 Western Great Plains Cliff and Outcrop

CES303.665 CLASSIFICATION

Concept Summary: This system includes cliffs and outcrops throughout the Western Great Plains Division. Substrate can range from sandstone and limestone, which can often form bands in the examples of this system. Vegetation is restricted to shelves, cracks and crevices in the rock. However, this system differs from ~Western Great Plains Badlands (CES303.663)$$ in that often the soil is slightly developed and less erodible, and some grass and shrub species can occur at greater than 10%. Common species in this system include short shrubs such as *Rhus trilobata* and *Artemisia longifolia* and mixedgrass species such as *Bouteloua curtipendula* and *Bouteloua gracilis* and *Calamovilfa longifolia*. Drought and wind erosion are the most common natural dynamics affecting this system. Vegetation is typically restricted to shelves, cracks, and crevices where soil can accumulate.

- High Plains: Wooded Cliff (3104) [CES303.665.4] (Elliott 2013) **<**
- Western Great Plains Cliff and Outcrop (Rolfsmeier and Steinauer 2010) **=**

Distribution: This system ranges throughout the Western Great Plains Division from northern Texas to southern Canada.
Nations: CA, US
Concept Source: S. Menard and K. Kindscher
Description Author: S. Menard and K. Kindscher

CES303.665 CONCEPTUAL MODEL

Environment: This system is includes cliff and outcrops with slopes typically greater than 80% throughout the Western Great Plains Division with substrate ranging from sandstone to limestone. These areas are often found along river breaks and escarpments. Areas of shelves, cracks, and crevices accumulate materials and allow soils to develop enough to support more vegetation.
Key Processes and Interactions: Drought and wind erosion are the major influences affecting this system.
Threats/Stressors:
Ecosystem Collapse Thresholds:

6.B.1.Nb. Western North American Temperate Cliff, Scree & Rock Vegetation

M887. Western North American Cliff, Scree & Rock Vegetation

CES206.903 Central California Coast Ranges Cliff and Canyon

CES206.903 CLASSIFICATION

Concept Summary: Found from foothill and montane elevations of California's Coast Ranges, these are barren and sparsely vegetated areas (<10% plant cover) of steep cliff faces, narrow canyons, and smaller rock outcrops of various igneous, sedimentary, and metamorphic bedrock. This system also includes unstable scree and talus slopes typically occurring below cliff faces. Scattered vegetation may include *Pseudotsuga menziesii, Pinus contorta var. murrayana, Pinus ponderosa*, and *Pinus jeffreyi*. There may be shrubs including species of *Arctostaphylos* or *Ceanothus*. Soil development is limited as is herbaceous cover.

CES206.905 Mediterranean California Serpentine Barrens

CES206.905 CLASSIFICATION

Concept Summary: This uncommon system is found in the central and southern Sierra Nevada, Central and Northern Coast Ranges, and Klamath Ranges at elevations between 150 to 1800 m (450-5500 feet), where serpentine outcrops and related soils are common. Not all serpentinite outcrops support distinct vegetation. Only those with very low Ca:Mg ratio impact biotic composition. This system is usually found on steep slopes with loosely consolidated soils and harsh soil chemical conditions (large rock outcrops and gravelly soil). There is typically a very low cover (<10%) of herbaceous species, including *Streptanthus* spp., *Hesperolinon* spp., *Allium falcifolium, Allium cratericola, Asclepias solanoana, Eriogonum ursinum*, and *Eriogonum nudum*.
Related Concepts:

CES206.905 CONCEPTUAL MODEL

Environment: This system is found in central and southern Sierra Nevada, central and northern Coast Ranges, and Klamath Mountains at elevations between 150 and 1800 m (450-5500 feet), where serpentine or ultramafic outcrops and related soils are common. Not all serpentinite outcrops support distinct vegetation. Only those with very low Ca:Mg ratio impact biotic composition. This system is usually found on steep slopes where loosely consolidated soils and harsh soil chemical conditions (large rock outcrops and gravelly soil) combine with xeric conditions (low rainfall or south- or west-facing, excessively-drained). Soils on ultramafics are usually shallow and skeletal, with little profile development. Ultramafic soils impose the following stresses on plants: imbalance of calcium and magnesium, magnesium toxicity, low availability of molybdenum, toxic levels of heavy metals, sometime high alkalinity, low concentrations of some essential nutrients, and low soil water storage capacity (Kruckeberg 1984, Sanchez-Mata 2007). In some cases, the steepness of the slopes and general sparseness of the vegetation result in continual erosion. Jimerson et al. (1995) found one plant community in this system to occur on convex, ridgetop or spur ridge positions where moisture conditions are extremely dry [often south- or west-facing]; exposed bare ground, gravel and rock have high cover. Occurrences are generally physiognomically distinct from the adjacent predominant forest or shrubland/chaparral vegetation; they can cover 100s of hectares.
Key Processes and Interactions: The low cover of vascular plants combined with exposed sites leads to sheet erosion and soil loss being the major disturbance processes. Fine soil materials may be "captured" by micro-terraces leading to plant establishment and slow development of an organic soil horizon (Jimerson et al. 1995). Potential for alteration from fire is very low due to the high amount of soil and rock and low vegetation cover. Due the general lack of exotic species which tend to be intolerant of the ultramafic soils, this system is rich in native and endemic flora (Safford et al. 2005, Sanchez-Mata 2007). The interaction between serpentine soils and soil algae or fungi and small invertebrates is largely unstudied; Pegtel (1980) and Hopkins (1987) found that on barrens such as these the few tolerant plants are likely to be mycorrhizal. Harrison and Shapiro (1988) describe features of population biology of butterflies occurring on serpentines in northern California.
Threats/Stressors: Conversion of this type has commonly come from direct impacts from mine development, geothermal energy development and road building. Conversion to agriculture is not a factor as the soil types and slope positions are not conducive to agricultural use. Invasive plant species that are often threats to other California ecosystems may be less of threat in serpentine ecosystems; however, some invasives are finding their way into serpentine soils (Batten et al. 2006). Open ridgetop areas such as these barrens are attractive to hikers and other recreationists who may cause damage to the few plants occurring there (Jimerson et al. 1995). Severe soil erosion can be triggered by any disturbance, such as vehicular traffic, road building, and other such activities (Kruckeberg 1984, Jimerson et al. 1995).

In the west central coast regions, regional climate models project mean annual temperature increases of 1.6-1.9°C by 2070. The projected impacts will be warmer winter temperatures, earlier warming in spring and increased summer temperatures. Regional models project a decrease in mean annual rainfall of 61-188 mm by 2070. While there is greater uncertainty about the precipitation projections than for temperature, some projections call for a slightly drier future climate relative to current conditions (PRBO Conservation Science 2011). Potential climate change effects on this ecological system are hard to predict, given it is already adapted to extreme climate and soil conditions; fires rarely occur and then only on the edges of occurrences where some woody plants may occur; temperature increases will increase water-stress on the herbaceous species that are the majority of vascular plants. Potential climate change effects in general could include (PRBO Conservation Science 2011): deep-rooted or phreatophytic species under greater stress and death; drop in groundwater table; more and larger fires; increased fire frequency due to warmer temperatures resulting in drier fuels; increased invasive species due to lack of competition from native species whose vigor is reduced by drought stress, and increased fire intervals favor certain invasive species (Brooks and Minnich 2006);and increased competition for water from all users, and stresses on the already overtaxed water allocation of California agricultural system (PRBO Conservation Science 2011).

Ecosystem Collapse Thresholds: Ecological collapse tends to result from occurrences being small in size (less than 5 acres/2 ha) and surrounded by non-natural land uses; mining activities have impacted much of the occurrences; or mining restoration has introduced undesirable shrubs; fragmentation has occurred and connectivity between occurrences is gone; rare native or endemic forbs and grasses have been eliminated from the occurrence; invertebrates such as butterflies no longer occur; loss of native vascular plants has resulted in broken mycorrhizal relationships and even loss of soil fungi or microbes.

Environmental Degradation: High-severity environmental degradation appears where occurrence is less than 5 acres/2 ha in size; the occurrence is no longer in a native land cover landscape, <20% natural or semi-natural habitat in surroundings; the soil has been disrupted due to vehicular traffic or road building and erosion is severe through most of the occurrence. Moderate-severity appears where occurrence is 5-40 acres/2-16 ha in size; embedded in 20-60% natural or semi-natural habitat; connectivity is generally low, but varies with mobility of species and arrangement on landscape; the soil has been disrupted in some areas due to vehicular traffic or road building and erosion is severe through some of the occurrence.

Disruption of Biotic Processes: High-severity disruption of biotic processes appears where overall species richness has declined, with fewer than 4 of the expected native species occurring in the herb layers; rare or endemic plant species have been lost from the occurrence; invertebrates such as butterflies no longer occur; loss of native vascular plants has resulted in broken mycorrhizal relationships and even loss of soil fungi or microbes. Moderate-severity appears where overall species richness has declined, but at least 4 to 9 of the expected native species occur in the herb layers; loss of some native vascular plants has resulted in diminished richness of soil fungi or microbes; native invertebrates are reduced in abundance and richness.

CES204.092 North Pacific Active Volcanic Rock and Cinder Land

CES204.092 CLASSIFICATION

Concept Summary: This ecological system includes active volcanic landscapes dominated by ash, pyroclastic deposits, lava, landslides and other exposed bare mineral and rock. Periodic eruptions and earthquakes are the primary processes maintaining a primarily barren environment. Decades of inactivity slowly provide opportunity for development of other systems, such as ~North American Glacier and Ice Field (CES100.728)$$ or ~North Pacific Wooded Volcanic Flowage (CES204.883)$$, or primary successional stages of surrounding vegetated systems to develop.

Related Concepts:

Distribution: This system is found in the Cascade Range from northern California north to Washington and is limited to barren and sparsely vegetated volcanic substrates.

Nations: US

Concept Source: R. Crawford

Description Author: R. Crawford

CES204.093 North Pacific Montane Massive Bedrock-Cliff and Talus

CES204.093 CLASSIFICATION

Concept Summary: This ecological system is found from foothill to subalpine elevations and includes barren and sparsely vegetated landscapes (generally <10% vascular plant cover) of steep cliff faces, narrow canyons, and larger rock outcrops of various igneous, sedimentary, and metamorphic bedrock types. Also included are unstable scree and talus that typically occur below cliff faces. The dominant process is drought, especially farther south in its distribution, and other extreme growing conditions created by exposed rock or unstable slopes typically associated with steep slopes. Alaskan montane rock and talus probably has a significant component on nonvascular species, and is not drought-limited. Fractures in the rock surface and less steep or more stable slopes may be occupied by small patches of dense vegetation, typically scattered trees and/or shrubs. Characteristic trees includes *Callitropsis nootkatensis, Tsuga* spp., *Thuja plicata, Pseudotsuga menziesii* (not in Alaska), or *Abies* spp. There may be scattered shrubs present, such as *Acer circinatum, Alnus viridis*, and *Ribes* spp. Soil development is limited as is herbaceous cover. Mosses or lichens may be very dense, well-developed and display cover well over 10%.

Related Concepts:

Distribution: This system occurs from northern California (north of ~Sierra Nevada Cliff and Canyon (CES206.901)$$) to southeastern Alaska.

Nations: CA, US

CES204.095 North Pacific Serpentine Barren

CES204.095 CLASSIFICATION

Concept Summary: This uncommon ecological system is found in the east and west Cascades. It is usually found on steep slopes with loosely consolidated soils and harsh soil chemical conditions (large rock outcrops and gravelly soil), although exposed ridges occur. This system occurs primarily in the Wenatchee Mountains in the east Cascades between 760 and 2100 m elevation (2500-7000 feet) on thin rocky, ultramafic (peridotite, serpentinite) soils of varying extent up to several square km. Most sites support often stunted conifers, typically stress-tolerant species. Not all ultramafic outcrops support a distinct vegetation. Only those with very low Ca:Mg ratio impact biotic composition, whereas others reflect increased influence of soil drought on ultramafic material. These systems are highly variable and are described here to include barren slopes to patches of nearly closed forests. Low-elevation sites support *Pseudotsuga menziesii, Pinus ponderosa*, and *Pinus monticola* trees with a sparse ground cover with *Aspidotis densa, Arctostaphylos nevadensis*, and *Pseudoroegneria spicata*. Higher elevations have *Pinus contorta var. latifolia, Pinus albicaulis, Abies lasiocarpa*, and *Tsuga mertensiana* with *Juniperus communis, Ledum glandulosum, Vaccinium scoparium, Poa curtifolia*, and *Festuca viridula*.

CES306.815 Rocky Mountain Cliff, Canyon and Massive Bedrock

CES306.815 CLASSIFICATION

Concept Summary: This ecological system of barren and sparsely vegetated landscapes (generally <10% plant cover) is found from foothill to subalpine elevations on steep cliff faces, narrow canyons, and smaller rock outcrops of various igneous (intrusives), sedimentary, and metamorphic bedrock types. It is located throughout the Rocky Mountains and northeastern Cascade Range in North America. Also included are unstable scree and talus slopes that typically occur below cliff faces. In general these are the dry sparsely vegetated places on a landscape. The biota on them reflect what is surrounding them, unless it is an extreme parent material. There may be small patches of dense vegetation, but it typically includes scattered trees and/or shrubs. Characteristic trees include species from the surrounding landscape, such as *Pseudotsuga menziesii, Pinus ponderosa, Pinus flexilis, Populus tremuloides, Abies concolor, Abies lasiocarpa*, or *Pinus edulis* and *Juniperus* spp. at lower elevations. There may be scattered shrubs present, such as species of *Holodiscus, Ribes, Physocarpus, Rosa, Juniperus*, and *Jamesia americana, Mahonia repens, Rhus trilobata*, or *Amelanchier alnifolia*. Soil development is limited, as is herbaceous cover.

CES206.901 Sierra Nevada Cliff and Canyon

CES206.901 CLASSIFICATION

Concept Summary: Found from foothill to subalpine elevations throughout the Sierra Nevada and nearby mountain ranges, these are barren and sparsely vegetated areas (<10% plant cover) of steep cliff faces, narrow canyons, and smaller rock outcrops of various igneous, sedimentary, and metamorphic bedrock. This system also includes unstable scree and talus slopes typically occurring below cliff faces. Scattered vegetation may include *Abies magnifica, Pseudotsuga menziesii, Pinus contorta var. murrayana, Pinus ponderosa, Pinus jeffreyi, Populus tremuloides*, or *Pinus monophylla, Juniperus osteosperma*, and *Cercocarpus ledifolius* at lower elevations. There may be shrubs including species of *Arctostaphylos* or *Ceanothus*. Soil development is limited as is herbaceous cover.

CES206.904 Southern California Coast Ranges Cliff and Canyon

CES206.904 CLASSIFICATION

Concept Summary: Found from foothill and montane elevations of California's Transverse and Peninsular ranges, these are barren and sparsely vegetated areas (<10% plant cover) of steep cliff faces, narrow canyons, and smaller rock outcrops of various igneous, sedimentary, and metamorphic bedrock type. This system also includes unstable scree and talus slopes typically occurring below cliff faces. Scattered vegetation may include shrub species from surrounding coastal chaparral, such as *Ceanothus megacarpus, Ceanothus leucodermis, Cercocarpus montanus var. minutiflorus (= Cercocarpus minutiflorus), Arctostaphylos glauca*, and *Xylococcus bicolor*. Soil development is limited as is herbaceous cover.
